The reflex sympathetic dystrophy syndrome is now referred to as *complex regional pain syndrome, type 1*, according to the new classification system of the International Association for the Study of Pain. This syndrome is characterized by pain and swelling, usually of a distal extremity, accompanied by vasomotor instability, trophic skin changes, and the rapid development of bony demineralization. Complex regional pain syndrome, including its treatment, is covered in greater detail in **Chap. 440**.

TIETZE SYNDROME AND COSTOCHONDRITIS

Tietze syndrome is manifested by painful swelling of one or more costochondral articulations. The age of onset is usually before 40, and both sexes are affected equally. In most patients, only one joint is involved, usually the second or third costochondral joint. The onset of anterior chest pain may be sudden or gradual. The pain may radiate to the arms or shoulders and is aggravated by sneezing, coughing, deep inspirations, or twisting motions of the chest. The term *costochondritis* is often used interchangeably with *Tietze syndrome*, but some restrict the former term to pain of the costochondral articulations without swelling. Costochondritis is observed in patients aged >40 years; it tends to affect the third, fourth, and fifth costochondral joints, and occurs more often in women. Both syndromes may superficially mimic cardiac or upper abdominal causes of pain. Rheumatoid arthritis, ankylosing spondylitis, and reactive arthritis may involve costochondral joints but are distinguished easily by their other clinical features. Other skeletal causes of anterior chest wall pain are xiphoidalgia and the slipping rib syndrome, which usually involves the tenth rib and causes reproducible pain below the rib cage. Malignancies such as breast cancer, prostate cancer, plasma cell cytoma, and sarcoma can invade the ribs, thoracic spine, or chest wall and produce symptoms suggesting Tietze's syndrome. Patients with osteomalacia may have significant rib pain, with or without documented microfractures. These conditions should be distinguishable by radiography, bone scanning, vitamin D measurement, or biopsy. Analgesics, NSAIDs, and local glucocorticoid injections usually relieve symptoms of costochondritis/Tietze's syndrome. Care should be taken to avoid overdiagnosing these syndromes in patients with acute chest pain syndromes.

MYOFASCIAL PAIN SYNDROME

Myofascial pain syndrome is characterized by multiple areas of localized musculoskeletal pain and tenderness in association with tender points. The pain is deep and aching and may be accompanied by a burning sensation. Myofascial pain may be regional and follow trauma, overuse, or prolonged static contraction of a muscle or muscle group, which may occur when an individual is reading or writing at a desk or working at a computer. In addition, this syndrome may be associated with underlying osteoarthritis of the neck or low back. Pain may be referred from tender points to defined areas distant from the area of original tenderness. Palpation of the tender point reproduces or accentuates the pain. The tender points are usually located in the center of a muscle belly, but they can occur at other sites such as costosternal junctions, the xiphoid process, ligamentous and tendinous insertions, fascia, and fatty areas. Tender point sites in muscle have been described as feeling indurated and taut, and palpation may cause the muscle to twitch. These findings, however, have been shown not to be unique to myofascial pain syndrome: in a controlled study, they were also present in some "normal" subjects. Myofascial pain most often involves the posterior neck, low back, shoulders, and chest. Chronic pain in the muscles of the posterior neck may involve referral of pain from a tender point in the erector neck muscle or upper trapezius to the head, leading to persistent headaches that may last for days. Tender points in the paraspinal muscles of the low back may refer pain to the buttock. Pain may be referred down the leg from a tender point in the gluteus medius and can mimic sciatica. A tender point in the infraspinatus muscle may produce local and referred pain over the lateral deltoid and down the outside of the arm into the hand. Injection of a local anesthetic such as 1% lidocaine into the tender point site often results in transient pain relief. Another useful technique is first to spray an agent such as ethyl chloride from the tender point toward the area of referred pain and then to stretch the muscle. This maneuver may need to be repeated several times. Massage and application of ultrasound to

the affected area also may be beneficial. Patients should be instructed in methods to prevent muscle stresses related to work and recreation. The prognosis in most patients is good. In some patients, regionally localized myofascial pain syndrome may evolve into more generalized fibromyalgia **(Chap. 373)**. Nonrestorative sleep is a common accompaniment in these patients and may need to be specifically addressed.

NEOPLASIAS AND ARTHRITIS

Primary tumors and tumor-like disorders of synovium are uncommon but should be considered in the differential diagnosis of monarticular joint disease. In addition, metastases to bone and primary bone tumors adjacent to a joint may produce joint symptoms.

Pigmented villonodular synovitis (*PVNS*), likely the same process causing tenosynovial giant cell tumors, is characterized by the slowly progressive, benign proliferation of tenosynovial tissue. This usually involves a single large joint or tendon. The most common age of onset is in the third decade, and women are affected slightly more often than men. The proliferating tissue usually displays clonal chromosomal translocations; most of these aberrations appear to involve the colony stimulating factor-1 (CSF-1) pathway, which influences the proliferation and maturation of mononuclear cells and macrophages.

The synovium has a brownish color and numerous large, fingerlike villi that fuse to form pedunculated nodules. There is marked hyperplasia of synovial cells in the stroma of the villi. Hemosiderin and lipids are found in the cytoplasm of macrophages and in the interstitial tissue. Multinucleated giant cells may be present. The proliferative synovium may behave as a simple mass or as a more diffuse invasive tissue growing into the adjacent cartilage and bone.

The clinical picture of PVNS is characterized by the insidious onset of progressive swelling and pain in affected joints or tendons, most commonly the knee or flexor tendons of the hand. Other commonly affected joints include the hips, ankles, calcaneocuboid joints, elbows, and small joints of the fingers or toes; multifocal form is less common. Tendon sheaths in the wrist, ankle, or foot may be involved. Symptoms of pain, a catching sensation, or stiffness may initially be mild and intermittent and may be present for years before the patient seeks medical attention. Radiographs may show joint space narrowing, erosions, and subchondral cysts. The diagnosis of PVNS is strongly suggested by gradient echo MRI, which reveals a synovial mass lesion of low signal intensity typical of tissue containing hemosiderin **(Fig. 374-3)**. The joint fluid contains blood and is dark red or almost black in color. Lipid-containing macrophages may be present in the fluid. The joint fluid may be clear if hemorrhage has not occurred.

The treatment for PVNS, if needed, is complete open or arthroscopic synovectomy. Irradiation of the involved joint has been successful in some patients but may cause a delayed malignant transformation. Treatment directed at inhibiting the CSF-1 pathway activated kinase has demonstrated efficacy.

FIGURE 374-3 Pigmented villonodular synovitis. MRI gradient echo sagittal image showing a mass that abuts the neck of the talus with marked low signal typical of tissue containing hemosiderin. *(Courtesy of Donald Flemming, MD; with permission.)*

Synovial chondromatosis is a disorder characterized by multiple focal metaplastic growths of normal-appearing cartilage in the synovium or tendon sheath. Segments of cartilage break loose and continue to grow as loose bodies. When calcification and ossification of loose bodies occur, the disorder is referred to as *synovial osteochondromatosis*. The disorder is usually monarticular and affects young to middle-aged individuals. The knee is most often involved, followed by hip, elbow, and shoulder. Symptoms are pain, swelling, and decreased motion of the joint. Radiographs may show several rounded calcifications within the joint cavity. Treatment is synovectomy; however, as in PVNS, the growths may recur.

Synovial sarcoma is a malignant neoplasm often found near a large joint of both upper and lower extremities, being more common in the lower extremity. It seldom arises within the joint itself. Synovial sarcomas constitute 10% of soft tissue sarcomas. The tumor is believed to arise from primitive mesenchymal tissue that differentiates into epithelial cells and/or spindle cells. Small foci of calcification may be present in the tumor mass. Synovial sarcoma occurs most often in young adults and is more common in men. The tumor presents as a slowly growing deep-seated mass near a joint, without much pain. The area of the knee is the most common site, followed by the foot, ankle, elbow, and shoulder. Other primary sites include the buttocks, abdominal wall, retroperitoneum, and mediastinum. The diagnosis is made by biopsy and must be distinguished from PVNS. Treatment consists of wide resection of the tumor, including adjacent muscle and regional lymph nodes, followed by chemotherapy and radiation therapy. Amputation of the involved distal extremity may be required. Chemotherapy may be beneficial in some patients with metastatic disease. Isolated sites of pulmonary metastasis can be surgically removed. The 5-year survival rate with treatment depends on the staging of the tumor, ranging from ~25% to ≥60%. Synovial sarcomas tend to recur locally and metastasize to regional lymph nodes, lungs, and skeleton.

In addition to the rare direct metastases of solid cell tumors to the highly vascular synovium, neoplasia arising from nonarticular organ sites can affect joints in other ways. Acute leukemias in children can mimic juvenile systemic inflammatory arthritis with severe joint pain and fever. In adults, chronic and acute myeloid leukemia rarely infiltrate the synovium. Hairy cell leukemia has a peculiar tendency to cause episodic inflammatory oligoarthritis and tenosynovitis; these episodes are dramatic and mimic acute gout flares. They respond to potent anti-inflammatory therapy with glucocorticoids; with remission of the leukemia, they may abate. Lymphomas, usually of T-cell origin, may also involve the synovium.

Carcinomas can be associated with several paraneoplastic articular syndromes, including HOA (discussed above). Acute palmar fasciitis with polyarthritis is a well-described but rare condition associated with certain cancers, mainly adenocarcinomas. Clinically, this syndrome is abrupt in onset, with pain in the metacarpophalangeal and proximal interphalangeal joints of the hands and rapidly evolving contractures of the fingers due to thickening of the palmar (flexor) tendons. A similar syndrome, although less dramatic in onset, can occur in diabetics. Paraneoplastic arthritis has been described and may occur in several patterns: asymmetric disease predominantly affecting the lower extremity joints and symmetric polyarthritis with hand joint involvement. Tumors are often found after the onset of the arthritis, and many patients have a preceding period of malaise or weight loss. The onset is often acute, and patients tend to be older men. These features should raise the question of an underlying malignancy as the cause of the arthritis. In one series, the symptoms resolved with successful therapy for the malignancy and did not recur with relapse of the malignancy. Dermatomyositis has a well-described association with neoplasms and may include joint pain and arthritis. Malignancy-associated arthritis may be responsive to NSAIDs and to treatment of the primary neoplasm.

Immune checkpoint inhibitors, increasingly used to treat various malignancies, are now well recognized to frequently elicit severe autoimmune, inflammatory, organ-targeted reactions including myositis, polymyalgia rheumatica, and polyarthritis.

375 Periarticular Disorders of the Extremities

Carol A. Langford

Periarticular disorders are common musculoskeletal abnormalities that can affect people throughout a wide range of ages. This chapter discusses some of the more common periarticular disorders.

BURSITIS

Bursitis is inflammation of a bursa, which is a thin-walled sac lined with synovial tissue. The function of the bursa is to facilitate movement of tendons and muscles over bony prominences. Excessive frictional forces from overuse, trauma, systemic disease (e.g., rheumatoid arthritis, gout), or infection may cause bursitis. *Subacromial bursitis* (subdeltoid bursitis) is the most common form of bursitis. The subacromial bursa, which is contiguous with the subdeltoid bursa, is located between the undersurface of the acromion and the humeral head and is covered by the deltoid muscle. Bursitis often accompanies rotator cuff tendinitis. Another frequently encountered form is *trochanteric bursitis*, which involves the bursa around the insertion of the gluteus medius onto the greater trochanter of the femur. Patients experience pain over the lateral aspect of the hip and upper thigh and have tenderness over the posterior aspect of the greater trochanter. External rotation and resisted abduction of the hip elicit pain, as will direct pressure applied to the bursa. *Olecranon bursitis* occurs over the posterior elbow and, when the area is acutely inflamed, infection or gout should be excluded by aspirating the bursa and performing a Gram stain and culture on the fluid as well as examining the fluid for urate crystals. *Achilles bursitis* involves the bursa located above the insertion of the tendon to the calcaneus and results from overuse and wearing tight shoes. *Retrocalcaneal bursitis* involves the bursa that is located between the calcaneus and posterior surface of the Achilles tendon. The pain is experienced at the back of the heel, and swelling appears on the medial and/or lateral side of the tendon. It occurs in association with spondyloarthritides, rheumatoid arthritis, gout, or trauma. *Ischial bursitis* affects the bursa separating the gluteus medius from the ischial tuberosity and develops from prolonged sitting and pivoting on hard surfaces. *Iliopsoas bursitis* affects the bursa that lies between the iliopsoas muscle and hip joint and is lateral to the femoral vessels. Pain is experienced over this area and is made worse by hip extension and flexion. *Anserine bursitis* is an inflammation of the sartorius bursa located over the medial side of the tibia just below the knee and under the conjoint tendon and is manifested by pain on climbing stairs. Tenderness is present over the insertion of the conjoint tendon of the sartorius, gracilis, and semitendinosus. *Prepatellar bursitis* occurs in the bursa situated between the patella and overlying skin and is caused by kneeling on hard surfaces. Gout or infection may also occur at this site. Bursitis is typically diagnosed by history and physical examination, but visualization by ultrasound may play a useful role in selected instances for diagnosis and directed guidance of glucocorticoid injection. Treatment of bursitis consists of prevention of any aggravating situation, rest of the involved part, administration of a nonsteroidal anti-inflammatory drug (NSAID) where appropriate for an individual patient, or local glucocorticoid injection.

ROTATOR CUFF TENDINITIS AND IMPINGEMENT SYNDROME

Tendinitis of the rotator cuff is the major cause of a painful shoulder and is currently thought to be caused by inflammation of the tendon(s). The rotator cuff consists of the tendons of the supraspinatus, infraspinatus, subscapularis, and teres minor muscles, and inserts on the humeral tuberosities. Of the tendons forming the rotator cuff, the supraspinatus tendon is the most often affected, probably because of its repeated impingement (*impingement syndrome*) between the humeral head and the undersurface of the anterior third of the acromion and coracoacromial ligament above as well as the reduction in its blood supply that occurs with abduction of the arm **(Fig. 375-1)**. The tendon of the infraspinatus and that of the long head of the biceps are less commonly involved. Subacromial bursitis also accompanies this syndrome. Symptoms can appear without a triggering cause or after injury or overuse, especially with activities involving elevation of the arm with some degree of forward flexion. Impingement syndrome occurs in persons participating in baseball, tennis, swimming, or occupations that require repeated elevation of the arm. Those aged >40 years are particularly susceptible. Patients complain of a dull aching in the shoulder, which may interfere with sleep. Severe pain is experienced when the arm is actively abducted into an overhead position. The arc between 60° and 120° is especially painful. Tenderness is present over the lateral aspect of the humeral head just below the acromion. NSAIDs, local glucocorticoid injection, and physical therapy may relieve symptoms. Surgical decompression of the subacromial space may be necessary in patients refractory to conservative treatment.

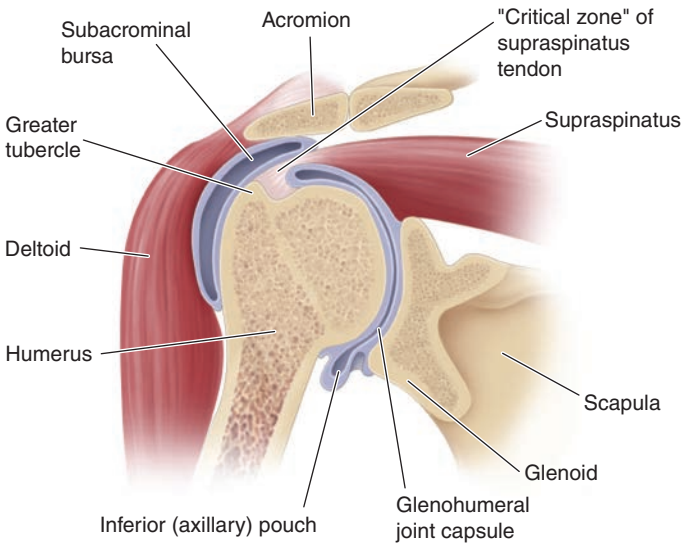

FIGURE 375-1 Coronal section of the shoulder illustrating the relationships of the glenohumeral joint, the joint capsule, the subacromial bursa, and the rotator cuff (supraspinatus tendon). *(Reproduced with permission from F Kozin, in WJ Koopman [ed]: Arthritis and Allied Conditions, 13th ed, Baltimore, Williams & Wilkins, 1997.)*

Patients may tear the supraspinatus tendon acutely by falling on an outstretched arm or lifting a heavy object. Symptoms are pain along with weakness of abduction and external rotation of the shoulder. Atrophy of the supraspinatus muscles develops. The diagnosis is established by ultrasound, magnetic resonance imaging (MRI), or arthrogram. Surgical repair may be necessary in patients who fail to respond to conservative measures. In patients with moderate-to-severe tears and functional loss, surgery is indicated.

CALCIFIC TENDINITIS

This condition is characterized by deposition of calcium salts, primarily hydroxyapatite, within a tendon. The exact mechanism of calcification is not known but may be initiated by ischemia or degeneration of the tendon. The supraspinatus tendon is most often affected because it is frequently impinged on and has a reduced blood supply when the arm is abducted. The condition usually develops after age 40. Calcification within the tendon may evoke acute inflammation, producing sudden and severe pain in the shoulder. However, it may be asymptomatic or not related to the patient's symptoms. Diagnosis of calcific tendonitis can be made by ultrasound or radiograph. Most cases are self-limited and respond to conservative therapy with physical therapy and/or NSAIDs. A subset of patients is refractory and requires ultrasound-guided percutaneous needle aspiration and lavage or surgery.

BICIPITAL TENDINITIS AND RUPTURE

Bicipital tendinitis, or tenosynovitis, is produced by friction on the tendon of the long head of the biceps as it passes through the bicipital groove. When the inflammation is acute, patients experience anterior shoulder pain that radiates down the biceps into the forearm. Abduction and external rotation of the arm are painful and limited. The bicipital groove is very tender to palpation. Pain may be elicited along the course of the tendon by resisting supination of the forearm with the elbow at 90° (Yergason's supination sign). Acute rupture of the tendon may occur with vigorous exercise of the arm and is often painful. In a healthy and active patient, it should be repaired surgically as soon as possible after the rupture occurs. Rupture of the tendon in an older person may be associated with little or no pain and is recognized by the presence of persistent swelling of the biceps produced by the retraction of the long head of the biceps. Surgery is usually not necessary in this setting.

DE QUERVAIN'S TENOSYNOVITIS

In this condition, inflammation involves the abductor pollicis longus and the extensor pollicis brevis as these tendons pass through a fibrous sheath at the radial styloid process. The usual cause is repetitive twisting of the wrist. It may occur in pregnancy, and it also occurs in mothers who hold their babies with the thumb outstretched. Patients experience pain on grasping with their thumb, such as with pinching. Swelling and tenderness are often present over the radial styloid process. The Finkelstein sign is positive, which is elicited by having the patient place the thumb in the palm and close the fingers over it. The wrist is then ulnarly deviated, resulting in pain over the involved tendon sheath in the area of the radial styloid. Treatment consists initially of splinting the wrist and an NSAID. When severe or refractory to conservative treatment, glucocorticoid injections can be very effective.

PATELLAR TENDINITIS

Tendinitis involves the patellar tendon at its attachment to the lower pole of the patella. Patients may experience pain when jumping during sports, going up stairs, or doing deep knee squats. Tenderness is noted on examination over the lower pole of the patella. Treatment consists of rest, icing, and NSAIDs, followed by strengthening and increasing flexibility.

DRUG-INDUCED TENDINOPATHIES

With the broadening range of available pharmacologic agents, the potential for drug-induced tendinopathies has become increasingly recognized. The drug classes most associated with tendinopathies include quinolones, glucocorticoids, aromatase inhibitors, and statins. Although any tendon can be affected, the tendons of the lower extremities are most often impacted, particularly the Achilles tendon. The pathophysiologic mechanisms responsible for drug-induced tendinopathies remain unknown. Presenting features include pain and potentially swelling over the tendon, although some patients may first present with tendon rupture. Ultrasound and MRI can provide information on tendon structure and integrity in support of the diagnosis. When suspected, the potential agent should be withdrawn and not reintroduced where possible. Tendon ruptures may require surgery.

ILIOTIBIAL BAND SYNDROME

The iliotibial band is a thick connective tissue that runs from the ilium to the fibula. Patients with iliotibial band syndrome most commonly present with aching or burning pain at the site where the band courses over the lateral femoral condyle of the knee; pain may also radiate up the thigh, toward the hip. Predisposing factors for iliotibial band syndrome include a varus alignment of the knee, excessive running distance, poorly fitted shoes, or continuous running on uneven terrain. Treatment consists of rest, NSAIDs, physical therapy, and addressing risk factors such as shoes and running surface. Glucocorticoid injection into the area of tenderness can provide relief, but running must be avoided for at least 2 weeks after the injection. Surgical release of the iliotibial band has been helpful in rare patients for whom conservative treatment has failed.

ADHESIVE CAPSULITIS

Often referred to as "frozen shoulder," adhesive capsulitis is characterized by pain and restricted movement of the shoulder, usually in the absence of intrinsic shoulder disease. Adhesive capsulitis most often develops in the setting of reduced arm mobility following bursitis or tendinitis of the shoulder, fractures, or recovery from surgery but can occur without an antecedent event. It has been associated with systemic disorders such as diabetes mellitus, chronic pulmonary disease, myocardial infarction, and thyroid disease. Pathologically, the capsule of the shoulder is thickened, and a mild chronic inflammatory infiltrate and fibrosis may be present.

Adhesive capsulitis occurs more commonly in women aged >50 years. Pain and stiffness usually develop gradually but progress rapidly in some patients. Night pain is often present in the affected shoulder, and pain may interfere with sleep. The shoulder is tender to palpation, and both active and passive movements are restricted. Radiographs of the shoulder show osteopenia. The diagnosis is typically made by physical examination but can be confirmed if necessary by arthrography, in that only a limited amount of contrast material, usually <15 mL, can be injected under pressure into the shoulder joint.

In most patients, the condition improves spontaneously 1–3 years after onset. While pain usually improves, many patients are left with some limitation of shoulder motion. Early mobilization of the arm following an injury to the shoulder may prevent the development of this disease. Physical therapy provides the foundation of treatment for adhesive capsulitis. Local injections of glucocorticoids and NSAIDs may also provide relief of symptoms. Slow but forceful injection of contrast material into the joint may lyse adhesions and stretch the capsule, resulting in improvement of shoulder motion. Manipulation under anesthesia may be helpful in some patients.

LATERAL EPICONDYLITIS

Lateral epicondylitis, also known as tennis elbow, is a painful condition involving the soft tissue over the lateral aspect of the elbow. The pain originates at or near the site of attachment of the common extensors to the lateral epicondyle and may radiate into the forearm and dorsum of the wrist. The pain usually appears after work or recreational activities involving repeated motions of wrist extension and supination against resistance. Most patients with this disorder injure themselves in activities other than tennis, such as pulling weeds, carrying suitcases or briefcases, or using a screwdriver. The injury in tennis usually occurs when hitting a backhand with the elbow flexed. Shaking hands and opening doors can reproduce the pain. Striking the lateral elbow against a solid object may also induce pain.

The treatment is usually rest along with administration of an NSAID. Ultrasound, icing, and friction massage may also help relieve pain. When pain is severe, the elbow is placed in a sling or splinted at 90° of flexion. When the pain is acute and well localized, injection of a glucocorticoid using a small-gauge needle may be effective. Following injection, the patient should be advised to rest the arm for at least 1 month and avoid activities that would aggravate the elbow. Once symptoms have subsided, the patient should begin rehabilitation to strengthen and increase flexibility of the extensor muscles before resuming physical activity involving the arm. A forearm band placed 2.5–5.0 cm (1–2 in.) below the elbow may help to reduce tension on the extensor muscles at their attachment to the lateral epicondyle. The patient should be advised to restrict activities requiring forcible extension and supination of the wrist. Improvement may take several months. The patient may continue to experience mild pain but, with care, can usually avoid the return of debilitating pain. Occasionally, surgical release of the extensor aponeurosis may be necessary.

MEDIAL EPICONDYLITIS

Medial epicondylitis is an overuse syndrome resulting in pain over the medial side of the elbow with radiation into the forearm. The cause of this syndrome is considered to be repetitive resisted motions of wrist flexion and pronation, which lead to microtears and granulation tissue at the origin of the pronator teres and forearm flexors, particularly the flexor carpi radialis. This overuse syndrome is usually seen in patients aged >35 years and is much less common than lateral epicondylitis. It occurs most often in work-related repetitive activities and also occurs with recreational activities such as swinging a golf club or throwing a baseball. On physical examination, there is tenderness just distal to the medial epicondyle over the origin of the forearm flexors. Pain can be reproduced by resisting wrist flexion and pronation with the elbow extended. Radiographs are usually normal. The differential diagnosis of patients with medial elbow symptoms includes tears of the pronator teres, acute medial collateral ligament tear, and medial collateral ligament instability. Ulnar neuritis has been found in 25–50% of patients with medial epicondylitis and is associated with tenderness over the ulnar nerve at the elbow as well as hypesthesia and paresthesia on the ulnar side of the hand.

The initial treatment of medial epicondylitis is conservative, involving rest, NSAIDs, friction massage, ultrasound, and icing. Some patients may require splinting. Injections of glucocorticoids at the painful site may also be effective. Patients should be instructed to rest for at least 1 month. Also, patients should start physical therapy once the pain has subsided. In patients with chronic debilitating medial epicondylitis that remains unresponsive after at least a year of treatment, surgical release of the flexor muscle at its origin may be necessary and is often successful.

PLANTAR FASCIITIS

Plantar fasciitis is a common cause of foot pain in adults, with the peak incidence occurring in people between the ages of 40 and 60 years. The pain originates at or near the site of the plantar fascia attachment to the medial tuberosity of the calcaneus. Several factors that increase the risk of developing plantar fasciitis include obesity, pes planus (flat foot or absence of the foot arch when standing), pes cavus (high-arched foot), limited dorsiflexion of the ankle, prolonged standing, walking on hard surfaces, and faulty shoes. In runners, excessive running and a change to a harder running surface may precipitate plantar fasciitis.

The diagnosis of plantar fasciitis can usually be made on the basis of history and physical examination alone. Patients experience severe pain with the first steps on arising in the morning or following inactivity during the day. The pain usually lessens with weight-bearing activity only to increase with continued activity. Pain is made worse on walking barefoot or up stairs. On examination, maximal tenderness is elicited on palpation over the inferior heel corresponding to the site of attachment of the plantar fascia.

Imaging studies may be indicated when the diagnosis is not clear. Plain radiographs may show heel spurs, which are of little diagnostic significance. Ultrasonography in plantar fasciitis can demonstrate thickening of the fascia and diffuse hypoechogenicity, indicating edema at the attachment of the plantar fascia to the calcaneus. MRI is a sensitive method for detecting plantar fasciitis, but it is usually not required for establishing the diagnosis.

Resolution of symptoms occurs within 12 months in >80% of patients with plantar fasciitis. Initial treatment consists of ice, heat, massage, stretching, and eliminating inciting activities. Orthotics provide medial arch support and can be effective. Some patients may benefit from foot strapping or taping or by wearing a night splint designed to keep the ankle in a neutral position. A short course of NSAIDs can be given to patients when the benefits outweigh the risks. Local glucocorticoid injections have also been shown to be efficacious but may carry an increased risk for plantar fascia rupture. Plantar fasciotomy is reserved for those patients who have failed to improve after at least 6–12 months of conservative treatment.

Section 1 Endocrinology

376 Approach to the Patient with Endocrine Disorders

J. Larry Jameson

The management of endocrine disorders requires a broad understanding of intermediary metabolism, reproductive physiology, bone metabolism, and growth. Accordingly, the practice of endocrinology is intimately linked to a conceptual framework for understanding hormone secretion, hormone action, and principles of feedback control (Chap. 377). The endocrine system is evaluated primarily by measuring hormone concentrations, arming the clinician with valuable diagnostic information. Most disorders of the endocrine system are amenable to effective treatment once the correct diagnosis is established. Endocrine deficiency disorders are treated with physiologic hormone replacement; hormone excess conditions, which usually are caused by benign glandular adenomas, are managed by removing tumors surgically or reducing hormone levels medically.

SCOPE OF ENDOCRINOLOGY

Classically, the specialty of endocrinology encompasses the study of glands and the hormones they produce. Over time, the field has expanded because of the discovery of hormones and growth factors produced by the brain, gastrointestinal (GI) tract, musculoskeletal system, and other nonglandular organs. The term *endocrine* was coined by Starling to contrast the actions of hormones secreted internally (*endocrine*) with those secreted externally (*exocrine*) or into a lumen, such as the GI tract. The term *hormone*, derived from a Greek phrase meaning "to set in motion," aptly describes the dynamic actions of hormones as they elicit cellular responses and regulate physiologic processes through feedback mechanisms.

Unlike many other specialties in medicine, it is not possible to define endocrinology strictly along anatomic lines. The classic endocrine glands—pituitary, thyroid, parathyroid, pancreatic islets, adrenals, and gonads—communicate broadly with other organs through the nervous system, hormones, cytokines, and growth factors. In addition to its traditional synaptic functions, the brain produces a vast array of peptide hormones, and this has led to the discipline of neuroendocrinology. Through the production of hypothalamic releasing factors, the central nervous system (CNS) exerts a major regulatory influence over pituitary hormone secretion (Chap. 378). The peripheral nervous system stimulates the adrenal medulla. The immune and endocrine systems are also intimately intertwined. The adrenal hormone cortisol is a powerful immunosuppressant. Cytokines and interleukins (ILs) have profound effects on the functions of the pituitary, adrenal, thyroid, and gonads. Common endocrine diseases such as autoimmune thyroid disease and type 1 diabetes mellitus are caused by dysregulation of immune surveillance and tolerance. Less common diseases such as polyglandular failure, Addison's disease, and lymphocytic hypophysitis also have an immunologic basis. Immune therapies for cancer and various autoimmune diseases can initiate autoimmune endocrine disease as a side effect of treatment.

The interdigitation of endocrinology with physiologic processes in other specialties sometimes blurs the role of hormones. For example, hormones play an important role in maintenance of blood pressure, intravascular volume, and peripheral resistance in the cardiovascular system. Vasoactive substances such as catecholamines, angiotensin II, endothelin, and nitric oxide are involved in dynamic changes of vascular tone in addition to their multiple roles in other tissues. The heart is the principal source of atrial natriuretic peptide, which acts in classic endocrine fashion to induce natriuresis at a distant target organ (the kidney). Erythropoietin, a traditional circulating hormone, is made in the kidney and stimulates erythropoiesis in bone marrow (Chap. 63). The kidney is also integrally involved in the renin-angiotensin axis (Chap. 386) and is a primary target of several hormones, including parathyroid hormone (PTH), mineralocorticoids, fibroblast growth factor 23 (FGF23), and vasopressin. The GI tract produces a vast array of peptide hormones, such as glucagon-like peptide 1 (GLP1), cholecystokinin, ghrelin, gastrin, secretin, and vasoactive intestinal peptide, among many others. Carcinoid and islet tumors can secrete excessive amounts of these hormones, leading to specific clinical syndromes (Chap. 84). Many of these GI hormones are also produced in the CNS, where their functions are poorly understood. Adipose tissue produces leptin, which acts centrally to control appetite, along with adiponectin, resistin, and other hormones that regulate metabolism. As hormones such as inhibin, ghrelin, and leptin are discovered, they become integrated into the science and practice of medicine on the basis of their functional roles rather than their tissues of origin.

Characterization of hormone receptors frequently reveals unexpected relationships to factors in nonendocrine disciplines. The growth hormone (GH) and leptin receptors, for example, are members of the cytokine receptor family. The G protein–coupled receptors (GPCRs), which mediate the actions of many peptide hormones, are used in numerous physiologic processes, including vision, smell, and neurotransmission.

PATHOLOGIC MECHANISMS OF ENDOCRINE DISEASE

Endocrine diseases can be divided into three major types of conditions: (1) hormone excess, (2) hormone deficiency, and (3) hormone resistance (Table 376-1).

CAUSES OF HORMONE EXCESS

Syndromes of hormone excess can be caused by neoplastic growth of endocrine cells, autoimmune disorders, and excess hormone administration. Benign endocrine tumors, including parathyroid, pituitary, and adrenal adenomas, often retain the capacity to produce hormones, reflecting the fact that these tumors are relatively well differentiated. Many endocrine tumors exhibit subtle defects in their "set points" for feedback regulation. For example, in Cushing's disease, impaired feedback inhibition of adrenocorticotropic hormone (ACTH) secretion is associated with autonomous function. However, the tumor cells are not completely resistant to feedback, as evidenced by ACTH suppression by higher doses of dexamethasone (e.g., high-dose dexamethasone test) (Chap. 386). Similar set point defects are also typical of parathyroid adenomas and autonomously functioning thyroid nodules.

The molecular basis of some endocrine tumors, such as the multiple endocrine neoplasia (MEN) syndromes (MEN1, 2A, 2B), has provided important insights into tumorigenesis (Chap. 388). MEN1 is characterized primarily by the triad of parathyroid, pancreatic islet, and pituitary tumors. MEN2 predisposes to medullary thyroid carcinoma, pheochromocytoma, and hyperparathyroidism. The *MEN1* gene, located on chromosome 11q13, encodes a tumor-suppressor gene, menin. Analogous to the paradigm first described for retinoblastoma, the affected individual inherits a mutant copy of the *MEN1* gene, and tumorigenesis ensues after a somatic "second hit" leads to loss of function of the normal *MEN1* gene (through deletion or point mutations).

In contrast to inactivation of a tumor-suppressor gene, as occurs in MEN1 and most other inherited cancer syndromes, MEN2 is caused by activating mutations in a single allele. In this case, activating mutations of the *RET* protooncogene, which encodes a receptor tyrosine kinase, leads to thyroid C-cell hyperplasia in childhood before the development of medullary thyroid carcinoma. Elucidation of this pathogenic mechanism has allowed early genetic screening for *RET* mutations in

TABLE 376-1 Causes of Endocrine Dysfunction

TYPE OF ENDOCRINE DISORDER	EXAMPLES
Hyperfunction	
Neoplastic	
Benign	Pituitary adenomas, hyperparathyroidism, autonomous thyroid or adrenal nodules
Malignant	Adrenal cancer, medullary thyroid cancer, carcinoid
Ectopic	Ectopic ACTH, SIADH secretion
Multiple endocrine neoplasia (MEN)	MEN1, MEN2
Autoimmune	Graves' disease
Iatrogenic	Cushing's syndrome, hypoglycemia
Infectious/inflammatory	Subacute thyroiditis
Activating receptor mutations	LH, TSH, Ca^{2+}, PTH receptors, $G_s\alpha$
Hypofunction	
Autoimmune	Hashimoto's thyroiditis, type 1 diabetes mellitus, Addison's disease, polyglandular failure
Iatrogenic	Radiation-induced hypopituitarism, hypothyroidism, surgical
Infectious/inflammatory	Adrenal insufficiency, hypothalamic sarcoidosis
Hormone mutations	GH, LHβ, FSHβ, vasopressin
Enzyme defects	21-Hydroxylase deficiency
Developmental defects	Kallmann's syndrome, Turner's syndrome, transcription factors
Nutritional/vitamin deficiency	Vitamin D deficiency, iodine deficiency
Hemorrhage/infarction	Sheehan's syndrome, adrenal insufficiency
Hormone Resistance	
Receptor mutations	
Membrane	GH, vasopressin, LH, FSH, ACTH, GnRH, GHRH, PTH, leptin, Ca^{2+}
Nuclear	AR, TR, VDR, ER, GR, PPARγ
Signaling pathway mutations	Albright's hereditary osteodystrophy
Postreceptor	Type 2 diabetes mellitus, leptin resistance

Abbreviations: ACTH, adrenocorticotropic hormone; AR, androgen receptor; ER, estrogen receptor; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; GR, glucocorticoid receptor; LH, luteinizing hormone; PPAR, peroxisome proliferator activated receptor; PTH, parathyroid hormone; SIADH, syndrome of inappropriate antidiuretic hormone; TR, thyroid hormone receptor; TSH, thyroid-stimulating hormone; VDR, vitamin D receptor.

individuals at risk for MEN2, permitting identification of those who may benefit from prophylactic thyroidectomy and biochemical screening for pheochromocytoma and hyperparathyroidism.

Mutations that activate hormone receptor signaling have been identified in several GPCRs. For example, activating mutations of the luteinizing hormone (LH) receptor cause a dominantly transmitted form of male-limited precocious puberty, reflecting premature stimulation of testosterone synthesis in Leydig cells **(Chap. 391)**. Activating mutations in these GPCRs are located predominantly in the transmembrane domains and induce receptor coupling to $G_s\alpha$ even in the absence of hormone. Consequently, adenylate cyclase is activated, and cyclic adenosine monophosphate (AMP) levels increase in a manner that mimics hormone action. A similar phenomenon results from activating mutations in $G_s\alpha$. When these mutations occur early in development, they cause McCune-Albright syndrome. When they occur only in somatotropes, the activating $G_s\alpha$ mutations cause GH-secreting tumors and acromegaly **(Chap. 380)**.

In autoimmune Graves' disease, antibody interactions with the thyroid-stimulating hormone (TSH) receptor mimic TSH action, leading to hormone overproduction **(Chap. 382)**. Analogous to the effects of activating mutations of the TSH receptor, these stimulating autoantibodies induce conformational changes in the TSH receptor that release it from a constrained state, thereby triggering receptor coupling to G proteins.

CAUSES OF HORMONE DEFICIENCY

Most examples of hormone deficiency states can be attributed to glandular destruction caused by autoimmunity, surgery, infection, inflammation, infarction, hemorrhage, or tumor infiltration (Table 376-1). Autoimmune damage to the thyroid gland (Hashimoto's thyroiditis) and pancreatic islet β cells (type 1 diabetes mellitus) are examples of relatively common endocrine diseases. Mutations in a number of hormones, hormone receptors, transcription factors, enzymes, and channels can also lead to hormone deficiencies.

HORMONE RESISTANCE

Most severe hormone resistance syndromes are due to inherited defects in membrane receptors, nuclear receptors, or the pathways that transduce receptor signals. These disorders are characterized by defective hormone action despite the presence of increased hormone levels. In complete androgen resistance, for example, mutations in the androgen receptor result in a female phenotypic appearance in genetic (XY) males, even though LH and testosterone levels are increased **(Chap. 388)**. In addition to these relatively rare genetic disorders, more common acquired forms of functional hormone resistance include insulin resistance in type 2 diabetes mellitus, leptin resistance in obesity, and GH resistance in catabolic states. The pathogenesis of functional resistance involves receptor downregulation and postreceptor desensitization of signaling pathways; functional forms of resistance are generally reversible.

CLINICAL EVALUATION OF ENDOCRINE DISORDERS

Because most glands are relatively inaccessible, the physical examination usually focuses on the manifestations of hormone excess or deficiency as well as direct examination of palpable glands, such as the thyroid and gonads. For these reasons, it is important to evaluate patients in the context of their presenting symptoms, review of systems, family and social history, and exposure to medications that may affect the endocrine system. Astute clinical skills are required to detect subtle symptoms and signs suggestive of underlying endocrine disease. For example, a patient with Cushing's syndrome may manifest specific findings, such as central fat redistribution, skin striae, and proximal muscle weakness, in addition to features seen commonly in the general population, such as obesity, plethora, hypertension, and glucose intolerance. Similarly, the insidious onset of hypothyroidism—with mental slowing, fatigue, dry skin, and other features—can be difficult to distinguish from similar, nonspecific findings in the general population. Clinical judgment that is based on knowledge of disease prevalence

and pathophysiology is required to decide when to embark on more extensive evaluation of these disorders. Laboratory testing plays an essential role in endocrinology by allowing quantitative assessment of hormone levels and dynamics. Radiologic imaging tests such as computed tomography (CT) scan, magnetic resonance imaging (MRI), thyroid scan, and ultrasound are also used for the diagnosis of endocrine disorders. However, these tests generally are employed only after a hormonal abnormality has been established by biochemical testing.

HORMONE MEASUREMENTS AND ENDOCRINE TESTING

Immunoassays are the most important diagnostic tool in endocrinology, as they allow sensitive, specific, and quantitative determination of steady-state and dynamic changes in hormone concentrations. Immunoassays use antibodies to detect specific hormones. For many peptide hormones, these measurements are now configured to use two different antibodies to increase binding affinity and specificity. There are many variations of these assays; a common format involves using one antibody to capture the antigen (hormone) onto an immobilized surface and a second antibody, coupled to a chemiluminescent (immunochemiluminescent assay [ICMA]) or radioactive (immunoradiometric assay [IRMA]) signal, to detect the antigen. These assays are sensitive enough to detect plasma hormone concentrations in the picomolar to nanomolar range, and they can readily distinguish structurally related proteins, such as PTH from PTH-related peptide (PTHrP). A variety of other techniques are used to measure specific hormones, including mass spectroscopy, various forms of chromatography, and enzymatic methods; bioassays are now used rarely.

Most hormone measurements are based on plasma or serum samples. However, urinary hormone determinations remain useful for the evaluation of some conditions. Urinary collections over 24 h provide an integrated assessment of the production of a hormone or metabolite, many of which vary during the day. It is important to ensure complete collections of 24-h urine samples; simultaneous measurement of creatinine provides an internal control for the adequacy of collection and can be used to normalize some hormone measurements. A 24-h urine-free cortisol measurement largely reflects the amount of unbound cortisol, thus providing a reasonable index of biologically available hormone. Other commonly used urine determinations include 17-hydroxycorticosteroids, 17-ketosteroids, vanillylmandelic acid, metanephrine, catecholamines, 5-hydroxyindoleacetic acid, and calcium.

The value of quantitative hormone measurements lies in their correct interpretation in a clinical context. The normal range for most hormones is relatively broad, often varying by a factor of two- to tenfold. The normal ranges for many hormones are sex- and age-specific. Thus, using the correct normative database is an essential part of interpreting hormone tests. The pulsatile nature of hormones and factors that can affect their secretion, such as sleep, meals, and medications, must also be considered. Cortisol values increase fivefold between midnight and dawn; reproductive hormone levels vary dramatically during the female menstrual cycle.

For many endocrine systems, much information can be gained from basal hormone testing, particularly when different components of an endocrine axis are assessed simultaneously. For example, low testosterone and elevated LH levels suggest a primary gonadal problem, whereas a hypothalamic-pituitary disorder is likely if both LH and testosterone are low. Because TSH is a sensitive indicator of thyroid function, it is generally recommended as a first-line test for thyroid disorders. An elevated TSH level is almost always the result of primary hypothyroidism, whereas a low TSH is most often caused by thyrotoxicosis. These predictions can be confirmed by determining the free thyroxine level. In the less common circumstance when free thyroxine and TSH are both low, it is important to consider secondary hypopituitarism caused by hypothalamic-pituitary disease. Elevated calcium and PTH levels suggest hyperparathyroidism, whereas PTH is suppressed in hypercalcemia caused by malignancy or granulomatous diseases. A suppressed ACTH in the setting of hypercortisolemia, or increased urine free cortisol, is seen with hyperfunctioning adrenal adenomas.

It is not uncommon, however, for baseline hormone levels associated with pathologic endocrine conditions to overlap with the normal range. In this circumstance, dynamic testing is useful to separate the two groups further. There are a multitude of dynamic endocrine tests, but all are based on principles of feedback regulation, and most responses can be rationalized based on principles that govern the regulation of endocrine axes. *Suppression tests* are used in the setting of suspected endocrine hyperfunction. An example is the dexamethasone suppression test used to evaluate Cushing's syndrome **(Chaps. 380 and 386)**. *Stimulation tests* generally are used to assess endocrine hypofunction. The ACTH stimulation test, for example, is used to assess the adrenal gland response in patients with suspected adrenal insufficiency. Other stimulation tests use hypothalamic-releasing factors such as corticotropin-releasing hormone (CRH) and growth hormone–releasing hormone (GHRH) to evaluate pituitary hormone reserve **(Chap. 380)**. Insulin-induced hypoglycemia evokes pituitary ACTH and GH responses. Stimulation tests based on reduction or inhibition of endogenous hormones are now used infrequently. Examples include metyrapone inhibition of cortisol synthesis and clomiphene inhibition of estrogen feedback.

SCREENING AND ASSESSMENT OF COMMON ENDOCRINE DISORDERS

Many endocrine disorders are prevalent in the adult population **(Table 376-2)** and can be diagnosed and managed by general internists, family practitioners, or other primary health care providers.

TABLE 376-2 Examples of Prevalent Endocrine and Metabolic Disorders in the Adult

DISORDER	APPROXIMATE PREVALENCE IN ADULTS[a]	SCREENING/TESTING RECOMMENDATIONS[b]	CHAPTER(S)
Obesity	40% Obese, BMI ≥30 70% Overweight, BMI ≥25	Calculate BMI Measure waist circumference Exclude secondary causes Consider comorbid complications	402
Type 2 diabetes mellitus	>10%	Beginning at age 45, screen every 3 years, or earlier in high-risk groups: FPG >126 mg/dL Random plasma glucose >200 mg/dL An elevated HbA_{1c} Consider comorbid complications	403
Hyperlipidemia	20–25%	Cholesterol screening at least every 5 years; more often in high-risk groups Lipoprotein analysis (LDL, HDL) for increased cholesterol, CAD, diabetes Consider secondary causes	407

(*Continued*)

TABLE 376-2 Examples of Prevalent Endocrine and Metabolic Disorders in the Adult (Continued)

DISORDER	APPROXIMATE PREVALENCE IN ADULTS[a]	SCREENING/TESTING RECOMMENDATIONS[b]	CHAPTER(S)
Metabolic syndrome	35%	Measure waist circumference, FPG, BP, lipids	408
Hypothyroidism	5–10%, women 0.5–2%, men	TSH; confirm with free T_4	384
Graves' disease	1–3%, women 0.1%, men	TSH, free T_4	383
Thyroid nodules and neoplasia	2–5% palpable >25% by ultrasound	Physical examination or ultrasound of thyroid Fine-needle aspiration biopsy	385
Osteoporosis	5–10%, women 2–5%, men	Bone mineral density measurements in women >65 years or in postmenopausal women or men at risk Exclude secondary causes	411
Hyperparathyroidism	0.1–0.5%, women > men	Serum calcium PTH, if calcium is elevated Assess comorbid conditions	410
Infertility	10%, couples	Investigate both members of couple Semen analysis in male Assess ovulatory cycles in female Specific tests as indicated	391,392
Polycystic ovarian syndrome	5–10%, women	Free testosterone, DHEAS Consider comorbid conditions	392
Hirsutism	5–10%	Free testosterone, DHEAS Exclude secondary causes Additional tests as indicated	394
Menopause	Median age, 51	FSH	395
Hyperprolactinemia	15% in women with amenorrhea or galactorrhea	PRL level MRI, if not medication-related	380
Erectile dysfunction	10–25%	Careful history, PRL, testosterone Consider secondary causes (e.g., diabetes)	397
Hypogonadism, male	1–2%	Testosterone, LH	391
Gynecomastia	15%	Often, no tests are indicated Consider Klinefelter's syndrome Consider medications, hypogonadism, liver disease	391
Klinefelter's syndrome	0.2%, men	Karyotype Testosterone	390
Vitamin D deficiency	10%	Measure serum 25-OH vitamin D Consider secondary causes	409
Turner's syndrome	0.03%, women	Karyotype Consider comorbid conditions	390

[a]The prevalence of most disorders varies among ethnic groups and with aging. Data based primarily on U.S. population. [b]See individual chapters for additional information on evaluation and treatment. Early testing is indicated in patients with signs and symptoms of disease and in those at increased risk.

Abbreviations: BMI, body mass index; BP, blood pressure; CAD, coronary artery disease; DHEAS, dehydroepiandrosterone; FPG, fasting plasma glucose; FSH, follicle-stimulating hormone; HbA_{1c}, hemoglobin A_{1c}; HDL, high-density lipoprotein; LDL, low-density lipoprotein; LH, luteinizing hormone; MRI, magnetic resonance imaging; PRL, prolactin; PTH, parathyroid hormone; TSH, thyroid-stimulating hormone.

The high prevalence and clinical impact of certain endocrine diseases justify vigilance for features of these disorders during routine physical examinations; laboratory screening is indicated in selected high-risk populations.

377 Mechanisms of Hormone Action

J. Larry Jameson

Hormones function to integrate physiologic systems in the body. The endocrine system, composed of various glands and the hormones they produce, interacts with essentially every organ to regulate growth, metabolism, homeostasis, and reproduction. Because hormones circulate and act via receptors in target tissues, they serve to coordinate physiologic responses to external or internal cues. For example, the light-dark cycle, sensed through the visual system, modulates hypothalamic corticotropin-releasing hormone (CRH), which increases pituitary adrenocorticotropin hormone (ACTH) production, leading to increased adrenal cortisol production before the time of waking

in the morning. Increased cortisol, in turn, circulates throughout the body, acting via the nuclear glucocorticoid receptor, to activate numerous genetic programs that influence metabolism, the cardiovascular system, behavior, and the immune system. This chapter provides an overview of the different types of hormones and how they function at the cellular level to control myriad physiologic processes.

CLASSES OF HORMONES

Hormones can be divided into five major types: (1) *amino acid derivatives* such as dopamine, catecholamine, and thyroid hormone; (2) *small neuropeptides* such as gonadotropin-releasing hormone (GnRH), thyrotropin-releasing hormone (TRH), somatostatin, and vasopressin; (3) *large proteins* such as insulin, luteinizing hormone (LH), and parathyroid hormone (PTH); (4) *steroid hormones* such as cortisol and estrogen that are synthesized from cholesterol-based precursors; and (5) *vitamin derivatives* such as retinoids (vitamin A) and vitamin D. A variety of *peptide growth factors*, such as insulin-like growth factor 1 (IGF1), share actions with hormones but often act more locally. As a rule, amino acid derivatives and peptide hormones interact with cell-surface membrane receptors. Steroids, thyroid hormones, vitamin D, and retinoids are lipid-soluble and bind to intracellular nuclear receptors, although many also interact with membrane receptors or intracellular signaling proteins as well.

HORMONE AND RECEPTOR FAMILIES

Hormones and receptors can be grouped into families, reflecting structural similarities and evolutionary origins **(Table 377-1)**. The evolution of these families generates diverse but highly selective pathways of hormone action. Recognition of these relationships has proven useful for extrapolating information gleaned from one hormone or receptor to other family members.

The glycoprotein hormone family, consisting of thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), LH, and human chorionic gonadotropin (hCG), illustrates many features of evolutionarily related hormones. The glycoprotein hormones are heterodimers that share the α subunit in common; the β subunits are distinct and confer specific biologic actions. The overall three-dimensional architecture of the β subunits is similar, reflecting the locations of conserved disulfide bonds that constrain protein conformation. The cloning of the β-subunit genes from multiple species suggests that this family arose from a common ancestral gene, probably by gene duplication and subsequent divergence to evolve new biologic functions.

As hormone families enlarge and diverge, their receptors have co-evolved to create new biologic functions. Related G protein–coupled receptors (GPCRs), for example, have evolved for each of the glycoprotein hormones. These receptors are also structurally similar, and each is coupled predominantly to the $G_s\alpha$ signaling pathway. However, there is minimal overlap of hormone binding. For example, TSH binds with high specificity to the TSH receptor but interacts minimally with the LH or FSH receptors. Nonetheless, there can be subtle physiologic consequences of hormone cross-reactivity with other receptors. Very high levels of hCG during pregnancy stimulate the TSH receptor and increase thyroid hormone levels, resulting via feedback inhibition in a compensatory decrease in TSH.

IGF1 and IGF2 have structural similarities that are most apparent when precursor forms of the proteins are compared. In contrast to the high degree of specificity seen with the glycoprotein hormones, there is moderate cross-talk among the members of the insulin/IGF family. High concentrations of an IGF2 precursor produced by certain tumors (e.g., sarcomas) can cause hypoglycemia, partly because of binding to insulin and IGF1 receptors **(Chap. 410)**. High concentrations of insulin also bind to the IGF1 receptor, perhaps accounting for some of the clinical manifestations seen in conditions with chronic hyperinsulinemia.

Another important example of receptor cross-talk is seen with PTH and parathyroid hormone–related peptide (PTHrP) **(Chap. 410)**. PTH is produced by the parathyroid glands, whereas PTHrP is expressed at high levels during development and by a variety of tumors **(Chap. 93)**. These hormones have amino acid sequence similarity, particularly in their amino-terminal regions. Both hormones bind to the PTH1R receptor that is expressed in bone and kidney. Hypercalcemia and hypophosphatemia therefore may result from excessive production of either hormone, making it difficult to distinguish hyperparathyroidism from hypercalcemia of malignancy solely on the basis of serum chemistries. However, sensitive and specific assays for PTH and PTHrP now allow these disorders to be distinguished more readily.

Based on their specificities for DNA-binding sites, the nuclear receptor family can be subdivided into type 1 receptors (glucocorticoid receptor, mineralocorticoid receptor, androgen receptor, estrogen receptor, progesterone receptor) that bind steroids and type 2 receptors (thyroid hormone receptor, vitamin D receptor, retinoic acid receptor, peroxisome proliferator activated receptor) that bind thyroid hormone, vitamin D, retinoic acid, or lipid derivatives, respectively. Certain functional domains in nuclear receptors, such as the zinc finger DNA-binding domains, are highly conserved. However, selective amino acid differences within this domain confer DNA sequence specificity. The hormone-binding domains are more variable, providing great diversity in the array of small molecules that bind to different nuclear receptors. With few exceptions, hormone binding is highly specific for a single type of nuclear receptor. One exception involves the glucocorticoid and mineralocorticoid receptors. Because the mineralocorticoid receptor also binds glucocorticoids with high affinity, an enzyme (11β-hydroxysteroid dehydrogenase) in renal tubular cells inactivates glucocorticoids, allowing selective responses to mineralocorticoids such as aldosterone. However, when very high glucocorticoid concentrations occur, as in Cushing's syndrome, the glucocorticoid degradation pathway becomes saturated, allowing excessive cortisol levels to bind mineralocorticoid receptors leading to sodium retention and potassium wasting. This phenomenon is particularly pronounced in ectopic ACTH syndromes **(Chap. 386)**. Another example of relaxed nuclear receptor specificity involves the estrogen receptor, which can bind an array of compounds, some of which have little apparent structural similarity to the high-affinity ligand estradiol. This feature of the estrogen receptor makes it susceptible to activation by "environmental estrogens" such as resveratrol, octylphenol, and many other aromatic hydrocarbons. However, this lack of specificity provides an opportunity to

TABLE 377-1 Examples of Membrane Receptor Families and Signaling Pathways

RECEPTORS	EFFECTORS	SIGNALING PATHWAYS
G Protein–Coupled Seven-Transmembrane Receptor (GPCR)		
β-Adrenergic, LH, FSH, TSH	$G_s\alpha$, adenylate cyclase	Stimulation of cyclic AMP production, protein kinase A
Glucagon, PTH, PTHrP, ACTH, MSH, GHRH, CRH	Ca^{2+} channels	Calmodulin, Ca^{2+}-dependent kinases
α-Adrenergic, somatostatin	$G_i\alpha$	Inhibition of cyclic AMP production Activation of K^+, Ca^{2+} channels
TRH, GnRH	G_q, G_{11}	Phospholipase C, diacylglycerol, IP_3, protein kinase C, voltage-dependent Ca^{2+} channels
Receptor Tyrosine Kinase		
Insulin, IGF-I	Tyrosine kinases, IRS	MAP kinases, PI 3-kinase; AKT
EGF, NGF	Tyrosine kinases, ras	Raf, MAP kinases, RSK
Cytokine Receptor–Linked Kinase		
GH, PRL	JAK, tyrosine kinases	STAT, MAP kinase, PI 3-kinase, IRS-1
Serine Kinase		
Activin, TGF-β, MIS	Serine kinase	Smads

Abbreviations: IP_3, inositol triphosphate; IRS, insulin receptor substrates; MAP, mitogen-activated protein; MSH, melanocyte-stimulating hormone; NGF, nerve growth factor; PI, phosphatidylinositol; RSK, ribosomal S6 kinase; TGF-β, transforming growth factor β. For all other abbreviations, see text. Note that most receptors interact with multiple effectors and activate networks of signaling pathways.

synthesize clinically useful antagonists (e.g., tamoxifen) and selective estrogen response modulators (SERMs) such as raloxifene. These compounds generate distinct estrogen receptor conformations that alter receptor interactions with components of the transcription machinery (see below), thereby conferring their unique actions.

HORMONE SYNTHESIS AND PROCESSING

The synthesis of peptide hormones and their receptors occurs through a classic pathway of gene expression: transcription → mRNA → protein → posttranslational protein processing → intracellular sorting, followed by membrane integration or secretion.

Many hormones are embedded within larger precursor polypeptides that are proteolytically processed to yield the biologically active hormone. Examples include proopiomelanocortin (POMC) → ACTH; proglucagon → glucagon; proinsulin → insulin; and pro-PTH → PTH, among others. In many cases, such as POMC and proglucagon, these precursors generate multiple biologically active peptides. For example, proglucagon generates glucagon, as well as glucagon-like peptide 1 (GLP1), among other peptides. It is provocative that hormone precursors are typically inactive, presumably adding an additional level of control through peptide processing. Prohormone conversion occurs not only for peptide hormones but also for certain steroids (testosterone → dihydrotestosterone) and thyroid hormone ($T_4 \rightarrow T_3$).

Peptide precursor processing is intimately linked to intracellular sorting pathways that transport proteins to appropriate vesicles and enzymes, resulting in specific cleavage steps, followed by protein folding and translocation to secretory vesicles. Hormones destined for secretion are translocated across the endoplasmic reticulum guided by an amino-terminal signal sequence that subsequently is cleaved. Cell-surface receptors are inserted into the membrane via short segments of hydrophobic amino acids that remain embedded within the lipid bilayer. During translocation through the Golgi and endoplasmic reticulum, hormones and receptors are subject to a variety of posttranslational modifications, such as glycosylation and phosphorylation, which can alter protein conformation, modify circulating half-life, and alter biologic activity.

Synthesis of most steroid hormones is based on modifications of the precursor, cholesterol. Multiple regulated enzymatic steps are required for the synthesis of testosterone **(Chap. 391)**, estradiol **(Chap. 392)**, cortisol **(Chap. 386)**, and vitamin D **(Chap. 409)**. This large number of synthetic steps predisposes to multiple genetic and acquired disorders of steroidogenesis.

Endocrine genes contain regulatory DNA elements similar to those found in many other genes, but their exquisite control by hormones reflects the presence of specific hormone response elements. For example, the TSH genes are repressed directly by thyroid hormones acting through the thyroid hormone receptor (TR), a member of the nuclear receptor family. Steroidogenic enzyme gene expression requires specific transcription factors, such as steroidogenic factor 1 (SF1), acting in conjunction with signals transmitted by trophic hormones (e.g., ACTH or LH). Once activated, SF1 functions as a master regulator, inducing a large array of genes required for steroidogenic and metabolic pathways required for steroid synthesis. For some hormones, substantial regulation occurs at the level of translational efficiency. Insulin biosynthesis, although it requires ongoing gene transcription, is regulated primarily at the translational and secretory levels in response to the levels of glucose or amino acids.

HORMONE SECRETION, TRANSPORT, AND DEGRADATION

The circulating level of a hormone is determined by its rate of secretion and its half-life. After protein processing, peptide hormones (e.g., GnRH, insulin, growth hormone [GH]) are stored in secretory granules. As these granules mature, they are poised beneath the plasma membrane for imminent release into the circulation. In most instances, the stimulus for hormone secretion is a releasing factor or neural signal that induces rapid changes in voltage-gated channel activity or intracellular calcium concentrations, leading to secretory granule fusion with the plasma membrane and release of its contents into the extracellular environment and bloodstream. Steroid hormones, in contrast, diffuse into the circulation as they are synthesized. Thus, their secretory rates are closely aligned with rates of synthesis. For example, ACTH and LH induce steroidogenesis by stimulating the activity of the *st*eroidogenic *a*cute *r*egulatory (StAR) protein, which transports cholesterol into the mitochondrion, along with other rate-limiting steps (e.g., cholesterol side-chain cleavage enzyme, CYP11A1) in the steroidogenic pathway.

Hormone transport and degradation dictate the rapidity with which a hormonal signal decays. Some hormone signals are evanescent (e.g., somatostatin), whereas others are longer-lived (e.g., TSH). Because somatostatin exerts effects in virtually every tissue, a short half-life allows its concentrations and actions to be controlled locally. Structural modifications that impair somatostatin degradation have been useful for generating long-acting therapeutic analogues such as octreotide **(Chap. 380)**. In contrast, the actions of TSH are highly specific for the thyroid gland. Its prolonged half-life generates relatively constant serum levels even though TSH is secreted in discrete pulses.

An understanding of circulating hormone half-life is important for achieving physiologic hormone replacement, as the frequency of dosing and the time required to reach steady state are intimately linked to rates of hormone decay. T_4, for example, has a circulating half-life of 7 days. Consequently, >1 month is required to reach a new steady state, and single daily doses are sufficient to achieve constant hormone levels. T_3, in contrast, has a half-life of 1 day. Its administration is associated with more dynamic serum levels, and it must be administered two to three times per day. Similarly, synthetic glucocorticoids vary widely in their half-lives; those with longer half-lives (e.g., dexamethasone) are associated with greater suppression of the hypothalamic-pituitary-adrenal (HPA) axis. Most protein hormones (e.g., ACTH, GH, prolactin [PRL], PTH, LH) have relatively short half-lives (<20 min), leading to sharp peaks of secretion and decay. The only accurate way to profile the pulse frequency and amplitude of these hormones is to measure levels in frequently sampled blood (every 10 min or less) over long durations (8–24 h). Because this is not practical in a clinical setting, an alternative strategy is to pool three to four blood samples drawn at about 30-min intervals or interpret the results in the context of a relatively wide normal range. Rapid hormone decay is useful in certain clinical settings. For example, the short half-life of PTH allows the use of intraoperative PTH levels to confirm successful removal of a parathyroid adenoma. This is particularly valuable diagnostically when there is a possibility of multicentric disease or parathyroid hyperplasia, as occurs with multiple endocrine neoplasia (MEN) or renal insufficiency.

Many hormones circulate in association with serum-binding proteins. Examples include (1) T_4 and T_3 binding to thyroxine-binding globulin (TBG), albumin, and thyroxine-binding prealbumin (TBPA); (2) cortisol binding to cortisol-binding globulin (CBG); (3) androgen and estrogen binding to sex hormone–binding globulin (SHBG); (4) IGF1 and IGF2 binding to multiple IGF-binding proteins (IGFBPs); (5) GH interactions with GH-binding protein (GHBP), a circulating fragment of the GH receptor extracellular domain; and (6) activin binding to follistatin. These interactions provide a hormone reservoir, prevent otherwise rapid degradation of unbound hormones, restrict hormone access to certain sites (e.g., IGFBPs), and modulate the levels of unbound, or "free," hormone concentrations. Although a variety of binding protein abnormalities have been identified, most have little clinical consequence aside from creating diagnostic problems. For example, TBG deficiency can reduce total thyroid hormone levels greatly, but the free concentrations of T_4 and T_3 remain normal. Liver disease and certain medications can also influence binding protein levels (e.g., estrogen increases TBG) or cause displacement of hormones from binding proteins (e.g., salsalate displaces T_4 from TBG). In general, only unbound hormone is available to interact with receptors and thus elicit a biologic response. Short-term perturbations in binding proteins change the free hormone concentration, which in turn induces compensatory adaptations through feedback loops. SHBG changes in women are an exception to this self-correcting mechanism. When SHBG decreases because of insulin resistance or androgen excess, the unbound testosterone concentration is increased, potentially contributing to hirsutism in women with polycystic ovary syndrome (PCOS)

(Chap. 394). The increased unbound testosterone level does not result in an adequate compensatory feedback correction because estrogen, not testosterone, is the primary regulator of the reproductive axis.

An additional exception to the unbound hormone hypothesis involves megalin, a member of the low-density lipoprotein (LDL) receptor family that serves as an endocytotic receptor for thyroglobulin, carrier-bound vitamins A and D, and SHBG-bound androgens and estrogens. After internalization, the carrier proteins are degraded in lysosomes and release their bound ligands within the cells. Other membrane transporters have also been identified for thyroid hormones.

Hormone degradation can be an important mechanism for regulating concentrations locally. As noted above, 11β-hydroxysteroid dehydrogenase inactivates glucocorticoids in renal tubular cells, preventing actions through the mineralocorticoid receptor. Thyroid hormone deiodinases convert T_4 to T_3 and can inactivate T_3. During development, degradation of retinoic acid by Cyp26b1 prevents primordial germ cells in the male from entering meiosis, as occurs in the female ovary.

HORMONE ACTION THROUGH RECEPTORS

Receptors for hormones are divided into two major classes: membrane and nuclear. *Membrane receptors* primarily bind peptide hormones and catecholamines. *Nuclear receptors* bind small molecules that can diffuse across the cell membrane, such as steroids and vitamin D. Certain general principles apply to hormone-receptor interactions regardless of the class of receptor. Hormones bind to receptors with specificity and an affinity that generally coincides with the dynamic range of circulating hormone concentrations. Low concentrations of free hormone (usually 10^{-12} to 10^{-9} *M*) rapidly associate and dissociate from receptors in a bimolecular reaction such that the occupancy of the receptor at any given moment is a function of hormone concentration and the receptor's affinity for the hormone. Receptor numbers vary greatly in different target tissues, providing one of the major determinants of tissue-specific responses to circulating hormones. For example, ACTH receptors are located almost exclusively in the adrenal cortex, and LH receptors are found predominantly in the gonads. In contrast, insulin and TRs are widely distributed, reflecting the need for metabolic responses in all tissues.

MEMBRANE RECEPTORS

Membrane receptors for hormones can be divided into several major groups: (1) seven transmembrane GPCRs, (2) tyrosine kinase receptors, (3) cytokine receptors, and (4) serine kinase receptors (Fig. 377-1). The *seven transmembrane GPCR family* binds a huge array of hormones, including large proteins (e.g., LH, PTH), small peptides (e.g., TRH, somatostatin), catecholamines (epinephrine, dopamine), and even minerals (e.g., calcium). The extracellular domains of GPCRs vary widely in size and are the major binding site for large hormones. The transmembrane-spanning regions are composed of hydrophobic α-helical domains that traverse the lipid bilayer. Like some channels, these domains are thought to circularize and form a hydrophobic pocket into which certain small ligands fit. Hormone binding induces conformational changes in these domains, transducing structural changes to the intracellular domain, which is a docking site for G proteins.

The large family of *G proteins*, so named because they bind guanine nucleotides (guanosine triphosphate [GTP], guanosine diphosphate [GDP]), provides great diversity for coupling receptors to different signaling pathways. G proteins form a heterotrimeric complex that is composed of various α and βγ subunits (Fig. 377-2). The α subunit contains the guanine nucleotide–binding site and an intrinsic GTPase that hydrolyzes GTP → GDP. The βγ subunits are tightly associated and modulate the activity of the α subunit as well as mediating their own effector signaling pathways. G protein activity is regulated by a cycle that involves GTP hydrolysis and dynamic interactions between the α and βγ subunits. Hormone binding to the receptor induces GDP

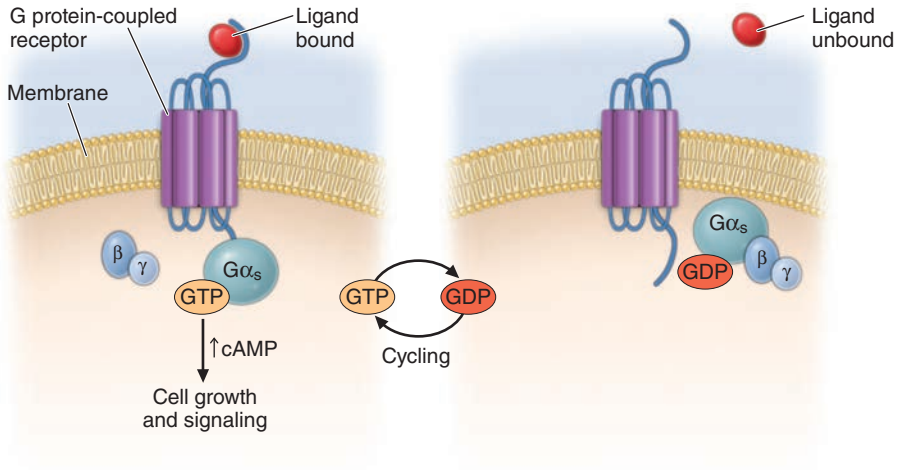

FIGURE 377-2 G protein signaling. G protein–coupled receptors (GPCRs) signal via the family of G proteins, so named because they bind guanylyl nucleotides. In the example shown, a GPCR bound to a ligand induces GDP dissociation, allowing $G_s\alpha$ to bind GTP and dissociate from the βγ complex. GTP-bound $G_s\alpha$ increases cAMP production by adenylyl cyclase and activates the protein kinase A pathway. Not shown are separate signaling pathways activated by the βγ complex. When GTP is converted to GDP by an intrinsic GTPase, the βγ subunits reassociate with GDP-bound $G_s\alpha$ and the complex returns to an inactive state. As noted in the text, mutations in $G_s\alpha$ that eliminate GTPase activity result in constitutive activation of receptor signaling pathways because GTP-bound $G_s\alpha$ cannot be converted to its GDP-bound inactive state. cAMP, cyclic adenosine 5′-monophosphate; GDP, guanosine diphosphate; $G_s\alpha$, G protein α; GTP, guanosine triphosphate.

dissociation, allowing Gα to bind GTP and dissociate from the βγ complex. Under these conditions, the Gα subunit is activated and mediates signal transduction through various enzymes, such as adenylate cyclase and phospholipase C. GTP hydrolysis to GDP allows reassociation with the βγ subunits and restores the inactive state. G proteins interact with other cellular proteins, including kinases, channels, G protein–coupled receptor kinases (GRKs), and arrestins, that mediate signaling as well as receptor desensitization and recycling.

A variety of endocrinopathies result from mutations in GPCRs that alter their interactions with G proteins **(Table 377-2)**. Loss-of-function mutations are generally recessive and inactivate the relevant hormone signaling pathway. Because many of these receptors are important for development as well as signaling, patient presentations resemble glandular failure syndromes (e.g., mutations in LH-R, FSH-R, TSH-R). Gain-of-function (GOF) mutations are more complex. Selected GOF mutations induce conformational changes in the GPCR that mimic the activated state normally induced by hormone binding. These GOF mutations result in a constitutively active state in which G protein coupling stimulates cell signaling pathways, most commonly via cyclic adenosine 5′-monophosphate (cAMP) and protein kinase A. When mutations occur in the germline, the conditions are heritable and present in early life (e.g., LH-R, TSH-R). Sporadic, somatic mutations can also occur and result in clonal expansion of hyperfunctioning cells.

TABLE 377-2 Genetic Causes of G protein Receptor Disorders

RECEPTOR	DISORDER	GENETICS
LH	Leydig cell hypoplasia (male) Primary amenorrhea, resistance to LH (female) Familial male precocious puberty (male) Leydig cell adenoma, precocious puberty (male)	AR, inactivating AR, inactivating AD, activating Sporadic, activating
FSH	Hypergonadotropic ovarian failure (female) Hypospermia (male) Ovarian hyperstimulation (female)	AR, inactivating AR, inactivating Sporadic, activating
TSH	Congenital hypothyroidism, TSH resistance Nonautoimmune familial hyperthyroidism Hyperfunctioning thyroid adenoma	AR, AD, inactivating AD, activating Sporadic, activating
GnRH	Hypogonadotropic hypogonadism	AR, inactivating
Kisspeptin	Hypogonadotropic hypogonadism Precocious puberty	AR, inactivating AD, activating
Prokineticin	Precocious puberty	Sporadic, activating
TRH	Central hypothyroidism	AR, inactivating
GHRH	GH deficiency	AR, inactivating
PTH	Blomstrand chondrodysplasia Jansen metaphyseal chondrodysplasia	AR, inactivating AD, activating
Calcium sensing receptor	Familial hypocalciuric hypercalcemia Neonatal severe hyperparathyroidism Familial hypocalcemic hypercalciura	AD, inactivating AR, inactivating AD, activating
Arginine vasopressin receptor 2	Nephrogenic diabetes insipidus Nephrogenic SIADH	XL, inactivating XL, activating
ACTH	Familial ACTH resistance ACTH-independent Cushing syndrome	AR, inactivating Sporadic, activating
Melanocortin 4	Severe obesity	Codominant, inactivating

Abbreviations: ACTH, adrenocorticotropin hormone; AD, autosomal dominant; AR, autosomal recessive; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PTH, parathyroid hormone; SIADH, syndrome of inappropriate antidiuretic hormone secretion; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone; XL, X-linked.

Mutations in the TSH-R illustrate the range of possible clinical consequences of GPCR mutations. Recessive inactivating mutations in the TSH-R cause congenital hypothyroidism with thyroid gland hypoplasia and resistance to TSH. Clinically, the hormone profile resembles primary hypothyroidism with low T_4 and high TSH. On the other hand, germline activating mutations cause congenital hyperthyroidism. The disorder is autosomal dominant because an activating mutation of one TSH-R allele is sufficient to induce cellular hyperfunction and disease. Because the TSH-R is activated in every cell of the thyroid, there is hyperplastic growth and hyperfunction that resembles the pathology seen in Graves' disease. This unusual disorder presents in infancy and must be distinguished from the more common clinical circumstance in which maternal antibodies in women with active or previously treated Graves' disease cross the placenta and stimulate the thyroid gland of the fetus. If an activating TSH-R mutation occurs later in life, in the somatic tissue, there is clonal expansion of the thyrocyte harboring the mutation, ultimately leading to an autonomous hyperfunctioning thyroid nodule. Of note, a similar condition can be caused by somatic mutations in $G_s\alpha$. In this case, the $G_s\alpha$ GTPase is inactivated and GTP cannot be converted to GDP. Consequently, the $G_s\alpha$ signaling pathway in this particular cell is constitutively active, mimicking chronic TSH stimulation and again leading to clonal expansion and an autonomous hyperfunctioning thyroid nodule. About one-third of hyperfunctioning "hot" thyroid nodules harbor sporadic mutations in either the TSH-R or $G_s\alpha$ (TSH-R mutations are more common).

$G_s\alpha$ mutations in tissues other than the thyroid can also cause endocrine disease. For example, $G_s\alpha$ mutations in pituitary somatotropes mimic activation of the growth hormone–releasing hormone (GHRH) pathway and lead to GH-producing adenomas and acromegaly. Rarely, mutations in other components of the protein kinase A pathway in somatotropes can also cause GH-producing adenomas. $G_s\alpha$ mutations that occur early in development (typically mosaic) cause McCune-Albright syndrome **(Chap. 412)**, and the clinical features are manifest because the activated G protein pathway mimics the actions of various hormones (PTH, melanocyte-stimulating hormone [MSH], TSH, GHRH) in different tissues. Germline inactivating $G_s\alpha$ mutations cause a range of disorders that are transmitted and expressed in a complex manner because the locus is imprinted **(Chap. 410)**. These conditions include Albright's hereditary osteodystrophy (AHO), pseudopseudohypoparathyroidism (PPHP), and pseudohypoparathyroidism types 1b, 1c, and 2.

The *tyrosine kinase receptors* transduce signals for insulin and a variety of growth factors, such as IGF1, epidermal growth factor (EGF), nerve growth factor, platelet-derived growth factor, and fibroblast growth factors. The cysteine-rich extracellular domains contain binding sites for the growth factors. After ligand binding, this class of receptors undergoes autophosphorylation, inducing interactions with intracellular adaptor proteins such as Shc and insulin receptor substrates (IRS). In the case of the insulin receptor, multiple kinases are activated, including the Raf-Ras-MAPK and the Akt/protein kinase B pathways. The tyrosine kinase receptors play a prominent role in cell growth and differentiation as well as in intermediary metabolism.

The GH and PRL receptors belong to the *cytokine receptor* family. Analogous to the tyrosine kinase receptors, ligand binding induces receptor interaction with intracellular kinases—the Janus kinases (JAKs), which phosphorylate members of the signal transduction and activators of transcription (STAT) family—as well as with other signaling pathways (Ras, PI3-K, MAPK). The activated STAT proteins translocate to the nucleus and stimulate expression of target genes.

The *serine kinase receptors* mediate the actions of activins, transforming growth factor β, müllerian-inhibiting substance (MIS; also known as anti-müllerian hormone [AMH]), and bone morphogenic proteins (BMPs). This family of receptors (consisting of type I and II subunits) signals through proteins termed *smads* (fusion of terms for *Caenorhabditis elegans* sma + mammalian mad). Like the STAT proteins, the smads serve a dual role of transducing the receptor signal and acting as transcription factors. The pleomorphic actions of these growth factors dictate that they act primarily in a local (paracrine or autocrine)

manner. Binding proteins such as follistatin (which binds activin and other members of this family) function to inactivate the growth factors and restrict their distribution.

Disease-causing mutations also occur in each of these classes of receptors. For example, insulin receptor mutations cause an extreme form of insulin resistance. GH receptor mutations cause Laron-type dwarfism, characterized by low IGF1 and high GH. AMH receptor mutations cause persistent müllerian duct syndrome. These hormone resistance syndromes are autosomal recessive and relatively uncommon. Unlike the GPCRs, activating mutations are unusual, although they do occur for the RET tyrosine kinase receptor, which causes the autosomal dominant disorder MEN type 2 (MEN2) **(Chap. 388)**.

NUCLEAR RECEPTORS

The family of nuclear receptors has grown to nearly 100 members, many of which are still classified as orphan receptors because their ligands, if they exist, have not been identified **(Fig. 377-3)**. Otherwise, most nuclear receptors are classified on the basis of their ligands. Although all nuclear receptors ultimately act to increase or decrease gene transcription, some (e.g., glucocorticoid receptor) reside primarily in the cytoplasm, whereas others (e.g., TR) are located in the nucleus. After ligand binding, the cytoplasmically localized receptors translocate to the nucleus. There is growing evidence that certain nuclear receptors (e.g., glucocorticoid, estrogen) can also act at the membrane or in the cytoplasm to activate or repress signal transduction pathways, providing a mechanism for cross-talk between membrane and nuclear receptors.

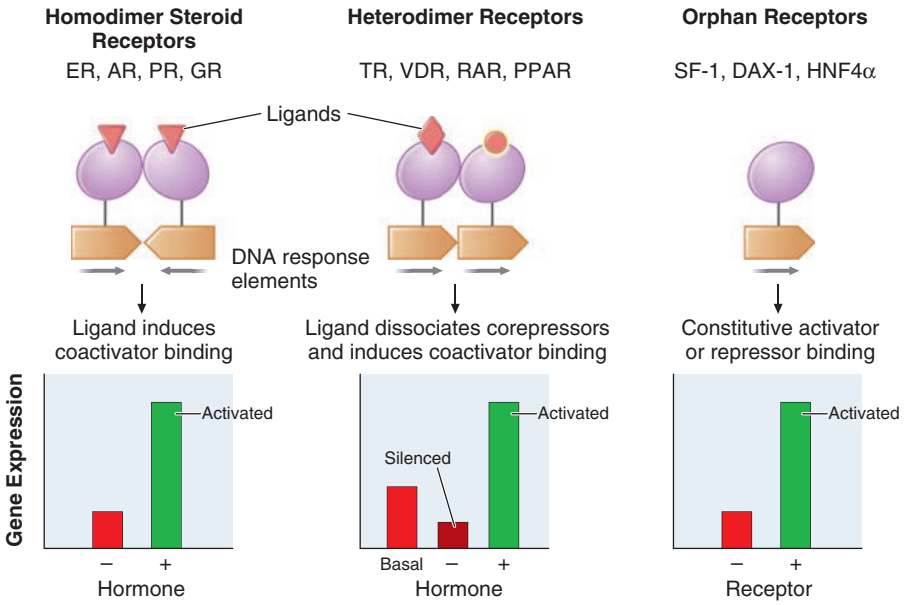

FIGURE 377-3 Nuclear receptor signaling. AR, androgen receptor; DAX, *d*osage-sensitive sex-reversal, *a*drenal hypoplasia congenita, *X* chromosome; ER, estrogen receptor; GR, glucocorticoid receptor; HNF4α, hepatic nuclear factor 4α; PPAR, peroxisome proliferator activated receptor; PR, progesterone receptor; RAR, retinoic acid receptor; SF-1, steroidogenic factor-1; TR, thyroid hormone receptor; VDR, vitamin D receptor.

The structures of nuclear receptors have been studied extensively, including by x-ray crystallography. The DNA-binding domain, consisting of two zinc fingers, contacts specific DNA recognition sequences in target genes. Most nuclear receptors bind to DNA as dimers. Consequently, each monomer recognizes an individual DNA motif, referred to as a "half-site." The steroid receptors, including the glucocorticoid, estrogen, progesterone, and androgen receptors, bind to DNA as homodimers. Consistent with this twofold symmetry, their DNA recognition half-sites are palindromic. The thyroid, retinoid, peroxisome proliferator activated, and vitamin D receptors bind to DNA preferentially as heterodimers in combination with retinoid X receptors (RXRs). Their DNA half-sites are typically arranged as direct repeats.

The carboxy-terminal hormone-binding domains mediate transcriptional control. For type II receptors such as TR and retinoic acid receptor (RAR), co-repressor proteins bind to the receptor in the absence of ligand and silence gene transcription. Hormone binding induces conformational changes, triggering the release of co-repressors and the recruitment of coactivators that stimulate transcription. Thus, these receptors are capable of mediating dynamic changes in the level of gene activity. Disease states can be associated with defective regulation of these events. For example, in promyelocytic leukemia, fusion of RARα to other nuclear proteins causes aberrant gene silencing that prevents normal cellular differentiation. Treatment with retinoic acid reverses this repression and allows cellular differentiation and apoptosis to occur. Most type 1 steroid receptors interact weakly with co-repressors, but ligand binding still induces interactions with an array of coactivators. X-ray crystallography shows that various SERMs induce distinct estrogen receptor conformations. The tissue-specific responses caused by these agents in breast, bone, and uterus appear to reflect distinct interactions with various coactivators. The receptor-coactivator complex stimulates gene transcription by several pathways, including (1) recruitment of enzymes (histone acetyl transferases) that modify chromatin structure, (2) interactions with additional transcription factors on the target gene, and (3) direct interactions with components of the general transcription apparatus to enhance the rate of RNA polymerase II–mediated transcription. Studies of nuclear receptor–mediated transcription reveal relatively rapid (e.g., 30–60 min) cycling of transcription complexes on any specific target gene.

Nuclear receptor mutations are an important cause of endocrine disease. Androgen receptor mutations cause androgen insensitivity syndrome (AIS) **(Chap. 390)**. Because the androgen receptor is located on the X chromosome, phenotypic expression is more commonly manifest than with other nuclear receptor disorders. Affected individuals with AIS are XY phenotypic females with retained testes and male-range testosterone levels. Tissue insensitivity to androgens varies based on the severity of the mutation. Müllerian structures are absent because Sertoli cells of the testis produce AMH during development. Female carriers of androgen receptor mutations are phenotypically normal. Recessive mutations of the estrogen, glucocorticoid, and vitamin D receptors occur but are rare.

Thyroid hormone receptor β (TRβ) mutations have an unusual pathophysiology. They are autosomal dominant and function via a "dominant negative" mechanism to cause resistance to thyroid hormone (RTH) **(Chap. 382)**. The mutations occur in selected regions of the TRβ hormone-binding domain and preserve the ability of the mutant receptor to heterodimerize with RXR, interact with co-repressors, and bind to DNA regulatory sites. The mutant receptors function as antagonists of receptors from the normal copy of the TRβ gene. Affected patients have high T_4 and T_3 and inappropriately elevated (unsuppressed) TSH, reflecting impaired feedback regulation of the hypothalamic-pituitary-thyroid axis. Organ systems are variably resistant to thyroid hormones based on the relative expression of TRβ and TRα. Mutations in the genes encoding TRα and PPARγ can also cause disease by functioning in an analogous dominant negative manner.

FUNCTIONS OF HORMONES

The functions of individual hormones are described in detail in subsequent chapters. Nevertheless, it is useful to illustrate how most biologic responses require the integration of several different hormone pathways. The physiologic functions of hormones can be divided into three general types: (1) growth and differentiation, (2) maintenance of homeostasis, and (3) reproduction.

GROWTH

Multiple hormones and nutritional factors mediate the complex phenomenon of growth **(Chap. 378)**. Short stature may be caused by GH

deficiency, hypothyroidism, Cushing's syndrome, precocious puberty, malnutrition, chronic illness, or genetic abnormalities that affect the epiphyseal growth plates (e.g., *FGFR3* and *SHOX* mutations). Many factors (GH, IGF1, thyroid hormones) stimulate growth, whereas others (sex steroids) lead to epiphyseal closure. Understanding these hormonal interactions is important in the diagnosis and management of growth disorders. For example, delaying exposure to high levels of sex steroids may enhance the efficacy of GH treatment.

MAINTENANCE OF HOMEOSTASIS

Although virtually all hormones affect homeostasis, the most important among them are the following:

1. Thyroid hormone—controls ~25% of basal metabolism in most tissues.
2. Cortisol—exerts a permissive action for many hormones in addition to its own direct effects.
3. PTH—regulates calcium and phosphorus levels.
4. Vasopressin—regulates serum osmolality by controlling renal free-water clearance.
5. Mineralocorticoids—control vascular volume and serum electrolyte (Na^+, K^+) concentrations.
6. Insulin—maintains euglycemia in the fed and fasted states.

The defense against hypoglycemia is an impressive example of integrated hormone action **(Chap. 406)**. In response to the fasting state and falling blood glucose, insulin secretion is suppressed, resulting in decreased glucose uptake and enhanced glycogenolysis, lipolysis, proteolysis, and gluconeogenesis to mobilize fuel sources. If hypoglycemia develops (usually from insulin administration or sulfonylureas), an orchestrated counterregulatory response occurs—glucagon and epinephrine rapidly stimulate glycogenolysis and gluconeogenesis, whereas GH and cortisol act over several hours to raise glucose levels and antagonize insulin action.

Although free-water clearance is controlled primarily by vasopressin, cortisol and thyroid hormone are also important for facilitating renal tubular responses to vasopressin **(Chap. 381)**. PTH and vitamin D function in an interdependent manner to control calcium metabolism **(Chap. 409)**. PTH stimulates renal synthesis of 1,25-dihydroxyvitamin D, which increases calcium absorption in the gastrointestinal tract and enhances PTH action in bone. Increased calcium, along with vitamin D, feeds back to suppress PTH, thus maintaining calcium balance.

Depending on the severity of a specific stress and whether it is acute or chronic, multiple endocrine and cytokine pathways are activated to mount an appropriate physiologic response. In severe acute stress such as trauma or shock, the sympathetic nervous system is activated, and catecholamines are released, leading to increased cardiac output and a primed musculoskeletal system. Catecholamines also increase mean blood pressure and stimulate glucose production. Multiple stress-induced pathways converge on the hypothalamus, stimulating several hormones, including vasopressin and CRH. These hormones, in addition to cytokines (tumor necrosis factor α, interleukin [IL] 2, IL-6), increase ACTH and GH production. ACTH stimulates the adrenal gland, increasing cortisol, which in turn helps sustain blood pressure and dampen the inflammatory response. Increased vasopressin acts to conserve free water.

REPRODUCTION

The stages of reproduction include (1) sex determination during fetal development **(Chap. 390)**; (2) sexual maturation during puberty **(Chaps. 391 and 392)**; (3) conception, pregnancy, lactation, and child rearing **(Chap. 392)**; and (4) cessation of reproductive capability at menopause **(Chap. 395)**. Each of these stages involves an orchestrated interplay of multiple hormones, a phenomenon well illustrated by the dynamic hormonal changes that occur during each 28-day menstrual cycle. In the early follicular phase, pulsatile secretion of LH and FSH stimulates the progressive maturation of the ovarian follicle. This results in gradually increasing estrogen and progesterone levels, leading to enhanced pituitary sensitivity to GnRH, which, when combined with accelerated GnRH secretion, triggers the LH surge and rupture of the mature follicle. Inhibin, a protein produced by the granulosa cells, enhances follicular growth and feeds back to the pituitary to selectively suppress FSH without affecting LH. Growth factors such as EGF and IGF1 modulate follicular responsiveness to gonadotropins. Vascular endothelial growth factor and prostaglandins play a role in follicle vascularization and rupture.

During pregnancy, the increased production of PRL, in combination with placentally derived steroids (e.g., estrogen and progesterone), prepares the breast for lactation. Estrogens induce the production of progesterone receptors, allowing for increased responsiveness to progesterone. In addition to these and other hormones involved in lactation, the nervous system and oxytocin mediate the suckling response and milk release.

HORMONAL FEEDBACK REGULATORY SYSTEMS

Feedback control, both negative and positive, is a fundamental feature of endocrine systems. Each of the major hypothalamic-pituitary-hormone axes is governed by negative feedback, a process that maintains hormone levels within a relatively narrow range **(Chap. 378)**. Examples of hypothalamic-pituitary negative feedback include (1) thyroid hormones on the TRH-TSH axis, (2) cortisol on the CRH-ACTH axis, (3) gonadal steroids on the GnRH-LH/FSH axis, and (4) IGF1 on the GHRH-GH axis **(Fig. 377-4)**. These regulatory loops include both positive (e.g., TRH, TSH) and negative (e.g., T_4, T_3) components, allowing for exquisite control of hormone levels. As an example, a small reduction of thyroid hormone triggers a rapid increase of TRH and TSH secretion, resulting in thyroid gland stimulation and increased thyroid hormone production. When thyroid hormone reaches a normal level, it feeds back to suppress TRH and TSH, and a new steady state is attained. Feedback regulation also occurs for endocrine systems that do not involve the pituitary gland, such as calcium feedback on PTH, glucose inhibition of insulin secretion, and leptin feedback on the hypothalamus. An understanding of feedback regulation provides important insights into endocrine testing paradigms (see below).

Positive feedback control also occurs but is not well understood. The primary example is estrogen-mediated stimulation of the midcycle LH surge. Although chronic low levels of estrogen are inhibitory, gradually rising estrogen levels stimulate LH secretion. This effect, which is

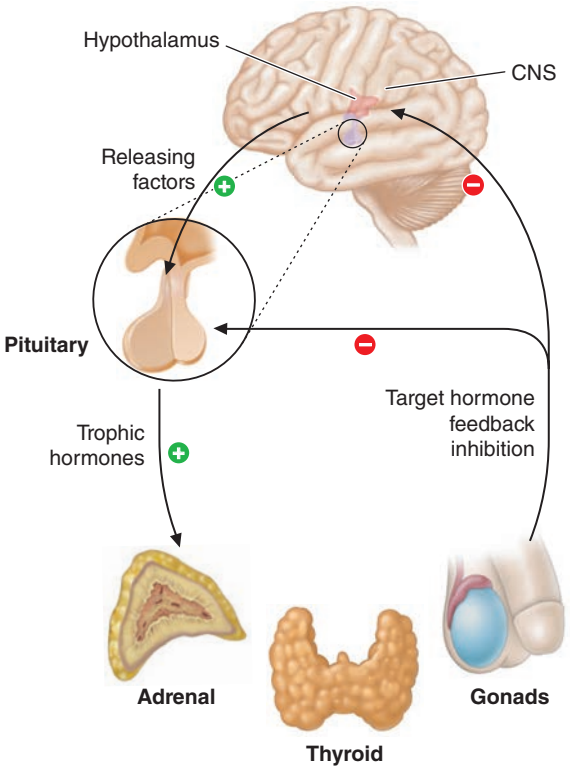

FIGURE 377-4 Feedback regulation of endocrine axes. CNS, central nervous system.

illustrative of an endocrine rhythm (see below), involves activation of the hypothalamic GnRH pulse generator. In addition, estrogen-primed gonadotropes are extraordinarily sensitive to GnRH, leading to amplification of LH release.

PARACRINE AND AUTOCRINE CONTROL

The previously mentioned examples of feedback control involve classic endocrine pathways in which hormones are released by one gland and act on a distant target gland. However, local regulatory systems, often involving growth factors, are increasingly recognized. *Paracrine regulation* refers to factors released by one cell that act on an adjacent cell in the same tissue. For example, somatostatin secretion by pancreatic islet δ cells inhibits insulin secretion from nearby β cells. *Autocrine regulation* describes the action of a factor on the same cell from which it is produced. IGF1 acts on many cells that produce it, including chondrocytes, breast epithelium, and gonadal cells. Unlike endocrine actions, paracrine and autocrine control are difficult to document because local growth factor concentrations cannot be measured readily.

Anatomic relationships of glandular systems also greatly influence hormonal exposure: the physical organization of islet cells enhances their intercellular communication; the portal vasculature of the hypothalamic-pituitary system exposes the pituitary to high concentrations of hypothalamic releasing factors; testicular seminiferous tubules gain exposure to high testosterone levels produced by the interdigitated Leydig cells; the pancreas receives nutrient information and local exposure to peptide hormones (incretins) from the gastrointestinal tract; and the liver is the proximal target of insulin action because of portal drainage from the pancreas.

HORMONAL RHYTHMS

The feedback regulatory systems described above are superimposed on hormonal rhythms that are used for adaptation to the environment. Seasonal changes, the daily occurrence of the light-dark cycle, sleep, meals, and stress are examples of the many environmental events that affect hormonal rhythms. The *menstrual cycle* is repeated on average every 28 days, reflecting the time required to follicular maturation, ovulation, and potential implantation **(Chap. 392)**. Essentially all pituitary hormone rhythms are entrained to sleep and to the *circadian cycle*, generating reproducible patterns that are repeated approximately every 24 h. The HPA axis, for example, exhibits characteristic peaks of ACTH and cortisol production in the early morning, with a nadir during the night. Recognition of these rhythms is important for endocrine testing and treatment. Patients with Cushing's syndrome characteristically exhibit increased midnight cortisol levels compared with normal individuals **(Chap. 386)**. In contrast, morning cortisol levels are similar in these groups, as cortisol is normally high at this time of day in normal individuals. The HPA axis is more susceptible to suppression by glucocorticoids administered at night as they blunt the early-morning rise of ACTH. Understanding these rhythms allows glucocorticoid replacement that mimics diurnal production by administering larger doses in the morning than in the afternoon. Disrupted sleep rhythms can alter hormonal regulation. For example, sleep deprivation causes mild insulin resistance, food craving, and hypertension, which are reversible, at least in the short term. Emerging evidence indicates that circadian clock pathways not only regulate sleep-wake cycles but also play important roles in virtually every cell type. For example, tissue-specific deletion of clock genes alters rhythms and levels of gene expression, as well as metabolic responses in liver, adipose, and other tissues.

Other endocrine rhythms occur on a more rapid time scale. Many peptide hormones are secreted in discrete bursts every few hours. LH and FSH secretion are exquisitely sensitive to GnRH pulse frequency. Intermittent pulses of GnRH are required to maintain pituitary sensitivity, whereas continuous exposure to GnRH causes pituitary gonadotrope desensitization. This feature of the hypothalamic-pituitary-gonadotrope axis forms the basis for using long-acting GnRH agonists to treat central precocious puberty or to decrease testosterone levels in the management of prostate cancer. It is important to be aware of the pulsatile nature of hormone secretion and the rhythmic patterns of hormone production in relating serum hormone measurements to normal values. For some hormones, integrated markers have been developed to circumvent hormonal fluctuations. Examples include 24-h urine collections for cortisol, the measurement of IGF1 as a biologic marker of GH action, and HbA_{1c} as an index of long-term (weeks to months) blood glucose control.

Often, one must interpret endocrine data only in the context of other hormones. For example, PTH levels typically are assessed in combination with serum calcium concentrations. A high serum calcium level in association with elevated PTH is suggestive of hyperparathyroidism, whereas a suppressed PTH in the setting of hypercalcemia is more likely to be caused by hypercalcemia of malignancy, or other causes of hypercalcemia. Similarly, when T_4 and T_3 concentrations are low, TSH should be elevated, reflecting reduced feedback inhibition. When this is not the case, it is important to consider secondary hypothyroidism, which is caused by a defect at the level of the pituitary.

378 Physiology of Anterior Pituitary Hormones

Shlomo Melmed, J. Larry Jameson

The anterior pituitary often is referred to as the "master gland" because, together with the hypothalamus, it orchestrates the complex regulatory functions of many other endocrine glands. The anterior pituitary gland produces six major hormones: (1) prolactin (PRL), (2) growth hormone (GH), (3) adrenocorticotropic hormone (ACTH), (4) luteinizing hormone (LH), (5) follicle-stimulating hormone (FSH), and (6) thyroid-stimulating hormone (TSH) **(Table 378-1)**. Pituitary hormones are secreted in a pulsatile manner, reflecting regulation by an array of specific hypothalamic releasing factors. Each of these pituitary hormones elicits specific trophic responses in peripheral target tissues including the adrenal, thyroid, and gonads, as well as tissues involved in metabolism (e.g., liver, breast, bone). Elicited hormonal products of peripheral glands, in turn, exert feedback control at the level of the hypothalamus and pituitary to modulate pituitary function **(Fig. 378-1)**. Pituitary tumors cause characteristic hormone excess syndromes. Hormone deficiency may be inherited or acquired. Fortunately, there are efficacious treatments for many pituitary hormone excess and deficiency syndromes. Nonetheless, these diagnoses are often elusive; this emphasizes the importance of recognizing subtle clinical manifestations and performing the correct laboratory diagnostic tests. **For discussion of disorders of the posterior pituitary or neurohypophysis, see Chap. 381.**

ANATOMY AND DEVELOPMENT

ANATOMY

The pituitary gland weighs ~600 mg and is located within the sella turcica ventral to the diaphragma sella; it consists of anatomically and functionally distinct anterior and posterior lobes. The bony sella is

contiguous to vascular and neurologic structures, including the cavernous sinuses, cranial nerves, and optic chiasm. Thus, expanding intrasellar pathologic processes may have significant central mass effects in addition to their endocrinologic impact.

Hypothalamic neural cells synthesize specific releasing and inhibiting hormones that are secreted directly into the portal vessels of the pituitary stalk. Blood supply of the pituitary gland comes from the superior and inferior hypophyseal arteries **(Fig. 378-2)**. The hypothalamic-pituitary portal plexus provides the major blood source for the anterior pituitary, allowing reliable transmission of hypothalamic peptide pulses without significant systemic dilution; consequently, anterior pituitary cells are exposed to specific releasing or inhibiting factors and in turn release their respective hormones as discrete pulses into the systemic circulation **(Fig. 378-3)**.

The posterior pituitary is supplied by the inferior hypophyseal arteries. In contrast to the anterior pituitary, the posterior lobe is directly innervated by hypothalamic neurons (supraopticohypophyseal and tuberohypophyseal nerve tracts) via the pituitary stalk **(Chap. 381)**. Thus, posterior pituitary production of vasopressin (antidiuretic hormone [ADH]) and oxytocin is particularly sensitive to neuronal damage by lesions that affect the pituitary stalk or hypothalamus.

PITUITARY DEVELOPMENT

The embryonic differentiation and maturation of anterior pituitary cells have been elucidated in considerable detail. Pituitary development from Rathke's pouch involves a complex interplay of lineage-specific transcription factors expressed in pluripotent Sox2-expressing precursor cells and gradients of locally produced growth factors (Table 378-1). The transcription factor Prop-1 induces pituitary development of Pit-1-specific lineages as well as gonadotropes. The transcription factor Pit-1 determines cell-specific expression of GH, PRL, and TSH in somatotropes, lactotropes, and thyrotropes. Expression of high levels of estrogen receptors in cells that contain Pit-1 favors PRL expression, whereas thyrotrope embryonic factor (TEF) induces TSH expression. Pit-1 binds to GH, PRL, and TSH gene regulatory elements, providing a mechanism for determining specific pituitary hormone phenotypic stability. Gonadotrope cell development is further defined by the cell-specific expression of the nuclear receptors steroidogenic factor (SF-1) and *d*osage-sensitive sex reversal, *a*drenal hypoplasia critical region, on chromosome *X*, gene *1* (DAX-1). Development of corticotrope cells, which express the proopiomelanocortin (*POMC*) gene, requires the T-Pit transcription factor. Abnormalities of pituitary development can be caused by inherited mutations of developmental transcription factors including Pit-1, Prop-1, SF-1, DAX-1, and T-Pit, resulting in selective or combined pituitary hormone deficit syndromes.

ANTERIOR PITUITARY HORMONES

Each anterior pituitary hormone is under unique control, and each exhibits highly specific normal and dysregulated secretory characteristics.

PROLACTIN

Synthesis PRL consists of 198 amino acids and has a molecular mass of 21,500 kDa; it is weakly homologous to GH and human placental lactogen (hPL), reflecting the duplication and divergence of a common GH-PRL-hPL precursor gene. PRL is synthesized in lactotropes, which constitute ~20% of anterior pituitary cells. Lactotropes and somatotropes are derived from a common precursor cell that may give rise to a tumor that secretes both PRL and GH. Marked lactotrope cell hyperplasia develops during pregnancy and the first few months of lactation. These transient functional changes in the lactotrope population are induced by estrogen to increase PRL production.

Secretion Normal adult serum PRL levels are about 10–25 μg/L in women and 10–20 μg/L in men. PRL secretion is pulsatile, with the highest secretory peaks occurring during non–rapid eye movement (non-REM) sleep. Peak serum PRL levels (up to 30 μg/L) occur between 4:00 and 6:00 A.M. The circulating half-life of PRL is ~50 min.

PRL is unique among the pituitary hormones in that the predominant hypothalamic control mechanism is inhibitory, reflecting tonic dopamine-mediated suppression of PRL release. This regulatory pathway accounts for the spontaneous PRL hypersecretion that occurs with pituitary stalk section, often a consequence of head trauma or compressive mass lesions at the skull base. Pituitary dopamine type 2 (D_2) receptors mediate inhibition of PRL synthesis and secretion. Targeted disruption (gene knockout) of the murine D_2 receptor in mice results in hyperprolactinemia and lactotrope proliferation. As discussed below, dopamine agonists play a central role in the management of hyperprolactinemic disorders.

Thyrotropin-releasing hormone (TRH) (pyro Glu-His-Pro-NH_2) is a hypothalamic tripeptide that elicits PRL release within 15–30 min after intravenous injection. TRH primarily regulates TSH, and the physiologic relevance of TRH for PRL regulation is unclear **(Chap. 382)**.

Serum PRL levels rise transiently after exercise, meals, sexual intercourse, minor surgical procedures, general anesthesia, chest wall injury, acute myocardial infarction, and other forms of acute stress.

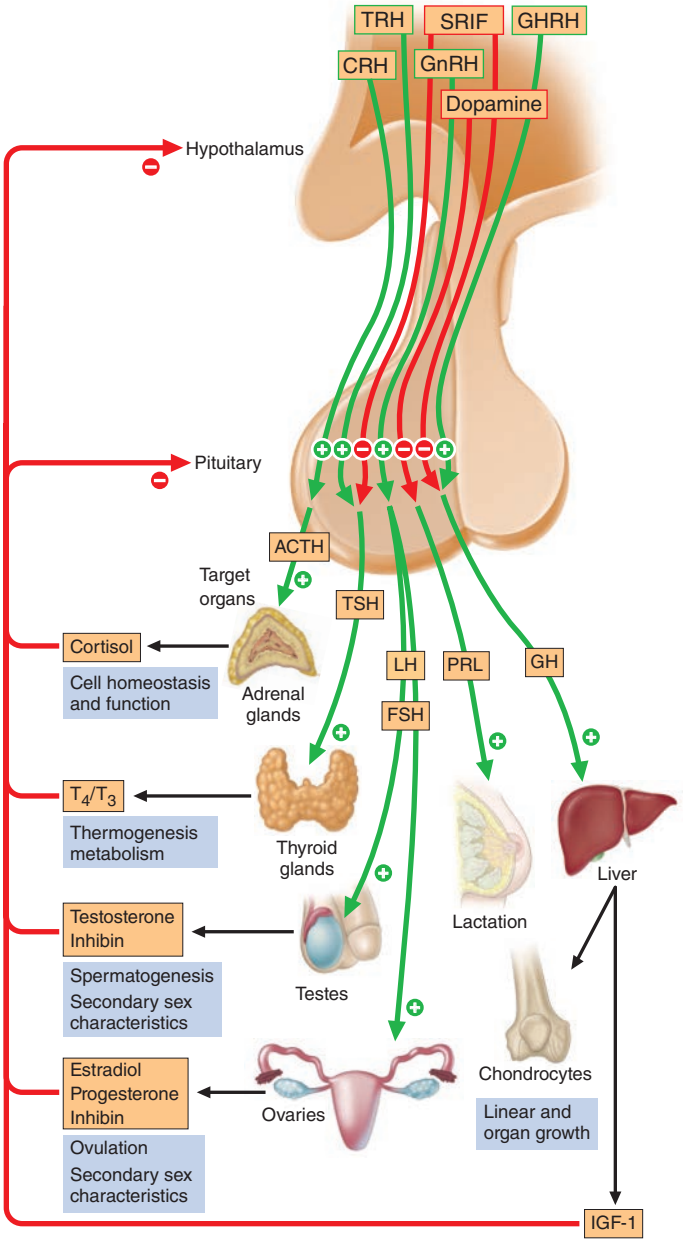

FIGURE 378-1 Diagram of pituitary axes. Hypothalamic hormones regulate anterior pituitary trophic hormones that in turn determine target gland secretion. Peripheral hormones feed back to regulate hypothalamic and pituitary hormones. For abbreviations, see text.

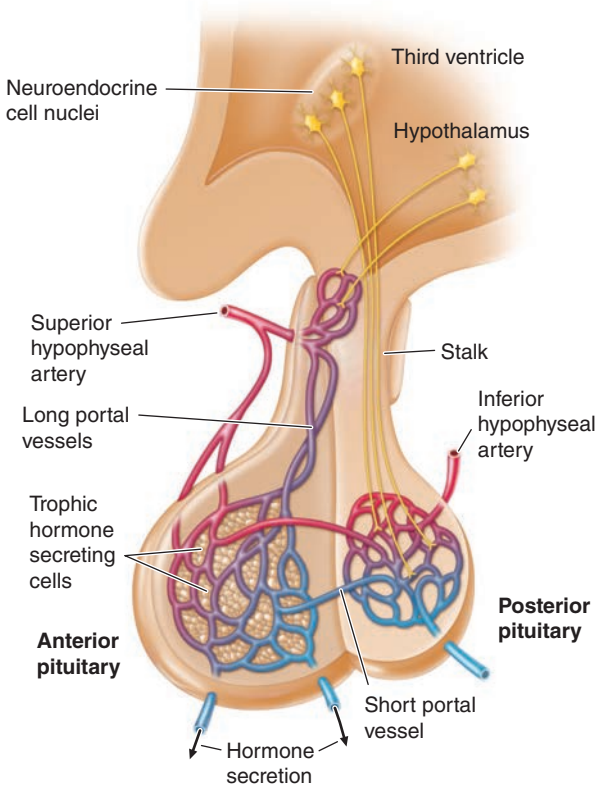

FIGURE 378-2 Diagram of hypothalamic-pituitary vasculature. The hypothalamic nuclei produce hormones that traverse the portal system and impinge on anterior pituitary cells to regulate pituitary hormone secretion. Posterior pituitary hormones are derived from direct neural extensions.

PRL levels increase markedly (about tenfold) during pregnancy and decline rapidly within 2 weeks of parturition. If breast-feeding is initiated, basal PRL levels remain elevated; suckling stimulates transient reflex increases in PRL levels that last for ~30–45 min. Breast suckling activates afferent neural pathways in the hypothalamus that induce PRL release. With time, suckling-induced responses diminish and interfeeding PRL levels return to normal.

Action The PRL receptor is a member of the type I cytokine receptor family that also includes GH and interleukin (IL) 6 receptors. Ligand binding induces receptor dimerization and intracellular signaling by Janus kinase (JAK), which stimulates translocation of the signal transduction and activators of transcription (STAT) family to activate target genes. Mutations of the PRL receptor result in PRL insensitivity, hyperprolactinemia, and oligomenorrhea. When homozygous, PRL receptor mutations cause agalactia, demonstrating that PRL action is necessary for lactation. In the breast, the lobuloalveolar epithelium proliferates in response to PRL, placental lactogens, estrogen, progesterone, and local paracrine growth factors, including insulin-like growth factor 1 (IGF-1).

PRL acts to induce and maintain lactation and to suppress both reproductive function and sexual drive. These functions are geared toward ensuring that maternal lactation is sustained and not interrupted by pregnancy. PRL inhibits reproductive function by suppressing hypothalamic gonadotropin-releasing hormone (GnRH) and pituitary gonadotropin secretion and by impairing gonadal steroidogenesis in both women and men. In the ovary, PRL blocks folliculogenesis and inhibits granulosa cell aromatase activity, leading to hypoestrogenism and anovulation. PRL also has a luteolytic effect, generating a shortened, or inadequate, luteal phase of the menstrual cycle. In men, attenuated LH secretion leads to low testosterone levels and decreased spermatogenesis. These hormonal changes decrease libido and reduce fertility in patients with hyperprolactinemia.

GROWTH HORMONE

Synthesis GH is the most abundant anterior pituitary hormone, and GH-secreting somatotrope cells constitute up to 50% of the total

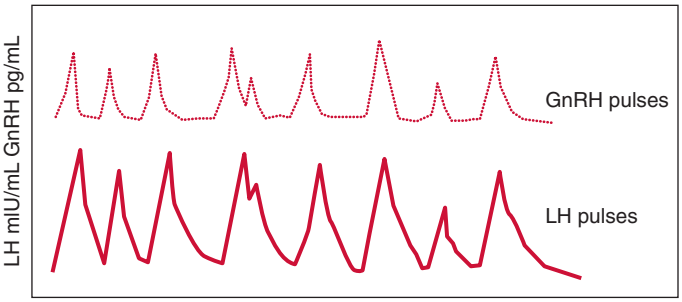

FIGURE 378-3 Hypothalamic gonadotropin-releasing hormone (GnRH) pulses induce secretory pulses of luteinizing hormone (LH).

anterior pituitary cell population. Mammosomatotrope cells, which coexpress PRL with GH, can be identified by using double immunostaining techniques. Somatotrope development and GH transcription are determined by expression of the cell-specific Pit-1 nuclear transcription factor. Five distinct genes encode GH and related proteins. The pituitary GH gene (*hGH-N*) produces two alternatively spliced products that give rise to 22-kDa GH (191 amino acids) and a less abundant 20-kDa GH molecule with similar biologic activity. Placental syncytiotrophoblast cells express a GH variant (*hGH-V*) gene; the related hormone human chorionic somatotropin (HCS) is expressed by distinct members of the gene cluster.

Secretion GH secretion is controlled by complex hypothalamic and peripheral factors. *GH-releasing hormone* (GHRH) is a 44-amino-acid hypothalamic peptide that stimulates GH synthesis and release. Ghrelin, an octanoylated gastric-derived peptide, and synthetic agonists of the *GHS-R* induce GHRH and also directly stimulate GH release. *Somatostatin* (somatotropin-release inhibiting factor [SRIF]) is synthesized in the medial preoptic area of the hypothalamus and inhibits GH secretion. GHRH is secreted in discrete spikes that elicit GH pulses, whereas SRIF sets basal GH secretory tone. SRIF also is expressed in many extrahypothalamic tissues, including the central nervous system (CNS), gastrointestinal tract, and pancreas, where it also acts to inhibit islet hormone secretion. *IGF-1*, the peripheral target hormone for GH, feeds back to inhibit GH; estrogen induces GH, whereas chronic glucocorticoid excess suppresses GH release, leading to growth delay in children.

Surface receptors on the somatotrope regulate GH synthesis and secretion. The GHRH receptor is a G protein–coupled receptor (GPCR) that signals through the intracellular cyclic AMP pathway to stimulate somatotrope cell proliferation as well as GH production. Inactivating mutations of the GHRH receptor cause profound dwarfism. A distinct surface receptor for ghrelin, the gastric-derived GH secretagogue, is expressed in both the hypothalamus and pituitary. Somatostatin binds to five distinct receptor subtypes (SST1 to SST5); SST2 and SST5 subtypes preferentially suppress GH (and TSH) secretion, while SST5 predominantly signals to suppress ACTH secretion.

GH secretion is pulsatile, with highest peak levels occurring at night, generally correlating with sleep onset. GH secretory rates decline markedly with age so that hormone levels in middle age are ~15% of pubertal levels. These changes are paralleled by an age-related decline in lean muscle mass. GH secretion is also reduced in obese individuals, although IGF-1 levels may not be suppressed, suggesting a change in the setpoint for feedback control. Elevated GH levels occur within an hour of deep sleep onset as well as after exercise, physical stress, and trauma and during sepsis. Integrated 24-h GH secretion is higher in women and is also enhanced by estrogen replacement, likely reflective of increased peripheral GH resistance. Using standard assays, random GH measurements are undetectable in ~50% of daytime samples obtained from healthy subjects and are also undetectable (<1 μg/L) in most obese and elderly subjects. Thus, single random GH measurements do not distinguish patients with adult GH deficiency from those with GH levels in the normal range.

GH secretion is profoundly influenced by nutritional factors. Using ultrasensitive GH assays with a sensitivity of 0.002 μg/L, a glucose load suppresses GH to <0.7 μg/L in women and to <0.07 μg/L in men. Increased GH pulse frequency and peak amplitudes occur with chronic malnutrition or prolonged fasting. GH is stimulated by oral ghrelin receptor agonists, intravenous L-arginine, dopamine, and apomorphine (a dopamine receptor agonist), as well as by α-adrenergic pathways. β-Adrenergic blockade induces basal GH and enhances GHRH- and insulin-evoked GH release.

Action The pattern of GH secretion may affect tissue responses. The higher GH pulsatility observed in men compared with the relatively continuous basal GH secretion in women may be an important biologic determinant of linear growth patterns and liver enzyme induction.

The 70-kDa peripheral GH receptor protein has structural homology with the cytokine/hematopoietic superfamily. A fragment of the receptor extracellular domain generates a soluble GH binding protein (GHBP) that binds to circulating GH. The liver and cartilage express the greatest number of GH receptors. GH binding to preformed receptor dimers is followed by internal rotation and subsequent signaling through the JAK/STAT pathway. Activated STAT proteins translocate to the nucleus, where they modulate expression of GH-regulated target genes. GH analogues that bind to the receptor but are incapable of mediating receptor signaling are potent antagonists of GH action. A GH receptor antagonist (pegvisomant) is approved for treatment of acromegaly.

GH induces protein synthesis and nitrogen retention and also impairs glucose tolerance by antagonizing insulin action. GH also stimulates lipolysis, leading to increased circulating fatty acid levels, reduced omental fat mass, and enhanced lean body mass. GH promotes sodium, potassium, and water retention and elevates serum levels of inorganic phosphate. Linear bone growth occurs as a result of complex hormonal and growth factor actions, including those of IGF-1. GH stimulates epiphyseal prechondrocyte differentiation. These precursor cells produce IGF-1 locally, and their proliferation is also responsive to the growth factor.

Insulin-Like Growth Factors Although GH exerts direct effects in target tissues, many of its physiologic effects are mediated indirectly through IGF-1, a potent growth and differentiation factor. The liver is the major source of circulating IGF-1. In peripheral tissues, IGF-1 also exerts local paracrine actions that appear to be both dependent on and independent of GH. Thus, GH administration induces circulating IGF-1 as well as stimulating local IGF-1 production in multiple tissues.

Both IGF-1 and IGF-2 are bound to high-affinity circulating IGF-binding proteins (IGFBPs) that regulate IGF availability and bioactivity. Levels of IGFBP3 are GH dependent, and it serves as the major carrier protein for circulating IGF-1. GH deficiency and malnutrition usually are associated with low IGFBP3 levels. IGFBP1 and IGFBP2 regulate local tissue IGF action but do not bind appreciable amounts of circulating IGF-1.

Serum IGF-1 concentrations are profoundly affected by physiologic factors. Levels increase during puberty, peak at 16 years, and subsequently decline by >80% during the aging process. IGF-1 concentrations are higher in women than in men. Because GH is the major determinant of hepatic IGF-1 synthesis, abnormalities of GH synthesis or action (including pituitary failure, GHRH receptor defect, GH receptor defect, or pharmacologic GH receptor blockade) lead to reduced IGF-1 levels. Hypocaloric states are associated with GH resistance; IGF-1 levels are therefore low with cachexia, malnutrition, and sepsis. In acromegaly, IGF-1 levels are invariably high and reflect a log-linear relationship with circulating GH concentrations.

IGF-1 PHYSIOLOGY Injected IGF-1 (100 μg/kg) induces hypoglycemia, and lower doses improve insulin sensitivity in patients with severe insulin resistance and diabetes. In cachectic subjects, IGF-1 infusion (12 μg/kg per h) enhances nitrogen retention and lowers cholesterol levels. Longer-term subcutaneous IGF-1 injections enhance protein synthesis and are anabolic. Although bone formation markers are induced, bone turnover also may be stimulated by IGF-1. IGF-1 is approved for use in patients with GH-resistance syndromes.

IGF-1 side effects are dose dependent, and overdose may result in hypoglycemia, hypotension, fluid retention, temporomandibular jaw pain, and increased intracranial pressure, all of which are reversible. Retinal damage and avascular femoral head necrosis have been reported. Chronic excess IGF-1 administration presumably would result in features of acromegaly.

ADRENOCORTICOTROPIC HORMONE

(See also Chap. 386)

Synthesis ACTH-secreting corticotrope cells constitute ~20% of the pituitary cell population. ACTH (39 amino acids) is derived from the POMC precursor protein (266 amino acids) that also generates several

other peptides, including β-lipotropin, β-endorphin, met-enkephalin, α-melanocyte-stimulating hormone (α-MSH), and corticotropin-like intermediate lobe protein (CLIP). The *POMC* gene is potently suppressed by glucocorticoids and induced by corticotropin-releasing hormone (CRH), arginine vasopressin (AVP), and proinflammatory cytokines, including IL-6, as well as leukemia inhibitory factor.

CRH, a 41-amino-acid hypothalamic peptide synthesized in the paraventricular nucleus as well as in higher brain centers, is the predominant stimulator of ACTH synthesis and release. The CRH receptor is a GPCR that is expressed on the corticotrope and signals to induce *POMC* transcription.

Secretion ACTH secretion is pulsatile and exhibits a characteristic circadian rhythm, peaking at about 6:00 A.M. and reaching a nadir about midnight. Adrenal glucocorticoid secretion, which is driven by ACTH, follows a parallel diurnal pattern. ACTH circadian rhythmicity is determined by variations in secretory pulse amplitude rather than changes in pulse frequency. Superimposed on this endogenous rhythm, ACTH levels are increased by physical and psychological stress, exercise, acute illness, and insulin-induced hypoglycemia.

Glucocorticoid-mediated negative regulation of the hypothalamic-pituitary-adrenal (HPA) axis occurs as a consequence of both hypothalamic CRH suppression and direct attenuation of pituitary *POMC* gene expression and ACTH release. In contrast, loss of cortisol feedback inhibition, as occurs in primary adrenal failure, results in extremely high ACTH levels.

Acute inflammatory or septic insults activate the HPA axis through the integrated actions of proinflammatory cytokines, bacterial toxins, and neural signals. The overlapping cascade of ACTH-inducing cytokines (tumor necrosis factor [TNF]; IL-1, -2, and -6; and leukemia inhibitory factor) activates hypothalamic CRH and AVP secretion, pituitary *POMC* gene expression, and local pituitary paracrine cytokine networks. The resulting cortisol elevation restrains the inflammatory response and enables host protection. Concomitantly, cytokine-mediated central glucocorticoid receptor resistance impairs glucocorticoid suppression of the HPA. Thus, the neuroendocrine stress response reflects the net result of highly integrated hypothalamic, intrapituitary, and peripheral hormone and cytokine signals acting to regulate cortisol secretion.

Action The major function of the HPA axis is to maintain metabolic homeostasis and mediate the neuroendocrine stress response. ACTH induces adrenocortical steroidogenesis by sustaining adrenal cell proliferation and function. The receptor for ACTH, designated *melanocortin-2 receptor*, is a GPCR that induces steroidogenesis by stimulating a cascade of steroidogenic enzymes **(Chap. 386)**.

GONADOTROPINS: FSH AND LH

Synthesis and Secretion Gonadotrope cells constitute ~10% of anterior pituitary cells and produce two gonadotropin hormones—LH and FSH. Like TSH and human chorionic gonadotropin, LH and FSH are glycoprotein hormones that comprise α and β subunits. The α subunit is common to these glycoprotein hormones; specificity of hormone function is conferred by the β subunits, which are expressed by separate genes.

Gonadotropin synthesis and release are dynamically regulated. This is particularly true in women, in whom rapidly fluctuating gonadal steroid levels vary throughout the menstrual cycle. Hypothalamic GnRH, a 10-amino-acid peptide, regulates the synthesis and secretion of both LH and FSH. Brain kisspeptin, a product of the *KISS1* gene, regulates hypothalamic GnRH release. GnRH is secreted in discrete pulses every 60–120 min, and the pulses in turn elicit LH and FSH pulses (Fig. 378-3). The pulsatile mode of GnRH input is essential to its action; pulses prime gonadotrope responsiveness, whereas continuous GnRH exposure induces desensitization. Based on this phenomenon, long-acting GnRH agonists are used to suppress gonadotropin levels in children with precocious puberty and in men with prostate cancer **(Chap. 87)** and are used in some ovulation-induction protocols to reduce levels of endogenous gonadotropins **(Chap. 392)**. Estrogens act at both the hypothalamus and the pituitary to modulate gonadotropin secretion. Chronic estrogen exposure is inhibitory, whereas rising estrogen levels, as occur during the preovulatory surge, exert positive feedback to increase gonadotropin pulse frequency and amplitude. Progesterone slows GnRH pulse frequency but enhances gonadotropin responses to GnRH. Testosterone feedback in men also occurs at the hypothalamic and pituitary levels and is mediated in part by its conversion to estrogens.

Although GnRH is the main regulator of LH and FSH secretion, FSH synthesis is also under distinct control by the gonadal peptides inhibin and activin, members of the transforming growth factor β (TGF-β) family. Inhibin selectively suppresses FSH, whereas activin stimulates FSH synthesis **(Chap. 392)**.

Action The gonadotropin hormones interact with their respective GPCRs expressed in the ovary and testis, evoking germ cell development and maturation and steroid hormone biosynthesis. In women, FSH regulates ovarian follicle development and stimulates ovarian estrogen production. LH mediates ovulation and maintenance of the corpus luteum. In men, LH induces Leydig cell testosterone synthesis and secretion, and FSH stimulates seminiferous tubule development and regulates spermatogenesis.

THYROID-STIMULATING HORMONE

Synthesis and Secretion TSH-secreting thyrotrope cells constitute 5% of the anterior pituitary cell population. TSH shares a common α subunit with LH and FSH but contains a specific TSH β subunit. TRH is a hypothalamic tripeptide (pyroglutamyl histidylprolinamide) that acts through a pituitary GPCR to stimulate TSH synthesis and secretion; it also stimulates the lactotrope cell to secrete PRL. TSH secretion is stimulated by TRH, whereas thyroid hormones, dopamine, somatostatin, and glucocorticoids suppress TSH by overriding TRH induction.

Thyrotrope cell proliferation and TSH secretion are both induced when negative feedback inhibition by thyroid hormones is removed. Thus, thyroid damage (including surgical thyroidectomy), radiation-induced hypothyroidism, chronic thyroiditis, and prolonged goitrogen exposure are associated with increased TSH levels. Long-standing untreated hypothyroidism can lead to elevated TSH levels, which may be associated with thyrotrope hyperplasia and pituitary enlargement and may sometimes be evident on magnetic resonance imaging.

Action TSH is secreted in pulses, although the excursions are modest in comparison to other pituitary hormones because of the low amplitude of the pulses and the relatively long half-life of TSH. Consequently, single determinations of TSH suffice to precisely assess its circulating levels. TSH binds to a GPCR on thyroid follicular cells to stimulate thyroid hormone synthesis and release **(Chap. 382)**.

379 Hypopituitarism

Shlomo Melmed, J. Larry Jameson

Deficient production of anterior pituitary hormones leads to features of hypopituitarism. Impaired production of one or more of the anterior pituitary trophic hormones can result from inherited disorders; more commonly, adult hypopituitarism is acquired and reflects the compressive mass effects of tumors or the consequences of local pituitary or hypothalamic traumatic, autoimmune, inflammatory, or vascular damage. These processes also may impair synthesis or secretion of hypothalamic hormones, with resultant pituitary failure (Table 379-1).

TABLE 379-1 Etiology of Hypopituitarism[a]

Development/structural
Midline cerebral defect syndromes
Pituitary dysplasia/aplasia
Primary empty sella
Congenital hypothalamic disorders (septo-optic dysplasia, Prader-Willi syndrome, Bardet-Biedl syndrome, Kallmann syndrome)
Congenital central nervous system mass, encephalocele
Genetic
Combined pituitary hormone deficiencies
Isolated primary hormone deficiencies
Traumatic
Surgical resection
Radiotherapy damage
Head injuries
Neoplastic
Pituitary adenoma
Parasellar mass (germinoma, ependymoma, glioma)
Rathke's cyst
Craniopharyngioma
Hypothalamic hamartoma, gangliocytoma
Pituitary metastases (breast, lung, colon carcinoma)
Lymphoma and leukemia
Meningioma
Infiltrative/inflammatory
Lymphocytic hypophysitis
Hemochromatosis
Sarcoidosis
Histiocytosis X
Granulomatous hypophysitis
Transcription factor antibodies
Immunotherapy
Vascular
Pituitary apoplexy
Pregnancy-related (infarction with diabetes; postpartum necrosis)
Subarachnoid hemorrhage
Sickle cell disease
Arteritis
Infections
Fungal (histoplasmosis)
Parasitic (toxoplasmosis)
Tuberculosis
Pneumocystis jirovecii

[a]Trophic hormone failure associated with pituitary compression or destruction usually occurs sequentially: growth hormone > follicle-stimulating hormone > luteinizing hormone > thyroid-stimulating hormone > adrenocorticotropic hormone. During childhood, growth retardation is often the presenting feature, and in adults, hypogonadism is the earliest symptom.

DEVELOPMENTAL CAUSES OF HYPOPITUITARISM

Pituitary dysplasia may result in aplastic, hypoplastic, or ectopic pituitary gland development. Because pituitary development follows midline cell migration from the nasopharyngeal Rathke's pouch, midline craniofacial disorders may be associated with pituitary dysplasia. Acquired pituitary failure in the newborn also can be caused by birth trauma, including cranial hemorrhage, asphyxia, and breech delivery.

A large number of transcription factors and growth factors are critical for the development of the hypothalamus and pituitary gland and the function of differentiated anterior pituitary cell lineages. Mutations have been described in the *HESX1, SOX2, SOX3, LHX3, LHX4, OTX, GLI2, PAX6, BMP4, ARNT2, FGF8, FGFR1, SHH, PROKR2, GPR161, IGSF1, PITX2,* and *CHD7* genes, among others. Heterozygous loss-of-function or autosomal recessive mutations disrupt hypothalamic and pituitary development at different developmental stages, causing a wide array of phenotypes ranging from severe syndromic midline and other defects to combined pituitary hormone defects or isolated hormone deficiencies. Depending on the gene involved, the pituitary may be hypoplastic, hyperplastic, or ectopic. Midline defects include variable combinations of abnormal development of the eyes, corpus collosum, vertebrae, and genital systems. Pituitary dysfunction ranges from isolated hormone deficiency to combined pituitary hormone deficiency (CPHD) and diabetes insipidus (DI).

In addition to these syndromic developmental disorders, some mutations affect specific pituitary cell lineages. For example, Pit-1 mutations cause combined growth hormone (GH), prolactin (PRL), and thyroid-stimulating hormone (TSH) deficiencies. These patients usually present with growth failure and varying degrees of hypothyroidism. The pituitary may appear hypoplastic on magnetic resonance imaging (MRI). Prop-1 is expressed early in pituitary development and appears to be required for Pit-1 function. Familial and sporadic *PROP1* mutations result in combined GH, PRL, TSH, and gonadotropin deficiency. Over 80% of these patients have growth retardation; by adulthood, all are deficient in TSH and gonadotropins, and a small minority later develop adrenocorticotropic hormone (ACTH) deficiency. Because of gonadotropin deficiency, these individuals do not enter puberty spontaneously. In some cases, the pituitary gland appears enlarged on MRI. *TPIT* mutations result in ACTH deficiency associated with hypocortisolism. Mutations in *NR5A1* (also known as steroidogenic factor 1 [SF1]) impair development of gonadotrope cells, as well as adrenal/gonadal development.

HYPOTHALAMIC ENDOCRINE DYSFUNCTION

Hypothalamic disorders can affect temperature regulation, appetite, sleep-wake cycles, autonomic systems, behavior, and memory, as well as multiple endocrine systems. Selected examples of hypothalamic disorders that affect the endocrine system are described below.

Kallmann Syndrome Kallmann syndrome results from defective hypothalamic gonadotropin-releasing hormone (GnRH) synthesis and is associated with anosmia or hyposmia due to olfactory bulb agenesis or hypoplasia (Chap. 391). Classically, the syndrome may also be associated with color blindness, optic atrophy, nerve deafness, cleft palate, renal abnormalities, cryptorchidism, and neurologic abnormalities such as mirror movements. The initial genetic cause was the X-linked *KAL* gene, mutations of which impair embryonic migration of GnRH neurons from the hypothalamic olfactory placode to the hypothalamus. Since then, more than a dozen additional genetic abnormalities, in addition to *KAL* mutations, have been found to cause isolated GnRH deficiency. Autosomal recessive (i.e., *GPR54, KISS1*) and dominant (i.e., *FGFR1*) modes of transmission have been described, and there is a growing list of genes associated with GnRH deficiency (including *GNRH1, PROK2, PROKR2, CHD7, PCSK1, FGF8, NELF, WDR11, TAC3, TACR3,* and *SEMA3E*). Some patients have oligogenic mutations in which mutations in a combination of different genes lead to the phenotype. Associated clinical features, in addition to GnRH deficiency, vary depending on the genetic cause. GnRH deficiency prevents progression through puberty. Males present with delayed puberty and pronounced hypogonadal features, including micropenis, probably the

result of low testosterone levels during infancy. Females present with primary amenorrhea and failure of secondary sexual development.

Kallmann syndrome and other causes of congenital GnRH deficiency are characterized by low luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels and low concentrations of sex steroids (testosterone or estradiol). In sporadic cases of isolated gonadotropin deficiency, the diagnosis is often one of exclusion after other known causes of hypothalamic-pituitary dysfunction have been eliminated. Repetitive GnRH administration restores normal pituitary gonadotropin responses, pointing to a hypothalamic defect in these patients.

Long-term treatment of males with human chorionic gonadotropin (hCG) or testosterone restores pubertal development and secondary sex characteristics; women can be treated with cyclic estrogen and progestin. Fertility may be restored by the administration of gonadotropins or by using a portable infusion pump to deliver subcutaneous, pulsatile GnRH.

Bardet-Biedl Syndrome This very rare genetically heterogeneous disorder is characterized by intellectual disability, renal abnormalities, obesity, and hexadactyly, brachydactyly, or syndactyly. Central DI may or may not be associated. GnRH deficiency occurs in 75% of males and half of affected females. Retinal degeneration begins in early childhood, and most patients are blind by age 30. Numerous subtypes of Bardet-Biedl syndrome (BBS) have been identified, with genetic linkage to at least nine different loci. Several of the loci encode genes involved in basal body cilia function, and this may account for the diverse clinical manifestations.

Leptin and Leptin Receptor Mutations Deficiencies of leptin or its receptor cause a broad spectrum of hypothalamic abnormalities, including hyperphagia, obesity, and central hypogonadism **(Chap. 401)**. Decreased GnRH production in these patients results in attenuated pituitary FSH and LH synthesis and release.

Prader-Willi Syndrome This is a contiguous gene syndrome that results from deletion of the paternal copies of the imprinted *SNRPN* gene, the *NECDIN* gene, and possibly other genes on chromosome 15q. Prader-Willi syndrome is associated with hypogonadotropic hypogonadism, hyperphagia-obesity, chronic muscle hypotonia, mental retardation, and adult-onset diabetes mellitus. Multiple somatic defects also involve the skull, eyes, ears, hands, and feet. Diminished hypothalamic oxytocin- and vasopressin-producing nuclei have been reported. Deficient GnRH synthesis is suggested by the observation that chronic GnRH treatment restores pituitary LH and FSH release.

ACQUIRED HYPOPITUITARISM

Hypopituitarism may be caused by accidental or neurosurgical trauma; vascular events such as apoplexy; pituitary or hypothalamic neoplasms, craniopharyngioma, lymphoma, or metastatic tumors; inflammatory disease such as lymphocytic hypophysitis; autoimmune hypophysitis associated with checkpoint inhibitor cancer immunotherapy; infiltrative disorders such as sarcoidosis, hemochromatosis **(Chap. 414)**, and tuberculosis; or irradiation.

Patients with brain injury, including from contact sports trauma, motor vehicle accidents, explosive causes, subarachnoid hemorrhage, and irradiation, can experience transient or long-term hypopituitarism. Long-term periodic endocrine follow-up is indicated because hypothalamic or pituitary dysfunction will develop in 25–40% of these patients.

Hypothalamic Infiltration Disorders Sarcoidosis, histiocytosis X, amyloidosis, and hemochromatosis frequently involve both hypothalamic and pituitary neuronal and neurochemical tracts. Consequently, DI is a common presentation, reported in half of patients with these disorders. Growth retardation is seen if attenuated GH secretion occurs before puberty. Hypogonadotropic hypogonadism and hyperprolactinemia are also common.

Inflammatory Lesions Pituitary damage and subsequent secretory dysfunction can be seen with chronic site infections such as tuberculosis, with opportunistic fungal infections associated with AIDS, and in tertiary syphilis. Other inflammatory processes, such as granulomas and sarcoidosis, should be considered in the differential diagnosis of imaging studies suggestive of a pituitary adenoma. These lesions may cause extensive hypothalamic and pituitary damage, leading to hormone deficiencies.

Cranial Irradiation Cranial irradiation may result in long-term hypothalamic and pituitary dysfunction, especially in children and adolescents, as they are more susceptible to damage after whole-brain or head and neck therapeutic irradiation. The development of subsequent hormonal abnormalities correlates strongly with irradiation dosage and the time interval after completion of radiotherapy. Up to two-thirds of patients ultimately develop hormone insufficiency after a median dose of 50 Gy (5000 rad) directed at the skull base. The development of hypopituitarism occurs over 5–15 years and usually reflects hypothalamic damage rather than primary destruction of pituitary cells. Although the pattern of hormone loss is variable, GH deficiency is most common, followed by gonadotropin, thyroid, and ACTH deficiency. When deficiency of one or more hormones is documented, the possibility of diminished reserve of other hormones is likely. Accordingly, anterior pituitary function should be continually evaluated over the long term in previously irradiated patients, and replacement therapy instituted when appropriate (see below).

Lymphocytic Hypophysitis This occurs most often in postpartum women; it usually presents with hyperprolactinemia and MRI evidence of a prominent pituitary mass that often resembles an adenoma, with mildly elevated PRL levels. Pituitary failure caused by diffuse lymphocytic infiltration may be transient or permanent but requires immediate evaluation and treatment. Rarely, isolated pituitary hormone deficiencies have been described, suggesting a selective autoimmune process targeted to specific cell types. Most patients manifest symptoms of progressive mass effects with headache and visual disturbance. The erythrocyte sedimentation rate often is elevated. Because it may be indistinguishable from a pituitary adenoma on MRI, hypophysitis should be considered in a postpartum woman with a newly diagnosed pituitary mass before an unnecessary surgical intervention is undertaken. The inflammatory process often resolves after several months of glucocorticoid treatment, and pituitary function may be restored, depending on the extent of damage.

Immunotherapy and Hypophysitis Pituitary cells express cytotoxic T lymphocyte antigen-4 (CTLA-4), and up to 20% of patients receiving cancer immunotherapy with CTLA-4 inhibitors (e.g., ipilimumab) may develop hypophysitis with heterogeneously associated thyroid, adrenal, islet, and gonadal failure. Hypophysitis is also reported with PD-1/PD-L1 inhibitors (e.g., pembrolizumab and nivolumab) and may show delayed presentation. Pituitary hormone replacement, with or without high-dose glucocorticoids, may be safely tolerated with continued immunotherapy.

Pituitary Apoplexy Acute intrapituitary hemorrhagic vascular events can cause substantial damage to the pituitary and surrounding sellar structures. Pituitary apoplexy may occur spontaneously in a preexisting pituitary adenoma; postpartum (Sheehan's syndrome); or in association with diabetes, hypertension, sickle cell anemia, or acute shock. The hyperplastic enlargement of the pituitary, which occurs normally during pregnancy, increases the risk for hemorrhage and infarction. Apoplexy is an endocrine emergency that may result in severe hypoglycemia, hypotension and shock, central nervous system (CNS) hemorrhage, and death. Acute symptoms may include severe headache with signs of meningeal irritation, bilateral visual changes, ophthalmoplegia, and, in severe cases, cardiovascular collapse and loss of consciousness. Pituitary computed tomography (CT) or MRI may reveal signs of intratumoral or sellar hemorrhage, with pituitary stalk deviation and compression of pituitary tissue.

Patients with no evident visual loss or impaired consciousness can be observed and managed conservatively with high-dose glucocorticoids. Those with significant or progressive visual loss, cranial nerve

palsy, or loss of consciousness require urgent surgical decompression. Visual recovery after sellar surgery is inversely correlated with the length of time after the acute event. Therefore, severe ophthalmoplegia or visual deficits are indications for early surgery. Hypopituitarism is common after apoplexy.

Empty Sella A partial or apparently totally empty sella is often an incidental MRI finding and may sometimes be associated with intracranial hypertension. These patients usually have normal pituitary function, implying that the surrounding rim of pituitary tissue is fully functional. Hypopituitarism, however, may develop insidiously. Pituitary adenomas also may undergo clinically silent infarction and involution with development of a partial or totally empty sella by cerebrospinal fluid (CSF) filling the dural herniation. Rarely, small but functional pituitary adenomas may arise within the rim of normal pituitary tissue, and they are not always visible on MRI.

PRESENTATION AND DIAGNOSIS

The clinical manifestations of hypopituitarism depend on which hormones are lost and the extent of the hormone deficiency (see below). GH deficiency causes growth disorders in children and leads to abnormal body composition in adults. Gonadotropin deficiency causes menstrual disorders and infertility in women and decreased sexual function, infertility, and loss of secondary sexual characteristics in men. TSH and ACTH deficiencies usually develop later in the course of pituitary failure. TSH deficiency causes growth retardation in children and features of hypothyroidism in children and adults. The secondary form of adrenal insufficiency caused by ACTH deficiency leads to hypocortisolism with relative preservation of mineralocorticoid production. PRL deficiency causes failure of lactation. When lesions involve the posterior pituitary, polyuria and polydipsia reflect loss of vasopressin secretion. In patients with long-standing pituitary damage, epidemiologic studies document an increased mortality rate, primarily from increased cardiovascular and cerebrovascular disease. Previous head or neck irradiation is also a determinant of increased mortality rates in patients with hypopituitarism, especially from cerebrovascular disease.

LABORATORY INVESTIGATION

Biochemical diagnosis of pituitary insufficiency is made by demonstrating low levels of respective pituitary trophic hormones in the setting of low levels of target organ hormones. For example, low free thyroxine in the setting of a low or inappropriately normal TSH level suggests secondary hypothyroidism. Similarly, a low testosterone level without elevation of gonadotropins suggests hypogonadotropic hypogonadism. Provocative tests may be required to assess pituitary reserve (Table 379-2). GH responses to insulin-induced hypoglycemia, arginine,

TABLE 379-2 Tests of Pituitary Sufficiency

HORMONE	TEST	BLOOD SAMPLES	INTERPRETATION
Growth hormone (GH)	Insulin tolerance test: Regular insulin (0.05–0.15 U/kg IV)	–30, 0, 30, 60, 120 min for glucose and GH	Glucose <40 mg/dL; GH should be >3 μg/L
	GHRH test: 1 μg/kg IV	0, 15, 30, 45, 60, 120 min for GH	Normal response is GH >3 μg/L
	L-Arginine test: 30 g IV over 30 min	0, 30, 60, 120 min for GH	Normal response is GH >3 μg/L
	L-Dopa test: 500 mg PO	0, 30, 60, 120 min for GH	Normal response is GH >3 μg/L
Prolactin	TRH test: 200–500 μg IV	0, 20, and 60 min for TSH and PRL	Normal prolactin is >2 μg/L and increase >200% of baseline
ACTH	Insulin tolerance test: regular insulin (0.05–0.15 U/kg IV)	–30, 0, 30, 60, 90 min for glucose and cortisol	Glucose <40 mg/dL Cortisol should increase by >7 μg/dL or to >20 μg/dL
	CRH test: 1 μg/kg ovine CRH IV at 8 A.M.	0, 15, 30, 60, 90, 120 min for ACTH and cortisol	Basal ACTH increases 2- to 4-fold and peaks at 20–100 pg/mL Cortisol levels >20–25 μg/dL
	Metyrapone test: Metyrapone (30 mg/kg) at midnight	Plasma 11-deoxycortisol and cortisol at 8 A.M.; ACTH can also be measured	Plasma cortisol should be <4 g/dL to assure an adequate response Normal response is 11-deoxycortisol >7.5 μg/dL or ACTH >75 pg/mL
	Standard ACTH stimulation test: ACTH 1-24 (cosyntropin), 0.25 mg IM or IV	0, 30, 60 min for cortisol and aldosterone	Normal response is cortisol >21 g/dL and aldosterone response >4 ng/dL above baseline
	Low-dose ACTH test: ACTH 1-24 (cosyntropin), 1 μg IV	0, 30, 60 min for cortisol	Cortisol should be >21 μg/dL
	3-day ACTH stimulation test consists of 0.25 mg ACTH 1-24 given IV over 8 h each day		Cortisol >21 μg/dL
TSH	Basal thyroid function tests: T_4, T_3, TSH	Basal measurements	Low free thyroid hormone levels in the setting of TSH levels that are not appropriately increased indicate pituitary insufficiency
	TRH test: 200–500 μg IV	0, 20, 60 min for TSH and PRL[a]	TSH should increase by >5 mU/L unless thyroid hormone levels are increased
LH, FSH	LH, FSH, testosterone, estrogen	Basal measurements	Basal LH and FSH should be increased in postmenopausal women Low testosterone levels in the setting of low LH and FSH indicate pituitary insufficiency
	GnRH test: GnRH (100 μg) IV	0, 30, 60 min for LH and FSH	In most adults, LH should increase by 10 IU/L and FSH by 2 IU/L Normal responses are variable
Multiple hormones	Combined anterior pituitary test: GHRH (1 μg/kg), CRH (1 μg/kg), GnRH (100 μg), TRH (200 μg) are given IV	–30, 0, 15, 30, 60, 90, 120 min for GH, ACTH, cortisol, LH, FSH, and TSH	Combined or individual releasing hormone responses must be elevated in the context of basal target gland hormone values and may not be uniformly diagnostic (see text)

[a]Evoked PRL response indicates lactotrope integrity.

Abbreviations: T_3, triiodothyronine; T_4, thyroxine; TRH, thyrotropin-releasing hormone. For other abbreviations, see text.

glucagon, L-dopa, growth hormone–releasing hormone (GHRH), or growth hormone–releasing orally active ghrelin receptor agonist macimorelin can be used to assess GH reserve. Corticotropin-releasing hormone (CRH) administration induces ACTH release, and administration of synthetic ACTH (cosyntropin) evokes adrenal cortisol release as an indirect indicator of pituitary ACTH reserve **(Chap. 386)**. ACTH reserve is most reliably assessed by measuring ACTH and cortisol levels during insulin-induced hypoglycemia. However, this test should be performed cautiously in patients with suspected adrenal insufficiency because of enhanced susceptibility to hypoglycemia and hypotension. Administering insulin to induce hypoglycemia is contraindicated in patients with active coronary artery disease or known seizure disorders.

TREATMENT

Hypopituitarism

Hormone replacement therapy, including glucocorticoids, thyroid hormone, sex steroids, GH, and vasopressin, is usually safe and free of complications. Treatment regimens that mimic physiologic hormone production allow for maintenance of satisfactory clinical homeostasis. Effective dosage schedules are outlined in **Table 379-3**. Patients in need of glucocorticoid replacement require especially careful dose adjustments during stressful events such as acute illness, dental procedures, trauma, and hospitalization.

DISORDERS OF GROWTH AND DEVELOPMENT

Skeletal Maturation and Somatic Growth The growth plate is dependent on a variety of hormonal stimuli, including GH, insulin-like growth factor (IGF)-1, sex steroids, thyroid hormones, paracrine and circulating growth factors (e.g., fibroblast growth factor family), and cytokines. The growth-promoting process also requires caloric energy, amino acids, vitamins, and trace metals and consumes ~10% of normal energy production. Malnutrition impairs chondrocyte activity, increases GH resistance, and leads to reduced circulating IGF-1 and IGF binding protein (IGFBP)-3 levels.

Linear bone growth rates are very high in infancy and are pituitary dependent. Mean growth velocity is ~6 cm/year in later childhood and usually is maintained within a given range on a standardized percentile chart. Peak growth rates occur during midpuberty when bone age is 12 (girls) or 13 (boys). Secondary sexual development is associated with elevated sex steroids that cause progressive epiphyseal growth plate closure. *Bone age* is delayed in patients with all forms of true GH deficiency or GH receptor defects that result in attenuated GH action.

Short stature may occur as a result of constitutive intrinsic growth defects or because of acquired extrinsic factors that impair growth. In general, delayed bone age in a child with short stature is suggestive of a hormonal or systemic disorder, whereas normal bone age in a short child is more likely to be caused by a genetic cartilage dysplasia or growth plate disorder **(Chap. 413)**.

TABLE 379-3 Hormone Replacement Therapy for Adult Hypopituitarism[a]

HORMONE DEFICIT	HORMONE REPLACEMENT
ACTH	Hydrocortisone (10–20 mg/d in divided doses)
	Cortisone acetate (15–25 mg/d in divided doses)
	Prednisone (5 mg A.M.)
TSH	L-Thyroxine (0.075–0.15 mg daily)
FSH/LH	Males
	Testosterone gel (5–10 g/d)
	Testosterone skin patch (5 mg/d)
	Testosterone enanthate (200 mg IM every 2 weeks)
	Females
	Conjugated estrogen (0.65–1.25 mg qd for 25 days)
	Progesterone (5–10 mg qd) on days 16–25
	Estradiol skin patch (0.025–0.1 mg every week), adding progesterone on days 16–25 if uterus intact
	For fertility: menopausal gonadotropins, human chorionic gonadotropins
GH	Adults: Somatotropin (0.1–1.25 mg SC qd)
	Children: Somatotropin (0.02–0.05 mg/kg per day)
Vasopressin	Intranasal desmopressin (5–20 g twice daily) Oral 300–600 μg qd

[a]All doses shown should be individualized for specific patients and should be reassessed during stress, surgery, or pregnancy. Male and female fertility requirements should be managed as discussed in **Chaps. 391 and 392**.

Note: For abbreviations, see text.

GH Deficiency in Children Isolated GH deficiency is characterized by short stature, micropenis, increased fat, high-pitched voice, and a propensity to hypoglycemia due to relatively unopposed insulin action. Familial modes of inheritance are seen in at least one-third of these individuals and may be autosomal dominant, recessive, or X-linked. About 10% of children with GH deficiency have mutations in the *GH-N* gene, including gene deletions and a wide range of point mutations. Mutations in transcription factors Pit-1 and Prop-1, which control somatotrope development (see above), result in GH deficiency in combination with other pituitary hormone deficiencies, which may become manifest only in adulthood. The diagnosis of *idiopathic GH deficiency* should be made only after known molecular defects have been rigorously excluded.

GHRH RECEPTOR MUTATIONS Recessive mutations of the GHRH receptor gene in subjects with severe proportionate dwarfism are associated with low basal GH levels that cannot be stimulated by exogenous GHRH, GH-releasing peptide, or insulin-induced hypoglycemia, as well as anterior pituitary hypoplasia. The syndrome exemplifies the importance of the GHRH receptor for determining somatotrope cell proliferation and hormonal responsiveness.

GH INSENSITIVITY This is caused by defects of GH receptor structure or signaling. Homozygous or heterozygous mutations of the GH receptor are associated with partial or complete GH insensitivity and growth failure (*Laron syndrome*). The diagnosis is based on normal or high GH levels, with decreased circulating GH-binding protein (GHBP), and low IGF-1 levels. Very rarely, defective IGF-1, IGF-1 receptor, or IGF-1 signaling defects are also encountered. *STAT5B* mutations result in both immunodeficiency as well as abrogated GH signaling, leading to short stature with normal or elevated GH levels and low IGF-1 levels. Circulating GH receptor antibodies may rarely cause peripheral GH insensitivity.

NUTRITIONAL SHORT STATURE Caloric deprivation and malnutrition, uncontrolled diabetes, and chronic renal failure represent secondary causes of abrogated GH receptor function. These conditions also stimulate production of proinflammatory cytokines, which act to exacerbate the block of GH-mediated signal transduction. Children with these conditions typically exhibit features of acquired short stature with normal or elevated GH and low IGF-1 levels.

PSYCHOSOCIAL SHORT STATURE Emotional and social deprivation lead to growth retardation accompanied by delayed speech, discordant hyperphagia, and an attenuated response to administered GH. A nurturing environment restores growth rates.

PRESENTATION AND DIAGNOSIS

Short stature is commonly encountered in clinical practice, and the decision to evaluate these children requires clinical judgment in association with auxologic data and family history. Short stature should be evaluated comprehensively if a patient's height is >3 standard deviations below the mean for age or if the growth rate has decelerated. Skeletal maturation is best evaluated by measuring a radiologic bone age, which is based mainly on the degree of wrist bone growth plate fusion. Final height can be predicted using standardized scales (Bayley-Pinneau or Tanner-Whitehouse) or estimated by adding 6.5 cm (boys) or subtracting 6.5 cm (girls) from the midparental height.

LABORATORY INVESTIGATION

Because GH secretion is pulsatile, GH deficiency is best assessed by examining the response to provocative stimuli, including exercise, insulin-induced hypoglycemia, and other pharmacologic tests that normally increase GH to >7 μg/L in children. Random GH measurements do not distinguish normal children from those with true GH deficiency. Adequate adrenal and thyroid hormone replacement should be assured before testing. Age-matched IGF-1 levels are not sufficiently sensitive or specific to make the diagnosis but can be useful to confirm GH deficiency. Pituitary MRI may reveal pituitary mass lesions or structural defects. Molecular analyses for known mutations should be undertaken when the cause of short stature remains cryptic or when additional clinical features suggest a genetic cause.

TREATMENT

Disorders of Growth and Development

Replacement therapy with recombinant GH (0.02–0.05 mg/kg per day SC) restores growth velocity in GH-deficient children to ~10 cm/year. If pituitary insufficiency is documented, other associated hormone deficits should be corrected, especially adrenal steroids. In selected situations, GH treatment may be combined with strategies to delay puberty (e.g., GnRH agonist) or reduce sex steroids (e.g., aromatase inhibitors) as a means to mitigate sex steroid effect on epiphyseal closure. GH treatment is also moderately effective for accelerating growth rates in children with Turner syndrome and chronic renal failure. Treating psychosocial or constitutional (idiopathic) short stature with GH is not uniformly recommended as these children may only experience modest additive growth, which should be weighed against GH cost and side effect profiles.

In patients with GH insensitivity and growth retardation due to mutations of the GH receptor, treatment with IGF-1 bypasses the dysfunctional GH receptor.

ADULT GH DEFICIENCY

Adult GH deficiency (AGHD) usually is caused by acquired hypothalamic or pituitary somatotrope damage. Acquired pituitary hormone deficiency follows a typical pattern in which loss of adequate GH reserve foreshadows subsequent hormone deficits. The sequential order of hormone loss is usually GH → FSH/LH → TSH → ACTH. Patients previously diagnosed with childhood-onset GH deficiency should be retested as adults to affirm the diagnosis.

PRESENTATION AND DIAGNOSIS

The clinical features of AGHD include changes in body composition, lipid metabolism, and quality of life and cardiovascular dysfunction **(Table 379-4)**. Body composition changes are common and include reduced lean body mass, increased fat mass with selective deposition of intraabdominal visceral fat, and increased waist-to-hip ratio. Hyperlipidemia, left ventricular dysfunction, hypertension, and increased plasma fibrinogen levels also may be present. Bone mineral content is reduced, with resultant increased fracture rates. Patients may experience social isolation, depression, and difficulty maintaining gainful employment. Adult hypopituitarism is associated with a threefold increase in cardiovascular mortality rates in comparison to age- and sex-matched controls, and this may be due to GH deficiency, as patients in these studies were replaced with other deficient pituitary hormones.

TABLE 379-4 Features of Adult Growth Hormone Deficiency

Clinical
Impaired quality of life
Decreased energy and drive
Poor concentration
Low self-esteem
Social isolation
Body composition changes
Increased body fat mass
Central fat deposition
Increased waist-to-hip ratio
Decreased lean body mass
Reduced exercise capacity
Reduced maximum O_2 uptake
Impaired cardiac function
Reduced muscle mass
Cardiovascular risk factors
Impaired cardiac structure and function
Abnormal lipid profile
Decreased fibrinolytic activity
Atherosclerosis
Omental obesity
Imaging
Pituitary: mass or structural damage
Bone: reduced bone mineral density
Abdomen: excess omental adiposity
Laboratory
Evoked GH <3 ng/mL
IGF-1 and IGFBP3 low or normal
Increased LDL cholesterol
Concomitant gonadotropin, TSH, and/or ACTH reserve deficits may be present

Abbreviation: LDL, low-density lipoprotein. For other abbreviations, see text.

LABORATORY INVESTIGATION

AGHD is rare, and in light of the nonspecific nature of associated clinical symptoms, patients appropriate for testing should be selected carefully on the basis of well-defined criteria. With few exceptions, testing should be restricted to patients with the following predisposing factors: (1) pituitary surgery, (2) pituitary or hypothalamic tumor or granulomas, (3) history of cranial irradiation, (4) radiologic evidence of a pituitary lesion, and (5) childhood requirement for GH replacement therapy. The transition of a GH-deficient adolescent to adulthood requires retesting to document subsequent AGHD. Up to 20% of patients previously treated for childhood-onset GH deficiency are found to be GH sufficient on repeat testing as adults.

A significant proportion (~25%) of truly GH-deficient adults have low-normal IGF-1 levels. Thus, as in the evaluation of GH deficiency in children, valid age-matched IGF-1 measurements provide a useful index of therapeutic responses but are not sufficiently precise for diagnostic purposes. The most validated test to distinguish pituitary-sufficient patients from those with AGHD is insulin-induced (0.05–0.1 U/kg) hypoglycemia. After glucose reduction to ~40 mg/dL, most individuals experience neuroglycopenic symptoms **(Chap. 406)**, and peak GH release occurs at 60 min and remains elevated for up to 2 h. About 90% of healthy adults exhibit GH responses >5 μg/L; AGHD is defined by a peak GH response to hypoglycemia of <3 μg/L. Although insulin-induced hypoglycemia is safe when performed under appropriate supervision, it is contraindicated in patients with diabetes, ischemic heart disease, cerebrovascular disease, or epilepsy and in elderly patients. Alternative stimulatory tests include intravenous arginine (30 g), GHRH (1 μg/kg), oral ghrelin receptor agonist (0.5 mg/kg), and glucagon (1 mg). Combinations of these tests may evoke GH secretion in subjects who are not responsive to a single test.

TREATMENT

Adult GH Deficiency

Once the diagnosis of AGHD is unequivocally established, replacement of GH may be indicated. Contraindications to therapy include the presence of an active neoplasm, intracranial hypertension, and uncontrolled diabetes and retinopathy. The starting adult dose of 0.1–0.2 mg/d should be titrated (up to a maximum of 1.25 mg/d) to maintain IGF-1 levels in the mid-normal range for age- and

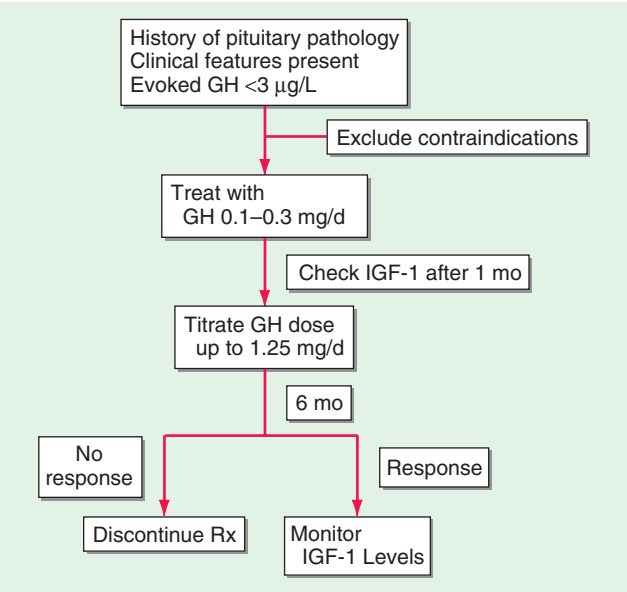

FIGURE 379-1 Management of adult growth hormone (GH) deficiency. IGF, insulin-like growth factor; Rx, treatment.

sex-matched controls **(Fig. 379-1)**. Women require higher doses than men, and elderly patients require less GH. Long-term GH maintenance sustains normal IGF-1 levels and is associated with persistent body composition changes (e.g., enhanced lean body mass and lower body fat). High-density lipoprotein cholesterol increases, but total cholesterol and insulin levels may not change significantly. Lumbar spine bone mineral density increases, but this response is gradual (>1 year). Many patients note significant improvement in quality of life when evaluated by standardized questionnaires. The effect of GH replacement on mortality rates in GH-deficient patients is currently the subject of long-term prospective investigation. Recently approved long-acting GH preparations for patients with AGHD require weekly injections. Ideally, dosing should be titrated to achieve normal but not supra-normal IGF-1 levels. Early reports indicate that side effects appear similar to subcutaneous formulations.

About 30% of patients exhibit reversible dose-related fluid retention, joint pain, and carpal tunnel syndrome, and up to 40% exhibit myalgias and paresthesia. Patients receiving insulin require careful monitoring for dosing adjustments, as GH is a potent counterregulatory hormone for insulin action. Patients with type 2 diabetes mellitus may initially develop further insulin resistance. However, glycemic control usually improves with the sustained loss of abdominal fat associated with long-term GH replacement. Headache, increased intracranial pressure, hypertension, and tinnitus occur rarely. Pituitary tumor regrowth and progression of skin lesions or other tumors have not been encountered in long-term surveillance programs with appropriate replacement doses.

ACTH DEFICIENCY

PRESENTATION AND DIAGNOSIS

Secondary adrenal insufficiency occurs as a result of pituitary ACTH deficiency. It is characterized by fatigue, weakness, anorexia, nausea, vomiting, and, occasionally, hypoglycemia. In contrast to primary adrenal failure, hypocortisolism associated with pituitary failure usually is not accompanied by hyperpigmentation or mineralocorticoid deficiency.

ACTH deficiency is commonly due to glucocorticoid withdrawal after treatment-associated suppression of the hypothalamic-pituitary-adrenal (HPA) axis. Isolated ACTH deficiency may occur after surgical resection of an ACTH-secreting pituitary adenoma that has suppressed the HPA axis; this phenomenon is in fact suggestive of a surgical cure. The mass effects of other pituitary adenomas or sellar lesions may lead to ACTH deficiency, usually in combination with other pituitary hormone deficiencies. Partial ACTH deficiency may be unmasked in the presence of an acute medical or surgical illness, when clinically significant hypocortisolism reflects diminished ACTH reserve. Rarely, *TPIT* or *POMC* mutations result in primary ACTH deficiency.

LABORATORY DIAGNOSIS

Inappropriately low ACTH levels in the setting of low cortisol levels are characteristic of diminished ACTH reserve. Low basal serum cortisol levels are associated with blunted cortisol responses to ACTH stimulation and impaired cortisol response to insulin-induced hypoglycemia or testing with metyrapone or CRH. **For a description of provocative ACTH tests, see Chap. 386.**

TREATMENT

ACTH Deficiency

Glucocorticoid replacement therapy improves most features of ACTH deficiency. The total daily dose of hydrocortisone replacement preferably should generally not exceed 20 mg daily, divided into two or three doses. Prednisone (5 mg each morning) is longer acting and has fewer mineralocorticoid effects than hydrocortisone. Some authorities advocate lower maintenance doses in an effort to avoid cushingoid side effects. Doses should be increased severalfold during periods of acute illness or stress. Patients should wear medical alert bracelets and/or carry identification cards with information about their glucocorticoid requirements.

GONADOTROPIN DEFICIENCY

Hypogonadism is the most common presenting feature of adult hypopituitarism even when other pituitary hormones are also deficient. It is often a harbinger of hypothalamic or pituitary lesions that impair GnRH production or delivery through the pituitary stalk. As noted below, hypogonadotropic hypogonadism is a common presenting feature of hyperprolactinemia.

A variety of inherited and acquired disorders are associated with *isolated hypogonadotropic hypogonadism* **(Chap. 391)**. Hypothalamic defects associated with GnRH deficiency include Kallmann syndrome and mutations in more than a dozen genes that regulate GnRH neuron migration, development, and function (see above). Mutations in *GPR54, DAX1, NR5A1*, kisspeptin, the GnRH receptor, and the LHβ or FSHβ subunit genes also cause pituitary gonadotropin deficiency. Acquired forms of GnRH deficiency leading to hypogonadotropism are seen in association with anorexia nervosa, stress, starvation, and extreme exercise but also may be idiopathic. Hypogonadotropic hypogonadism in these disorders is reversed by removal of the stressful stimulus or by caloric replenishment.

PRESENTATION AND DIAGNOSIS

In premenopausal women, hypogonadotropic hypogonadism presents as diminished ovarian function leading to oligomenorrhea or amenorrhea, infertility, decreased vaginal secretions, decreased libido, and breast atrophy. In hypogonadal adult men, secondary testicular failure is associated with decreased libido and potency, infertility, decreased muscle mass with weakness, reduced beard and body hair growth, soft testes, and characteristic fine facial wrinkles. Osteoporosis occurs in both untreated hypogonadal women and men.

LABORATORY INVESTIGATION

Central hypogonadism is associated with low or inappropriately normal serum gonadotropin levels in the setting of low sex hormone concentrations (testosterone in men, estradiol in women). Because gonadotropin secretion is pulsatile, valid assessments may require repeated measurements or the use of pooled serum samples. Men have reduced sperm counts.

Intravenous GnRH (100 μg) stimulates gonadotropes to secrete LH (which peaks within 30 min) and FSH (which plateaus during the ensuing 60 min). Normal responses vary according to menstrual cycle stage, age, and sex of the patient. Generally, LH levels increase about threefold, whereas FSH responses are less pronounced. In the setting of gonadotropin deficiency, a normal gonadotropin response to GnRH indicates intact pituitary gonadotrope function and suggests a hypothalamic abnormality. An absent response, however, does not reliably distinguish pituitary from hypothalamic causes of hypogonadism. For this reason, GnRH testing usually adds little to the information gained from baseline evaluation of the hypothalamic-pituitary-gonadotrope axis except in cases of isolated GnRH deficiency (e.g., Kallmann syndrome).

MRI examination of the sellar region and assessment of other pituitary functions usually are indicated in patients with documented central hypogonadism.

TREATMENT

Gonadotropin Deficiency

In males, testosterone replacement is necessary to achieve and maintain normal growth and development of the external genitalia, secondary sex characteristics, male sexual behavior, and androgenic anabolic effects, including maintenance of muscle function and bone mass. Testosterone may be administered by intramuscular injections every 1–4 weeks or by using skin patches or testosterone gels **(Chap. 391)**. Gonadotropin injections (hCG or human menopausal gonadotropin [hMG]) over 12–18 months are used to restore fertility. Pulsatile GnRH therapy (25–150 ng/kg every 2 h), administered by a subcutaneous infusion pump, is also effective for treatment of hypothalamic hypogonadism when fertility is desired.

In premenopausal women, cyclical replacement of estrogen and progesterone maintains secondary sexual characteristics and integrity of genitourinary tract mucosa and prevents premature osteoporosis **(Chap. 392)**. Gonadotropin therapy is used for ovulation induction. Follicular growth and maturation are initiated using hMG or recombinant FSH; hCG or human luteinizing hormone (hLH) is subsequently injected to induce ovulation. As in men, pulsatile GnRH therapy can be used to treat hypothalamic causes of gonadotropin deficiency.

Shlomo Melmed, J. Larry Jameson

HYPOTHALAMIC, PITUITARY, AND OTHER SELLAR MASSES

EVALUATION OF SELLAR MASSES

Local Mass Effects Clinical manifestations of sellar lesions vary, depending on the anatomic location of the mass and the direction of its extension **(Table 380-1)**. The dorsal sellar diaphragm presents the least resistance to soft tissue expansion from the sella; consequently, pituitary adenomas frequently extend in a suprasellar direction. Bony invasion may occur as well, especially through the sellar floor to the sphenoid sinus **(Fig. 380-1)**.

Headaches are common features of small intrasellar tumors, even with no demonstrable suprasellar extension. Because of the confined nature of the pituitary, small changes in intrasellar pressure stretch the dural plate; however, headache severity correlates poorly with adenoma size or extension.

Suprasellar extension can lead to visual loss by several mechanisms, the most common being compression of the optic chiasm. Rarely, direct invasion of the optic nerves or obstruction of cerebrospinal fluid (CSF) flow leading to secondary visual disturbances can occur. Pituitary stalk compression by a hormonally active or inactive intrasellar mass may compress the portal vessels, disrupting pituitary access to

TABLE 380-1 Features of Sellar Mass Lesions[a]

IMPACTED STRUCTURE	CLINICAL IMPACT
Pituitary	Hypogonadism Hypothyroidism Growth failure, adult growth hormone deficiency Hypoadrenalism Hyperprolactinema (stalk compression)
Optic chiasm	Loss of red perception Bitemporal hemianopia Superior or bitemporal field defect Scotoma Blindness
Hypothalamus	Temperature dysregulation Appetite and thirst disorders Obesity Diabetes insipidus Sleep disorders Behavioral dysfunction Autonomic dysfunction
Cavernous sinus	Ophthalmoplegia with or without ptosis or diplopia Facial numbness
Frontal lobe	Personality disorder Anosmia
Brain	Headache Hydrocephalus Psychosis Dementia Laughing seizures

[a]As the intrasellar mass expands, it first compresses intrasellar pituitary tissue, then usually invades dorsally through the dura to lift the optic chiasm or laterally to the cavernous sinuses. Bony erosion is rare, as is direct brain compression. Microadenomas may present with headache.

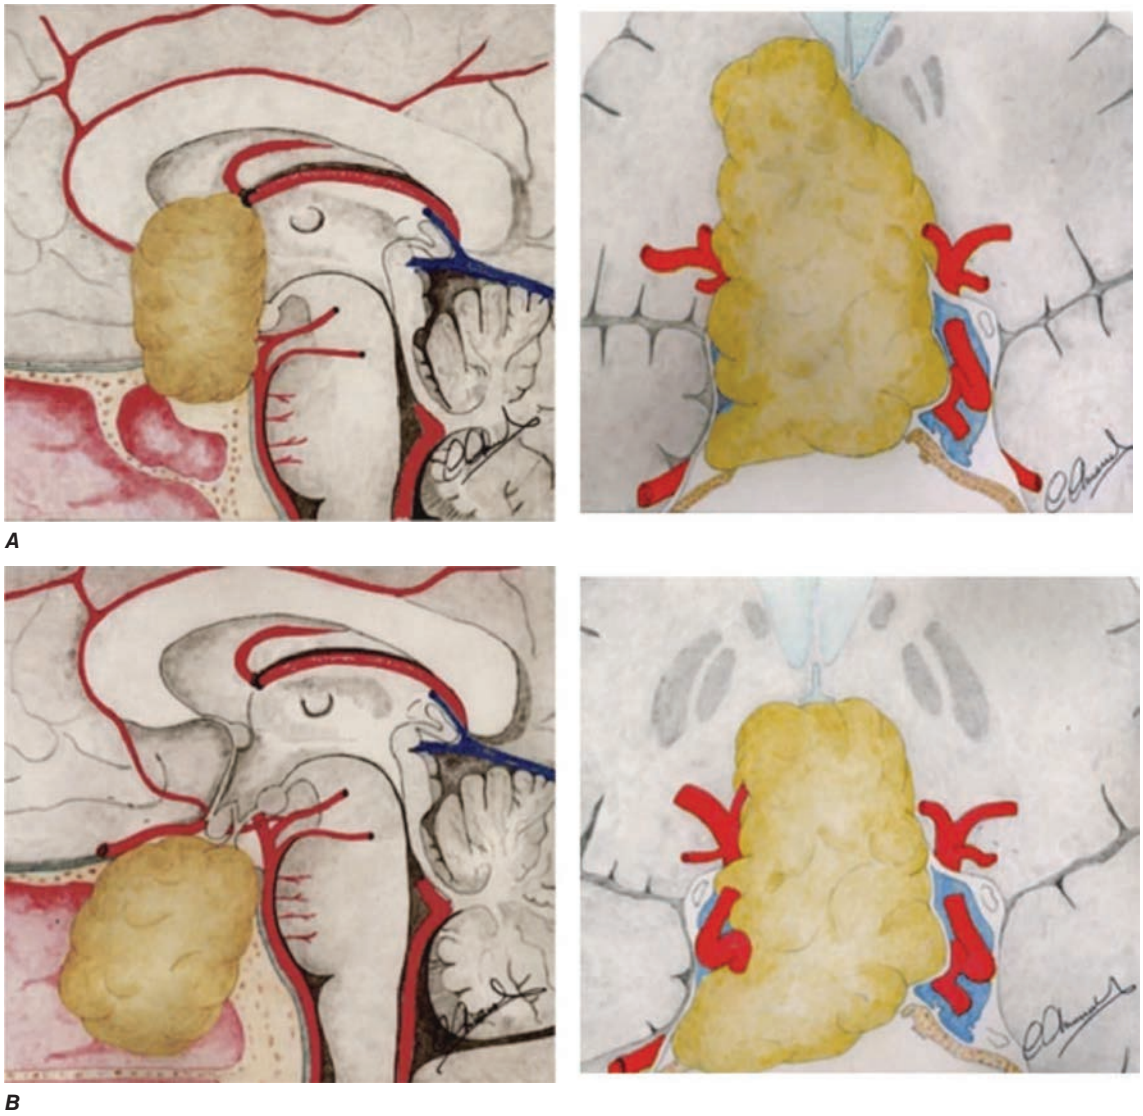

FIGURE 380-1 Expanding pituitary mass. Pituitary mass expansion may ***(A)*** impinge vital soft tissue structures and ***(B)*** invade the sphenoid sinus. *(Reproduced with permission from P Cappabianca et al: Size does not matter. The intrigue of giant adenomas: a true surgical challenge. Acta Neurochir (Wien) 156:2217, 2014.)*

hypothalamic hormones and dopamine; this results in early hyperprolactinemia and later concurrent loss of other pituitary hormones. This "stalk section" phenomenon may also be caused by trauma, whiplash injury with posterior clinoid stalk compression, or skull base fractures. Lateral mass invasion may impinge on the cavernous sinus and compress its neural contents, leading to cranial nerve III, IV, and VI palsies as well as effects on the ophthalmic and maxillary branches of the fifth cranial nerve (Chap. 441). Patients may present with diplopia, ptosis, ophthalmoplegia, and decreased facial sensation, depending on the extent of neural damage. Extension into the sphenoid sinus indicates that the pituitary mass has eroded through the sellar floor (Fig. 380-1). Aggressive tumors rarely invade the palate roof and cause nasopharyngeal obstruction, infection, and CSF leakage. Temporal and frontal lobe involvement may rarely lead to uncinate seizures, personality disorders, and anosmia. Direct hypothalamic encroachment by an invasive pituitary mass may cause important metabolic sequelae, including precocious puberty or hypogonadism, diabetes insipidus, sleep disturbances, dysthermia, and appetite disorders.

Magnetic Resonance Imaging Sagittal and coronal T1-weighted magnetic resonance imaging (MRI) before and after administration of gadolinium allows precise visualization of the pituitary gland with clear delineation of the hypothalamus, pituitary stalk, pituitary tissue and surrounding suprasellar cisterns, cavernous sinuses, sphenoid sinus, and optic chiasm. Pituitary gland height ranges from 6 mm in children to 8 mm in adults; during pregnancy and puberty, the height may reach 10–12 mm. The upper aspect of the adult pituitary is flat or slightly concave, but in adolescent and pregnant individuals, this surface may be convex, reflecting physiologic pituitary enlargement. The stalk should be midline and vertical.

Anterior pituitary gland soft tissue consistency is slightly heterogeneous on MRI, and signal intensity resembles that of brain matter on T1-weighted imaging (Fig. 380-2). Adenoma density is usually lower than that of surrounding normal tissue on T1-weighted imaging, and the signal intensity increases with T2-weighted images. Computed tomography (CT) scan is reserved to define the extent of bony erosion or the presence of calcification.

Sellar masses are encountered commonly as incidental findings on MRI, and most are pituitary adenomas (incidentalomas). In the absence of hormone hypersecretion, these small intrasellar lesions can be monitored safely with MRI, which is performed annually and then less often if there is no evidence of further growth. Resection should be considered for incidentally discovered larger macroadenomas, because about one-third become invasive or cause local pressure effects. If hormone hypersecretion is identified, specific therapies are indicated as described below. When larger masses (>1 cm) are encountered, they

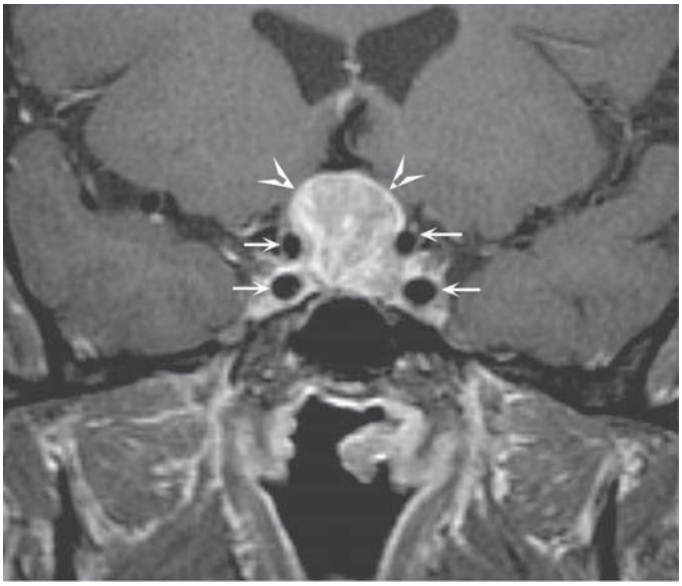

FIGURE 380-2 Pituitary adenoma. Coronal T1-weighted postcontrast magnetic resonance image shows a homogeneously enhancing mass (*arrowheads*) in the sella turcica and suprasellar region compatible with a pituitary adenoma; the *small arrows* outline the carotid arteries.

should also be distinguished from nonadenomatous lesions. Meningiomas often are associated with bony hyperostosis; craniopharyngiomas may have calcifications and are usually hypodense, whereas gliomas are hyperdense on T2-weighted images.

Ophthalmologic Evaluation Because optic tracts may be contiguous to an expanding pituitary mass, reproducible visual field assessment using perimetry techniques should be performed on all patients with sellar mass lesions that impinge the optic chiasm **(Chap. 32)**. Bitemporal hemianopia, often more pronounced superiorly, is observed classically. It occurs because nasal ganglion cell fibers, which cross in the optic chiasm, are especially vulnerable to compression of the ventral optic chiasm. Occasionally, homonymous hemianopia occurs from postchiasmal compression or monocular temporal field loss from prechiasmal compression. Invasion of the cavernous sinus can produce diplopia from ocular motor nerve palsy. Early diagnosis reduces the risk of optic atrophy, vision loss, or eye misalignment.

Laboratory Investigation The presenting clinical features of functional pituitary adenomas (e.g., acromegaly, prolactinoma, or Cushing's disease) should guide the laboratory studies **(Table 380-2)**. However, for a sellar mass with no obvious clinical features of hormone excess, laboratory studies are geared toward determining the nature of the tumor and assessing the possible presence of hypopituitarism. When a pituitary adenoma is suspected based on MRI, initial hormonal evaluation usually includes (1) basal prolactin (PRL); (2) insulin-like growth factor (IGF)-1; (3) 24-h urinary free cortisol (UFC) and/or overnight oral dexamethasone (1 mg) suppression test; (4) α subunit, follicle-stimulating hormone (FSH), and luteinizing hormone (LH); and (5) thyroid function tests. Additional hormonal evaluation may be indicated based on the results of these tests. Pending more detailed assessment of hypopituitarism, a menstrual history, measurement of testosterone and 8 A.M. cortisol levels, and thyroid function tests usually identify patients with pituitary hormone deficiencies that require hormone replacement before further testing or surgery **(Chap. 379)**.

Histologic Evaluation Immunohistochemical staining of pituitary tumor specimens obtained at transsphenoidal surgery for hormones as well as cell-type specific transcription factors confirms clinical and laboratory studies and provides a histologic diagnosis when hormone studies are equivocal and in cases of clinically nonfunctioning tumors.

TABLE 380-2 Screening Tests for Functional Pituitary Adenomas

	TEST	COMMENTS
Acromegaly	Serum IGF-1 Oral glucose tolerance test with GH obtained at 0, 30, and 60 min	Interpret IGF-1 relative to age- and sex-matched controls Normal subjects should suppress growth hormone to <1 μg/L
Prolactinoma	Serum PRL	Exclude medications MRI of the sella should be ordered if PRL is elevated
Cushing's disease	24-h urinary free cortisol Dexamethasone (1 mg) at 11 P.M. and fasting plasma cortisol measured at 8 A.M. Late night salivary cortisol ACTH assay	Ensure urine collection is total and accurate Normal subjects suppress to <5 μg/dL Distinguishes adrenal adenoma (ACTH suppressed) from ectopic ACTH or Cushing's disease (ACTH normal or elevated)
Gonadotropinoma	Baseline FSH, LH, free α subunit, ovarian hyperstimulation, estrogen (females), testosterone (males) TRH stimulation test with assays for LH, FSH, free α subunit, free LHβ, free FSHβ subunits	Rare; more commonly nonfunctioning adenomas Consider screening for hypopituitarism Some gonadotropinomas exhibit an inappropriate gonadotropin response to TRH
TSH-producing adenoma	Free T_4, free T_3, TSH, free α subunit	Key feature is an inappropriately normal or high TSH in the setting of elevated free T_4 and T_3

Abbreviations: ACTH, adrenocorticotropin hormone; FSH, follicle-stimulating hormone; GH, growth hormone; IGF-I, insulin-like growth factor I; LH, luteinizing hormone; MRI, magnetic resonance imaging; PRL, prolactin; TSH, thyroid-stimulating hormone.

TREATMENT

Hypothalamic, Pituitary, and Other Sellar Masses

OVERVIEW

Successful management of sellar masses requires accurate diagnosis as well as selection of optimal therapeutic modalities. Most pituitary tumors are benign and slow growing. Clinical features result from local mass effects and hormonal hyper- or hyposecretion syndromes caused directly by the adenoma or occurring as a consequence of treatment. Thus, lifelong management and follow-up are necessary for these patients.

MRI with gadolinium enhancement for pituitary visualization, new advances in transsphenoidal surgery and in stereotactic radiotherapy, and novel therapeutic agents have improved pituitary tumor management. The goals of pituitary tumor treatment include normalization of excess pituitary secretion, amelioration of symptoms and signs of hormonal hypersecretion syndromes, and shrinkage or ablation of large tumor masses with relief of adjacent structure compression. Residual anterior pituitary function should be preserved during treatment and sometimes can be restored by removing the tumor mass. Ideally, adenoma recurrence should be prevented.

TRANSSPHENOIDAL SURGERY

Transsphenoidal resection is the desired surgical approach for pituitary tumors, except for the rare invasive suprasellar mass surrounding the frontal or middle fossa or the optic nerves or invading posteriorly behind the clivus, which may require transcranial approaches. Intraoperative microscopy facilitates visual distinction between adenomatous and normal pituitary tissue as well as microdissection of small tumors that may not be visible by MRI **(Fig. 380-3)**. Endoscopic techniques with three-dimensional

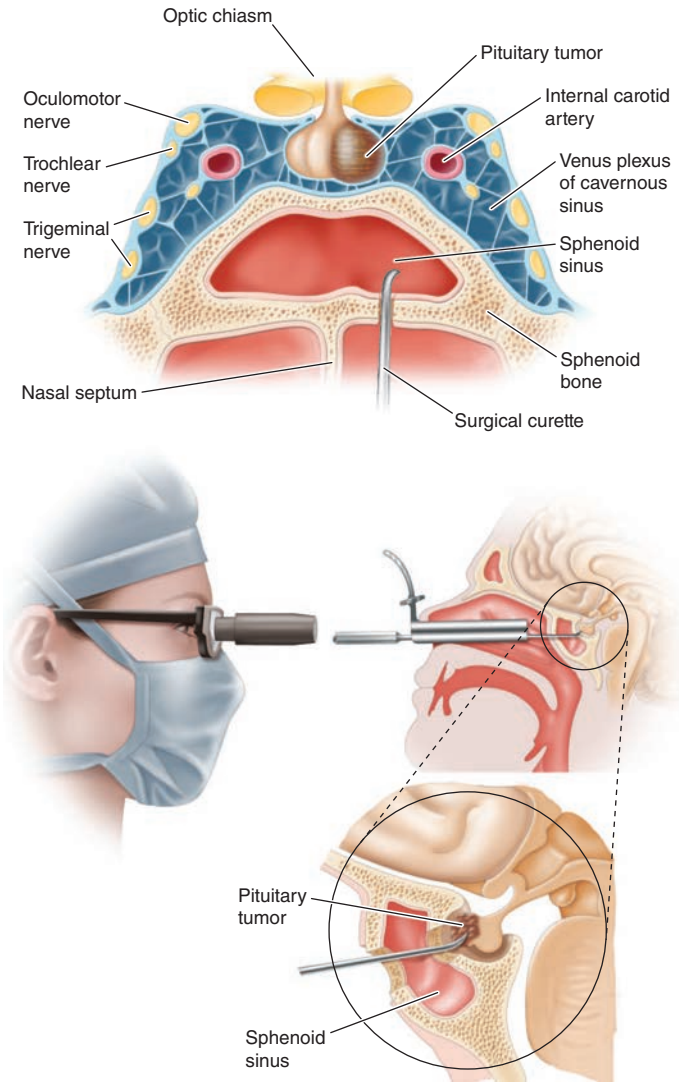

FIGURE 380-3 Transsphenoidal resection of pituitary mass via the endonasal approach.

intraoperative localization enable better visualization and access to tumor tissue. Transsphenoidal surgery also avoids cranial invasion and manipulation of brain tissue required by subfrontal surgical approaches. Individual surgical experience is a major determinant of outcome efficacy with these techniques.

In addition to correction of hormonal hypersecretion, pituitary surgery is indicated for mass lesions that impinge on surrounding structures. Surgical decompression and resection are required for an expanding pituitary mass, which may be asymptomatic or accompanied by persistent headache, progressive visual field defects, cranial nerve palsies, hydrocephalus, and, occasionally, intrapituitary hemorrhage and apoplexy. Transsphenoidal surgery rarely is used for pituitary tissue biopsy to establish a histologic diagnosis. Whenever possible, the pituitary mass lesion should be selectively excised; normal pituitary tissue should be manipulated or resected only when critical for effective mass dissection. Nonselective hemihypophysectomy or total hypophysectomy may be indicated if no hypersecreting mass lesion is clearly discernible, multifocal lesions are present, or the remaining nontumorous pituitary tissue is obviously necrotic. This strategy, however, increases the likelihood of postoperative hypopituitarism and the need for lifelong hormone replacement.

Preoperative mass effects, including visual field defects and compromised pituitary function, may be reversed by surgery, particularly when the deficits are not long-standing. For large and invasive tumors, it is necessary to determine the optimal balance between maximal tumor resection and preservation of anterior pituitary hormonal function, especially for preserving growth and reproductive function in younger patients. Tumor invasion outside the sella is rarely amenable to surgical cure, and the surgeon must judge the risk-versus-benefit ratio of extensive tumor resection.

Side Effects Tumor size, the degree of invasiveness, and experience of the surgeon largely determine the incidence of surgical complications. Operative mortality rate is ~1%. Transient diabetes insipidus and hypopituitarism occur in up to 20% of patients. Permanent diabetes insipidus, cranial nerve damage, nasal septal perforation, or visual disturbances may be encountered in up to 10% of patients. CSF leaks occur in 4% of patients. Less common complications include carotid artery injury, loss of vision, hypothalamic damage, and meningitis. Permanent side effects are rare after surgery for microadenomas.

RADIATION

Radiation is used either as a primary therapy for pituitary or parasellar masses or, more commonly, as an adjunct to surgery or medical therapy. Focused megavoltage irradiation is achieved by precise MRI localization, using a high-voltage linear accelerator and accurate isocentric rotational arcing. A major determinant of accurate irradiation is reproduction of the patient's head position during multiple visits and maintenance of absolute head immobility. A total of <50 Gy (5000 rad) is given as 180-cGy (180-rad) fractions divided over ~6 weeks. Stereotactic radiosurgery delivers a large single high-energy dose from a cobalt-60 source (Gamma Knife), linear accelerator, or cyclotron. Long-term effects of Gamma Knife surgery appear to be similar to those encountered with conventional radiation. Proton beam therapy is available in some centers and provides concentrated radiation doses within a localized region.

The role of radiation therapy in pituitary tumor management depends on the nature and anatomic location of the tumor, the age of the patient, and the availability of surgical and radiation expertise. Because of its relatively slow onset of action, radiation therapy is usually reserved for postsurgical management. As an adjuvant to surgery, radiation is used to treat residual tumor in an attempt to prevent persistent growth or recurrence. Irradiation offers the only means for potentially ablating significant postoperative residual nonfunctioning tumor tissue. By contrast, PRL-, growth hormone (GH)–, adrenocorticotropin hormone (ACTH)–, and thyrotropin (thyroid-stimulating hormone [TSH])–secreting residual tumor tissues are amenable to medical therapy.

Side Effects In the short term, radiation may cause transient nausea and weakness. Alopecia and loss of taste and smell may be more long-lasting. Failure of pituitary hormone synthesis is common in patients who have undergone head and neck or pituitary-directed irradiation. More than 50% of patients develop loss of GH, ACTH, TSH, and/or gonadotropin secretion within 10 years, usually due to hypothalamic damage. Lifelong follow-up with testing of anterior pituitary hormone reserve is therefore required after radiation treatment. Optic nerve damage with impaired vision due to optic neuritis is reported in ~2% of patients who undergo pituitary irradiation. Cranial nerve damage is uncommon now that radiation doses are <2 Gy (200 rad) at any one treatment session and the maximum dose is <50 Gy (5000 rad). The use of stereotactic radiotherapy reduces the risk of damage to adjacent structures. Conventional radiotherapy for pituitary tumors has been associated with adverse mortality rates, mainly from cerebrovascular disease. The cumulative risk of developing a secondary tumor after conventional radiation is 1.3% after 10 years and 1.9% after 20 years.

MEDICAL

Medical therapy for pituitary tumors is highly specific and depends on tumor type. For prolactinomas, dopamine agonists are the treatment of choice. For acromegaly, somatostatin receptor ligands (SRLs) and a GH receptor antagonist are indicated. For TSH-secreting tumors, SRLs and occasionally dopamine agonists

are indicated. ACTH-secreting tumors may respond to SRLs, and adrenal-directed therapy may also be of benefit. Nonfunctioning tumors are generally not responsive to medications and require surgery and/or irradiation.

SELLAR MASSES

Sellar masses may arise from brain, hypothalamic, or pituitary tissues. Each exhibit features related to the lesion location but also unique to the specific etiology. Unique MRI characteristics inform the differential diagnosis of pituitary masses **(Fig. 380-4)**.

Lesions involving the anterior and preoptic hypothalamic regions cause paradoxical vasoconstriction, tachycardia, and hyperthermia. Acute hyperthermia usually is due to a hemorrhagic insult, but poikilothermia may also occur. Central disorders of thermoregulation result from posterior hypothalamic damage. The *periodic hypothermia syndrome* is characterized by episodic attacks of rectal temperatures <30°C (86°F), sweating, vasodilation, vomiting, and bradycardia **(Chap. 464)**. Damage to the ventromedial hypothalamic nuclei by craniopharyngiomas, hypothalamic trauma, or inflammatory disorders may be associated with *hyperphagia* and *obesity*. This region appears to contain an energy-satiety center where melanocortin receptors are influenced by leptin, insulin, pro-opiomelanocortin (POMC) products, and gastrointestinal peptides **(Chap. 401)**. Polydipsia and hypodipsia are associated with damage to central osmoreceptors located in preoptic nuclei **(Chap. 381)**. Slow-growing hypothalamic lesions can cause increased somnolence and disturbed sleep cycles as well as obesity, hypothermia, and emotional outbursts. Lesions of the central hypothalamus may stimulate sympathetic neurons, leading to elevated serum catecholamine and cortisol levels. These patients are predisposed to cardiac arrhythmias, hypertension, and gastric erosions.

Craniopharyngiomas are benign, suprasellar cystic masses that present with headaches, visual field deficits, and variable degrees of hypopituitarism. They are derived from Rathke's pouch and arise near the pituitary stalk, commonly extending into the suprasellar cistern. Craniopharyngiomas are often large, cystic, and locally invasive. Many are partially calcified, exhibiting a characteristic appearance on skull x-ray and CT images. More than half of all patients present before age 20, usually with signs of increased intracranial pressure, including headache, vomiting, papilledema, and hydrocephalus. Associated symptoms include visual field abnormalities, personality changes and cognitive deterioration, cranial nerve damage, sleep difficulties, and weight gain accompanied by features of the metabolic syndrome. Hypopituitarism is documented in ~90%, and diabetes insipidus occurs in ~10% of patients. About half of affected children present with growth retardation. MRI is generally superior to CT for evaluating cystic structure and tissue components of craniopharyngiomas. CT is useful to define calcifications and evaluate invasion into surrounding bony structures and sinuses.

Treatment usually involves transcranial or transsphenoidal surgical resection followed by postoperative radiation of residual tumor. Surgery alone is curative in less than half of patients because of recurrences due to adherence to vital structures or because of small tumor deposits in the hypothalamus or brain parenchyma. The goal of surgery is to remove as much tumor as possible without risking complications associated with efforts to remove firmly adherent or inaccessible tissue. In the absence of radiotherapy, ~75% of craniopharyngiomas recur, and 10-year survival is <50%. In patients with incomplete resection, radiotherapy improves 10-year survival to 70–90% but is associated with increased risk of secondary malignancies. Most patients require lifelong pituitary hormone replacement. As some craniopharyngiomas (particularly papillary) are associated with activated *BRAF* V600E mutations, use of BRAF inhibitors (dabrafenib or vemurafenib) either alone or in combination with MEK inhibitors (trametinib or cobimetinib) has resulted in long-term growth responses in some patients.

Developmental failure of Rathke's pouch obliteration may lead to *Rathke's cysts*, which are small (<5 mm) cysts entrapped by squamous epithelium and are found in ~20% of individuals at autopsy. Although Rathke's cleft cysts do not usually grow and are often diagnosed incidentally, about a third present in adulthood with compressive symptoms, diabetes insipidus, and hyperprolactinemia due to stalk compression. Rarely, hydrocephalus develops. The diagnosis is suggested preoperatively by visualizing the cyst wall on MRI, which distinguishes these lesions from craniopharyngiomas. Cyst contents range from CSF-like fluid to mucoid material. *Arachnoid cysts* are rare and generate an MRI image that is isointense with CSF.

Sella chordomas usually present with bony clival erosion, local invasiveness, and, on occasion, calcification. Normal pituitary tissue may be visible on MRI, distinguishing chordomas from aggressive

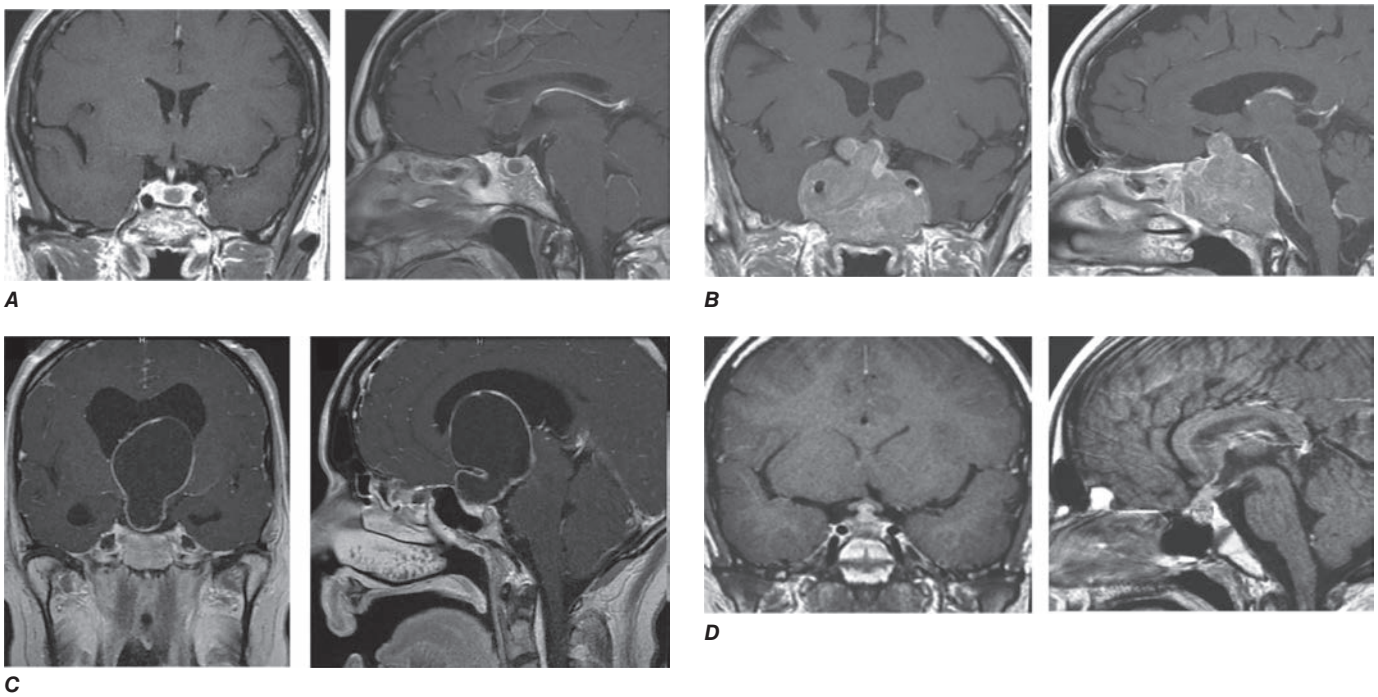

FIGURE 380-4 Imaging differential diagnosis of sellar masses. ***A.*** Microadenoma. ***B.*** Macroadenoma. ***C.*** Craniopharyngioma. ***D.*** Hypophysitis with stalk thickening. *(C: Reproduced with permission from Muller HL: Childhood craniopharyngioma. Recent advances in diagnosis, treatment and follow-up. Horm Res 69:193, 2008. A, B, D: Used with permission from Vivien Bonert, MD.)*

pituitary adenomas. Mucinous material may be obtained by fine-needle aspiration.

Meningiomas arising in the sellar region may be difficult to distinguish from nonfunctioning pituitary adenomas. Meningiomas typically enhance on MRI and may show evidence of calcification or bony erosion. Meningiomas may cause compressive symptoms.

Histiocytosis X includes a variety of syndromes associated with foci of eosinophilic granulomas. Diabetes insipidus, exophthalmos, and punched-out lytic bone lesions (*Hand-Schüller-Christian disease*) are associated with granulomatous lesions visible on MRI, as well as a characteristic axillary skin rash. Rarely, the pituitary stalk may be involved.

Pituitary metastases occur in ~3% of cancer patients. Bloodborne metastatic deposits are found almost exclusively in the posterior pituitary. Accordingly, diabetes insipidus can be a presenting feature of lung, gastrointestinal, breast, and other pituitary metastases. About half of pituitary metastases originate from breast cancer; ~25% of patients with metastatic breast cancer have such deposits. Rarely, pituitary stalk involvement results in anterior pituitary insufficiency. The MRI diagnosis of a metastatic lesion may be difficult to distinguish from an aggressive pituitary adenoma; the diagnosis may require histologic examination of excised tumor tissue. Primary or metastatic lymphoma, leukemias, and plasmacytomas also occur within the sella.

Hypothalamic hamartomas and *gangliocytomas* may arise from astrocytes, oligodendrocytes, and neurons with varying degrees of differentiation. These tumors may overexpress hypothalamic neuropeptides, including gonadotropin-releasing hormone (GnRH), growth hormone–releasing hormone (GHRH), and corticotropin-releasing hormone (CRH). With GnRH-producing tumors, children present with precocious puberty, psychomotor delay, and laughing-associated seizures. Medical treatment of GnRH-producing hamartomas with long-acting GnRH analogues effectively suppresses gonadotropin secretion and controls premature pubertal development. Rarely, hamartomas also are associated with craniofacial abnormalities; imperforate anus; cardiac, renal, and lung disorders; and pituitary failure as features of *Pallister-Hall syndrome*, which is caused by mutations in the carboxy terminus of the *GLI3* gene. Hypothalamic hamartomas are often contiguous with the pituitary, and preoperative MRI diagnosis may not be possible. Histologic evidence of hypothalamic neurons in tissue resected at transsphenoidal surgery may be the first indication of a primary hypothalamic lesion.

Hypothalamic gliomas and *optic gliomas* occur mainly in childhood and usually present with visual loss. Adults have more aggressive tumors; about a third are associated with neurofibromatosis.

Brain germ cell tumors may arise within the sellar region. They include *dysgerminomas*, which frequently are associated with diabetes insipidus and visual loss. They rarely metastasize. *Germinomas, embryonal carcinomas*, *teratomas*, and *choriocarcinomas* may arise in the parasellar region and produce human chorionic gonadotropin (hCG). These germ cell tumors present with precocious puberty, diabetes insipidus, visual field defects, and thirst disorders. Many patients are GH deficient with short stature.

PITUITARY ADENOMAS AND HYPERSECRETION SYNDROMES

Pituitary adenomas are the most common cause of pituitary hormone hypersecretion and hyposecretion syndromes in adults. They account for ~15% of all intracranial neoplasms and have been identified with a population prevalence of ~80/100,000. At autopsy, up to one-quarter of all pituitary glands harbor an unsuspected microadenoma (<10 mm diameter). Similarly, pituitary imaging detects small clinically inapparent pituitary lesions in at least 10% of individuals.

Pathogenesis Pituitary adenomas are benign neoplasms that arise from one of the five anterior pituitary cell types. The clinical and biochemical phenotypes of pituitary adenomas depend on the cell type from which they are derived. Thus, tumors arising from lactotrope (PRL), somatotrope (GH), corticotrope (ACTH), thyrotrope (TSH), or gonadotrope (LH, FSH) cells hypersecrete their respective hormones (Table 380-3). Plurihormonal tumors express various combinations of GH, PRL, TSH, ACTH, or the glycoprotein hormone α or β subunits. They may be diagnosed by careful immunocytochemistry of specific hormone and transcription factor expression or may manifest as clinical syndromes that combine features of these hormonal hypersecretory syndromes. Morphologically, these tumors may arise from a single polysecreting cell type or include cells with mixed function within the same tumor.

TABLE 380-3 Classification of Pituitary Adenomas[a]

ADENOMA CELL ORIGIN	HORMONE PRODUCT	CLINICAL SYNDROME
Lactotrope	PRL	Hypogonadism, galactorrhea
Gonadotrope	FSH, LH, subunits	Silent, ovarian hyperstimulation, hypogonadism
Somatotrope	GH	Acromegaly/gigantism
Corticotrope	ACTH/none	Cushing's disease or silent
Mixed growth hormone and prolactin cell	GH, PRL	Acromegaly, hypogonadism, galactorrhea
Other plurihormonal cell	Any	Mixed
Acidophil stem cell	PRL, GH	Hypogonadism, galactorrhea, acromegaly
Mammosomatotrope	PRL, GH	Hypogonadism, galactorrhea, acromegaly
Thyrotrope	TSH	Thyrotoxicosis
Null cell	None	Hypopituitarism/none
Oncocytoma	None	Hypopituitarism/none

[a]Hormone-secreting tumors are listed in decreasing order of frequency. All tumors may cause local pressure effects, including visual disturbances, cranial nerve palsy, and headache.

Note: For abbreviations, see text.

Source: Adapted with permission from S Melmed: Pathogenesis of pituitary tumors. Nat Rev Endocrinol 7:257, 2011.

Hormonally active tumors are characterized by autonomous hormone secretion with diminished feedback responsiveness to physiologic inhibitory pathways. Hormone production does not always correlate with tumor size. Small hormone-secreting adenomas may cause significant clinical perturbations, whereas larger adenomas that produce less hormone may be clinically silent and remain undiagnosed (if no central compressive effects occur). About one-third of all adenomas are clinically nonfunctioning and produce no distinct clinical hypersecretory syndrome. Most of them arise from gonadotrope cells and may secrete small amounts of α- and β-glycoprotein hormone subunits or, very rarely, intact circulating gonadotropins. True pituitary carcinomas with documented extracranial metastases are exceedingly rare.

Almost all pituitary adenomas are monoclonal in origin, implying the acquisition of one or more somatic mutations that confer a selective growth advantage. Consistent with their clonal origin, complete surgical resection of small pituitary adenomas usually cures hormone hypersecretion. Nevertheless, hypothalamic hormones such as GHRH and CRH also enhance mitotic activity of their respective pituitary target cells in addition to their role in pituitary hormone regulation. Thus, patients who harbor rare abdominal or chest tumors that elaborate ectopic GHRH or CRH may present with somatotrope or corticotrope hyperplasia with GH or ACTH hypersecretion.

Several etiologic genetic events have been implicated in the development of pituitary tumors. The pathogenesis of sporadic forms of acromegaly has been particularly informative as a model of tumorigenesis. GHRH, after binding to its G protein–coupled somatotrope receptor, uses cyclic adenosine monophosphate (AMP) as a second messenger to stimulate GH secretion and somatotrope proliferation. A subset (~35%) of GH-secreting pituitary tumors contains sporadic mutations in $G_s\alpha$. These mutations attenuate intrinsic GTPase activity, resulting in constitutive elevation of cyclic AMP, Pit-1 induction, and activation of cyclic AMP response element binding protein (CREB), thereby promoting somatotrope cell proliferation and GH secretion.

TABLE 380-4 Familial Pituitary Tumor Syndromes (see Chap. 388)

	GENE MUTATED	CLINICAL FEATURES
Multiple endocrine neoplasia 1 (MEN 1)	*MEN1* (11q13)	Hyperparathyroidism Pancreatic neuroendocrine tumors Foregut carcinoids Adrenal adenomas Skin lesions Pituitary adenomas (40%)
Multiple endocrine neoplasia 4 (MEN 4)	*CDKNIB* (12p13)	Hyperparathyroidism Pituitary adenomas Other tumors
Carney complex	*PRKAR1A* (17q23-24)	Pituitary hyperplasia and adenomas (10%) Atrial myxomas Schwannomas Adrenal hyperplasia Lentigines
Familial pituitary adenomas	*AIP* (11q13.2)	Acromegaly/gigantism (~15% of afflicted families)

Growth factors may also promote pituitary tumor proliferation. Basic fibroblast growth factor (bFGF) is abundant in the pituitary and stimulates pituitary cell mitogenesis, whereas epidermal growth factor receptor (EGFR) signaling induces both hormone synthesis and cell proliferation. Mutations of *USP8* may result in overexpressed EGFR in a subset of ACTH-secreting tumors. Other factors involved in initiation and promotion of pituitary tumors include loss of negative-feedback inhibition (as seen with primary hypothyroidism or hypogonadism) and estrogen-mediated or paracrine angiogenesis. Growth characteristics and neoplastic behavior also may be influenced by activated oncogenes, including *RAS* and pituitary tumor transforming gene (*PTTG*), or inactivation of growth suppressor genes, including *MEG3*. Pituitary adenomas exhibit lineage-specific features of cell-cycle disruption, including cellular senescence, with chromosomal instability and copy number alterations as well as elevated levels of CDK inhibitors. These features underlie the invariably benign nature of these adenomas.

Genetic Syndromes Associated with Pituitary Tumors Several familial syndromes are associated with pituitary tumors, and the genetic mechanisms for some of them have been unraveled (Table 380-4).

Multiple endocrine neoplasia (MEN) 1 is an autosomal dominant syndrome characterized primarily by a genetic predisposition to parathyroid, pancreatic islet, and pituitary adenomas (Chap. 388). MEN 1 is caused by inactivating germline mutations in *MENIN*, a constitutively expressed tumor-suppressor gene located on chromosome 11q13. Loss of heterozygosity or a somatic mutation of the remaining normal *MENIN* allele leads to tumorigenesis. About half of affected patients develop prolactinomas; acromegaly and Cushing's disease are less commonly encountered.

Carney complex is characterized by spotty skin pigmentation, myxomas, and endocrine tumors, including testicular, adrenal, and pituitary adenomas. Acromegaly occurs in ~20% of these patients. A subset of patients has mutations in the R1α regulatory subunit of protein kinase A (*PRKAR1A*).

McCune-Albright syndrome consists of polyostotic fibrous dysplasia, pigmented skin patches, and a variety of endocrine disorders, including acromegaly, adrenal adenomas, and autonomous ovarian function (Chap. 412). Hormonal hypersecretion results from constitutive cyclic AMP production caused by inactivation of the GTPase activity of $G_s\alpha$. The $G_s\alpha$ mutations occur postzygotically, leading to a mosaic pattern of mutant expression.

Familial acromegaly is a rare disorder in which family members may manifest either acromegaly or gigantism. A subset of families with a predisposition for familial pituitary tumors, especially acromegaly, has been found to harbor germline mutations in the *AIP* gene, which encodes the aryl hydrocarbon receptor interacting protein.

HYPERPROLACTINEMIA

Etiology Hyperprolactinemia is the most common pituitary hormone hypersecretion syndrome in both men and women. PRL-secreting pituitary adenomas (prolactinomas) are the most common cause of PRL levels >200 μg/L (see below). Less pronounced PRL elevation can also be seen with microprolactinomas but is more commonly caused by drugs, pituitary stalk compression, hypothyroidism, or renal failure (Table 380-5).

Pregnancy and lactation are the important physiologic causes of hyperprolactinemia. Sleep-associated hyperprolactinemia reverts to normal within an hour of awakening. Nipple stimulation and sexual orgasm also may increase PRL. Chest wall stimulation or trauma (including chest surgery and herpes zoster) invokes the reflex suckling arc with resultant hyperprolactinemia. Chronic renal failure elevates PRL by decreasing peripheral clearance. Primary hypothyroidism is associated with mild hyperprolactinemia, probably because of compensatory TRH secretion. Mutation of the PRL receptor is a rare cause of hyperprolactinemia.

Lesions of the hypothalamic-pituitary region that disrupt hypothalamic dopamine synthesis, portal vessel delivery, or lactotrope responses are associated with hyperprolactinemia. Thus, hypothalamic tumors, cysts, infiltrative disorders, and radiation-induced damage cause elevated PRL levels, usually in the range of 30–100 μg/L. Plurihormonal adenomas (including GH and ACTH tumors) may hypersecrete PRL directly. Pituitary masses, including clinically nonfunctioning pituitary tumors, may compress the pituitary stalk to cause hyperprolactinemia.

Drug-induced inhibition or disruption of dopaminergic receptor function is a common cause of hyperprolactinemia (Table 380-5). Thus, antipsychotics and antidepressants are a relatively common cause of mild hyperprolactinemia. Most patients receiving risperidone have elevated PRL levels, sometimes exceeding 200 μg/L. Methyldopa inhibits dopamine synthesis, and verapamil blocks dopamine release, also leading to hyperprolactinemia. Hormonal agents that induce PRL include estrogens and thyrotropin-releasing hormone (TRH).

Presentation and Diagnosis Amenorrhea, galactorrhea, and infertility are the hallmarks of hyperprolactinemia in women. If hyperprolactinemia develops before menarche, primary amenorrhea results. More commonly, hyperprolactinemia develops later in life and leads to oligomenorrhea and ultimately to amenorrhea. If hyperprolactinemia is sustained, vertebral bone mineral density can be reduced compared with age-matched controls, particularly when it is associated with pronounced hypoestrogenemia. Galactorrhea is present in up to 80% of hyperprolactinemic women. Although usually bilateral and spontaneous, it may be unilateral or expressed only manually. Patients also may complain of decreased libido, weight gain, and mild hirsutism.

In men with hyperprolactinemia, diminished libido, infertility, and visual loss (from optic nerve compression) are the usual presenting symptoms. Gonadotropin suppression leads to reduced testosterone, impotence, and oligospermia. True galactorrhea is uncommon in men with hyperprolactinemia. If the disorder is long-standing, secondary effects of hypogonadism are evident, including osteopenia, reduced muscle mass, and decreased beard growth.

The diagnosis of idiopathic hyperprolactinemia is made by exclusion of known causes of hyperprolactinemia in the setting of a normal pituitary MRI. Some of these patients may harbor small microadenomas below visible MRI sensitivity (~2 mm).

GALACTORRHEA

Galactorrhea, the inappropriate discharge of milk-containing fluid from the breast, is considered abnormal if it persists longer than 6 months after childbirth or discontinuation of breast-feeding. Postpartum galactorrhea associated with amenorrhea is a self-limiting disorder usually associated with moderately elevated PRL levels. Galactorrhea may occur spontaneously, or it may be elicited by nipple

Note: Hyperprolactinemia >200 μg/L almost invariably is indicative of a prolactin-secreting pituitary adenoma. Physiologic causes, hypothyroidism, and drug-induced hyperprolactinemia should be excluded before extensive evaluation.

pressure. In both men and women, galactorrhea may vary in color and consistency (transparent, milky, or bloody) and arise either unilaterally or bilaterally. Mammography or ultrasound is indicated for bloody discharges (particularly from a single nipple), which may be caused by breast cancer. Galactorrhea is commonly associated with hyperprolactinemia caused by any of the conditions listed in Table 380-5. Acromegaly is associated with galactorrhea in about one-third of patients. Treatment of galactorrhea usually involves managing the underlying disorder (e.g., replacing T_4 for hypothyroidism, discontinuing a medication, treating prolactinoma).

Laboratory Investigation Basal, fasting morning PRL levels (normally <20 μg/L) should be measured to assess hypersecretion. Both false-positive and false-negative results may be encountered. In patients with markedly elevated PRL levels (>1000 μg/L), reported results may be falsely lowered because of assay artifacts; sample dilution is required to measure these high values accurately. Falsely elevated values may be caused by aggregated forms of circulating PRL, which are usually biologically inactive (macroprolactinemia). Hypothyroidism should be excluded by measuring TSH and T_4 levels.

TREATMENT

Hyperprolactinemia

Treatment of hyperprolactinemia depends on the cause of elevated PRL levels. Regardless of the etiology, however, treatment should be aimed at normalizing PRL levels to alleviate suppressive effects on gonadal function, halt galactorrhea, and preserve bone mineral density. Dopamine agonists are effective for most causes of hyperprolactinemia (see the treatment section for prolactinoma, below) regardless of the underlying cause.

If the patient is taking a medication known to cause hyperprolactinemia, the drug should be withdrawn, if possible. For psychiatric patients who require neuroleptic agents, supervised dose titration or the addition of a dopamine agonist can help restore normoprolactinemia and alleviate reproductive symptoms. However, dopamine agonists may worsen the underlying psychiatric condition, especially at high doses. Hyperprolactinemia usually resolves after adequate thyroid hormone replacement in hypothyroid patients or after renal transplantation in patients undergoing dialysis. Resection of hypothalamic or sellar mass lesions can reverse hyperprolactinemia caused by stalk compression and reduced dopamine tone. Granulomatous infiltrates occasionally respond to glucocorticoid administration. In patients with irreversible hypothalamic damage, no treatment may be warranted. In up to 30% of patients with hyperprolactinemia—usually without a visible pituitary microadenoma—the condition may resolve spontaneously.

PROLACTINOMA

Etiology and Prevalence Tumors arising from lactotrope cells account for about half of all functioning pituitary tumors, with a population prevalence of ~10/100,000 in men and ~30/100,000 in women. Mixed tumors that secrete combinations of GH and PRL, ACTH and PRL, and rarely TSH and PRL are also seen. These plurihormonal tumors are usually recognized by immunohistochemistry, sometimes without apparent clinical manifestations from the production of additional hormones. Microadenomas are classified as <1 cm in diameter and usually do not invade the parasellar region. Macroadenomas are >1 cm in diameter and may be locally invasive and impinge on adjacent structures. The female-to-male ratio for microprolactinomas is 20:1, whereas the sex ratio is near 1:1 for macroadenomas. Tumor size generally correlates directly with PRL concentrations; values >250 μg/L usually are associated with macroadenomas. Men tend to present with larger tumors than women, possibly because the features of male hypogonadism are less readily evident. PRL levels remain stable in most patients, reflecting the slow growth of these tumors. About 5% of microadenomas progress in the long term to macroadenomas.

Presentation and Diagnosis Women usually present with amenorrhea, infertility, and galactorrhea. If the tumor extends outside the sella, visual field defects or other mass effects may be seen. Men often present with impotence, loss of libido, infertility, or signs of central nervous system (CNS) compression, including headaches and visual defects. Assuming that physiologic and medication-induced causes of

hyperprolactinemia are excluded (Table 380-5), the diagnosis of prolactinoma is likely with a PRL level >200 μg/L. PRL levels <100 μg/L may be caused by microadenomas, other sellar lesions that decrease dopamine inhibition, or nonneoplastic causes of hyperprolactinemia. For this reason, an MRI should be performed in all patients with hyperprolactinemia. It is important to remember that hyperprolactinemia caused secondarily by the mass effects of nonlactotrope lesions is also corrected by treatment with dopamine agonists despite failure to shrink the underlying mass. Consequently, PRL suppression by dopamine agonists does not necessarily indicate that the underlying lesion is a prolactinoma.

TREATMENT

Prolactinoma

Because microadenomas rarely progress to become macroadenomas, no treatment may be needed if patients are asymptomatic and fertility is not desired; these patients should be monitored by regular serial PRL measurements and MRI scans. For symptomatic microadenomas, therapeutic goals include control of hyperprolactinemia, reduction of tumor size, restoration of menses and fertility, and resolution of galactorrhea. Dopamine agonist doses should be titrated to achieve maximal PRL suppression and restoration of reproductive function **(Fig. 380-5)**. A normalized PRL level does not ensure reduced tumor size. However, tumor shrinkage usually is not seen in those who do not respond with lowered PRL levels. For macroadenomas, formal visual field testing should be performed before initiating dopamine agonists. MRI and visual fields should be assessed at 6- to 12-month intervals until the mass shrinks and annually thereafter until maximum size reduction has occurred.

Oral dopamine agonists (cabergoline and bromocriptine) are the mainstay of therapy for patients with micro- or macroprolactinomas. Dopamine agonists suppress PRL secretion and synthesis as well as lactotrope cell proliferation. In patients with microadenomas who have achieved normoprolactinemia and significant reduction of tumor mass, the dopamine agonist may be withdrawn after 2 years. These patients should be monitored carefully for evidence of prolactinoma recurrence. About 20% of patients (especially males) are resistant to dopaminergic treatment; these adenomas may exhibit decreased D_2 dopamine receptor numbers or a postreceptor defect. D_2 receptor gene mutations in the pituitary have not been reported.

Cabergoline An ergoline derivative, cabergoline is a long-acting dopamine agonist with high D_2 receptor affinity. The drug effectively suppresses PRL for >14 days after a single oral dose and induces prolactinoma shrinkage in most patients. Cabergoline (0.5–1.0 mg twice weekly) achieves normoprolactinemia and resumption of normal gonadal function in ~80% of patients with microadenomas; galactorrhea improves or resolves in 90% of patients. Cabergoline normalizes PRL and shrinks ~70% of macroprolactinomas. Mass effect symptoms, including headaches and visual disorders, usually improve dramatically within days after cabergoline initiation; improvement of sexual function requires several weeks of treatment but may occur before complete normalization of PRL levels. MRI should be repeated within 16 weeks after initial therapy of macroadenomas as shrinkage of invasive adenomas may be striking **(Fig. 380-6)**. After initial control of PRL levels has been achieved, cabergoline should be reduced to the lowest effective maintenance dose. In ~5% of treated patients harboring a microadenoma, hyperprolactinemia may resolve and not recur when dopamine agonists are discontinued after long-term treatment. Cabergoline also may be effective in patients resistant to bromocriptine. Adverse effects and drug intolerance are encountered less commonly than with bromocriptine.

Bromocriptine The ergot alkaloid bromocriptine mesylate is a dopamine receptor agonist that suppresses PRL secretion. Because it is short-acting, the drug is preferred when pregnancy is desired. Therapy is initiated by administering a low bromocriptine dose (0.625–1.25 mg) at bedtime with a snack, followed by gradually increasing the dose. Most patients are controlled with a daily dose of <7.5 mg (2.5 mg tid).

SIDE EFFECTS

Side effects of dopamine agonists include constipation, nasal stuffiness, dry mouth, nightmares, insomnia, and vertigo; decreasing the dose usually alleviates these problems. Nausea, vomiting, and postural hypotension with faintness may occur in ~25% of patients after the initial dose. These symptoms may persist in some patients. In general, fewer side effects are reported with cabergoline. For the ~15% of patients who are intolerant of oral bromocriptine,

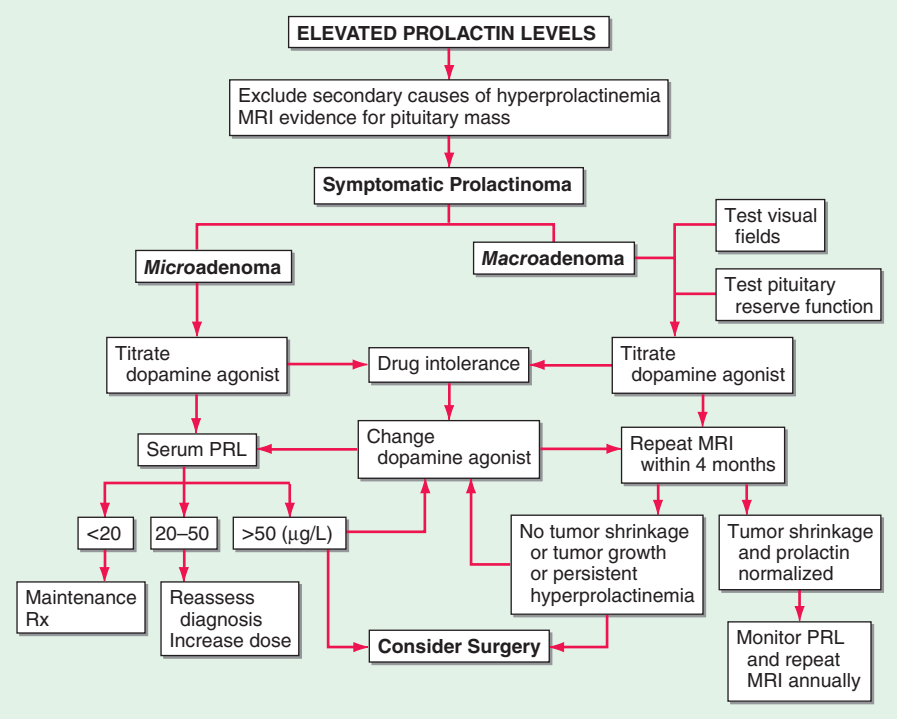

FIGURE 380-5 Management of prolactinoma. MRI, magnetic resonance imaging; PRL, prolactin.

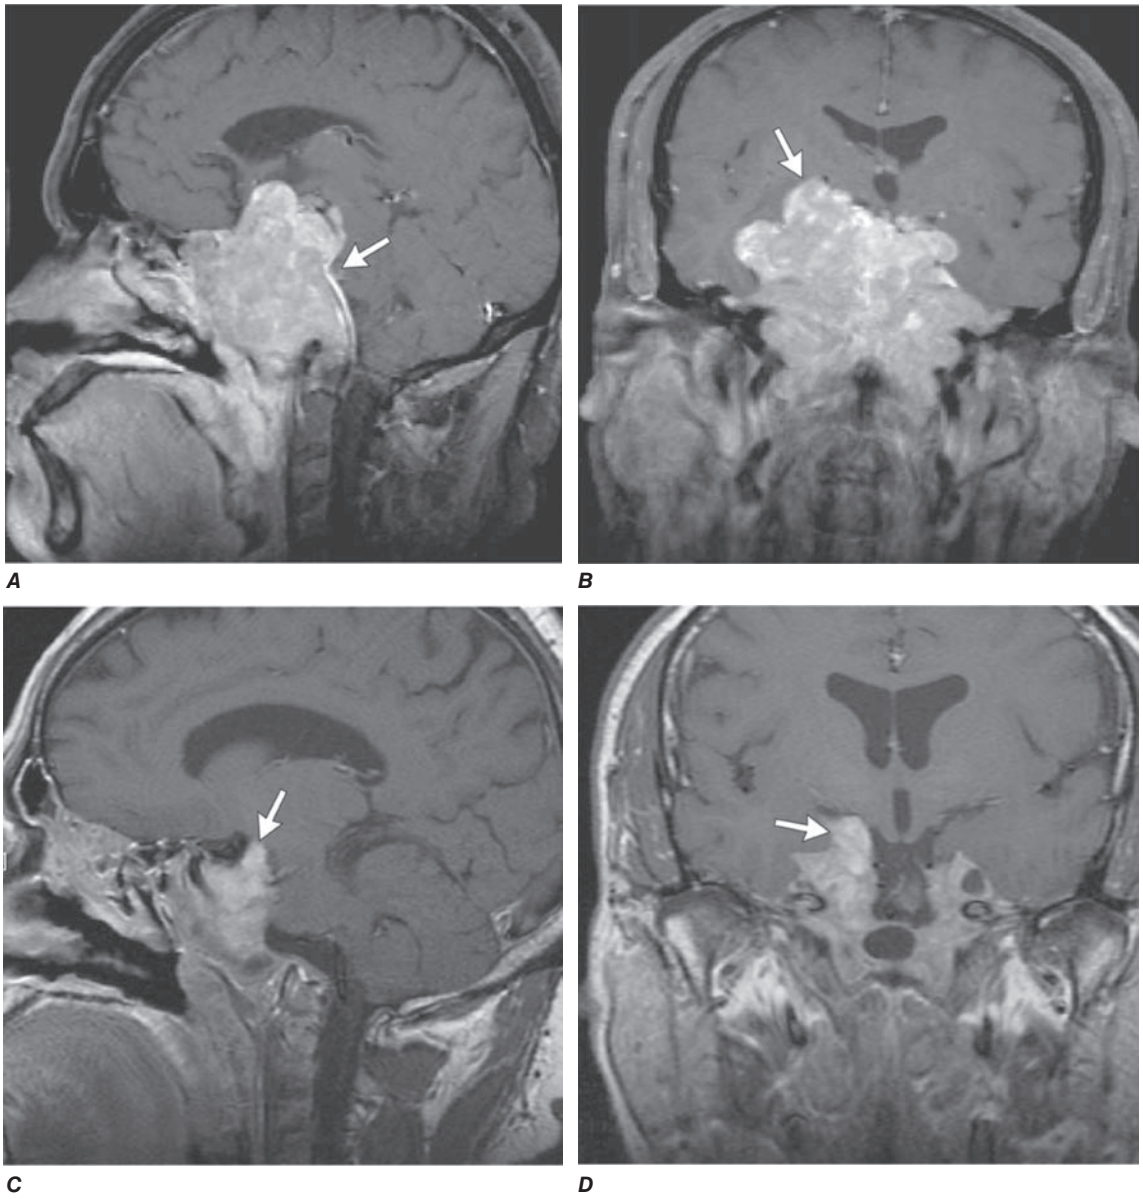

FIGURE 380-6 Large invasive prolactinoma successfully treated with cabergoline. ***A–B.*** Prolactin-secreting macroadenoma in a 32-year-old male measuring 5.6 × 6.9 cm invading the skull base. PRL level was 122,260 μg/L. Four days after cabergoline was started, PRL was 10,823 μg/L and dropped to 772 μg/L after 3 weeks. ***C–D.*** Substantial tumor regression after 40 months of treatment, with PRL levels stable at 25 μg/L. *(Reproduced with permission from M Ahmed, O Al-Nozha: Images in clinical medicine. Large prolactinoma. N Engl J Med 363:177, 2010.)*

cabergoline may be better tolerated. Intravaginal administration of bromocriptine is often efficacious in patients with intractable gastrointestinal side effects. Auditory hallucinations, delusions, and mood swings have been reported in up to 5% of patients and may be due to the dopamine agonist properties or to the lysergic acid derivative of the compounds. Rare reports of leukopenia, thrombocytopenia, pleural fibrosis, cardiac arrhythmias, and hepatitis have been described. Patients with Parkinson disease who receive at least 3 mg of cabergoline daily have been reported to be at risk for development of cardiac valve regurgitation. Studies analyzing >500 prolactinoma patients receiving recommended doses of cabergoline (up to 2 mg weekly) have shown no evidence for an increased incidence of valvular disorders. Nevertheless, because no controlled prospective studies in pituitary tumor patients are available, it is prudent to perform echocardiograms before initiating standard-dose cabergoline therapy.

Surgery Rarely, surgical adenoma debulking may be indicated for dopamine resistance or intolerance as well as the presence of an invasive macroadenoma with compromised vision that fails to improve after drug treatment. Initial PRL normalization is achieved in ~70% of microprolactinomas after surgical resection, but only 30% of macroadenomas can be resected successfully. Follow-up studies have shown that hyperprolactinemia recurs in up to 20% of patients within the first year after surgery; long-term recurrence rates may exceed 50% for macroadenomas. Radiotherapy for prolactinomas is reserved for patients with aggressive tumors that do not respond to maximally tolerated dopamine agonists and/or surgery.

PREGNANCY

The pituitary increases in size during pregnancy, reflecting the stimulatory effects of estrogen and perhaps other growth factors on pituitary vascularity and lactotrope cell hyperplasia. About 5% of microadenomas significantly increase in size, but 15–30% of macroadenomas grow during pregnancy. Bromocriptine has been used for >30 years to restore fertility in women with hyperprolactinemia, without evidence of teratogenic effects. Nonetheless, most authorities recommend strategies to minimize fetal exposure to the drug. For women taking bromocriptine who desire pregnancy, mechanical contraception should be used through three regular menstrual cycles to allow for conception timing. When pregnancy

is confirmed, bromocriptine should be discontinued and PRL levels followed serially, especially if headaches or visual symptoms occur. For women harboring macroadenomas, regular visual field testing is recommended, and the drug should be reinstituted if tumor growth is apparent. Although pituitary MRI may be safe during pregnancy, this procedure should be reserved for symptomatic patients with severe headache and/or visual field defects. Surgical decompression may be indicated if vision is threatened. Although comprehensive data support the efficacy and relative safety of bromocriptine-facilitated fertility, patients should be advised of potential unknown deleterious effects and the risk of tumor growth during pregnancy. Because cabergoline is long-acting with a high D_2-receptor affinity, it is not recommended for use in women when fertility is desired.

ACROMEGALY

Etiology GH hypersecretion is usually the result of a somatotrope adenoma but may rarely be caused by extrapituitary lesions (Table 380-6). In addition to the more common GH-secreting somatotrope adenomas, mixed mammosomatotrope tumors and acidophilic stem cell adenomas secrete both GH and PRL. In patients with acidophilic stem cell adenomas, features of hyperprolactinemia (hypogonadism and galactorrhea) predominate over the less clinically evident signs of acromegaly. Occasionally, mixed plurihormonal tumors are encountered that also secrete ACTH, the glycoprotein hormone α subunit, or TSH in addition to GH. Patients with partially empty sellae may present with GH hypersecretion due to a small GH-secreting adenoma within the compressed rim of pituitary tissue; some of these may reflect the spontaneous necrosis of tumors that were previously larger. GH-secreting tumors rarely arise from ectopic pituitary tissue remnants in the nasopharynx or midline sinuses.

There are case reports of ectopic GH secretion by tumors of pancreatic, ovarian, lung, or hematopoietic origin. Rarely, excess GHRH production may cause acromegaly because of chronic stimulation of somatotropes. These patients present with classic features of acromegaly, elevated GH levels, pituitary enlargement on MRI, and pathologic characteristics of pituitary hyperplasia. The most common cause of GHRH-mediated acromegaly is a chest or abdominal carcinoid tumor.

Although these tumors usually express positive GHRH immunoreactivity, clinical features of acromegaly are evident in only a minority of patients with carcinoid disease. Excessive GHRH also may be elaborated by hypothalamic tumors, usually choristomas or neuromas.

Presentation and Diagnosis Protean manifestations of GH and IGF-1 hypersecretion are indolent and often are not clinically diagnosed for 10 years or more. Acral bony overgrowth results in frontal bossing, increased hand and foot size, mandibular enlargement with prognathism, and widened space between the lower incisor teeth. In children and adolescents, initiation of GH hypersecretion before epiphyseal long bone closure is associated with development of pituitary gigantism (Fig. 380-7). Soft tissue swelling results in increased heel pad thickness, increased shoe or glove size, ring tightening, characteristic coarse facial features, and a large fleshy nose. Other commonly encountered clinical features include hyperhidrosis, a deep and hollow-sounding voice, oily skin, arthropathy, kyphosis, carpal tunnel syndrome, proximal muscle weakness and fatigue, acanthosis nigricans, and skin tags. Generalized visceromegaly occurs, including cardiomegaly, macroglossia, and thyroid gland enlargement.

The most significant clinical impact of GH excess occurs with respect to the cardiovascular system. Cardiomyopathy with arrhythmias, left ventricular hypertrophy, decreased diastolic function, and hypertension ultimately occur in most patients if untreated. Upper airway obstruction with sleep apnea occurs in >60% of patients and is associated with both soft tissue laryngeal airway obstruction and central sleep dysfunction. Diabetes mellitus develops in 25% of patients with acromegaly, and most patients are intolerant of a glucose load (as GH counteracts the action of insulin). Acromegaly is associated with an increased risk of colon polyps and mortality from colonic malignancy; polyps are diagnosed in up to one-third of patients. Overall mortality is increased about threefold and is due primarily to cardiovascular and cerebrovascular disorders and respiratory disease. Unless GH levels are controlled, survival is reduced by an average of 10 years compared with an age-matched control population.

Laboratory Investigation Age-matched serum IGF-1 levels are elevated in acromegaly. Consequently, an IGF-1 level provides a useful laboratory screening measure when clinical features raise the possibility of acromegaly. Owing to the pulsatility of GH secretion, measurement of a single random GH level is not useful for the diagnosis or exclusion of acromegaly and does not correlate with disease severity. The diagnosis of acromegaly is confirmed by demonstrating the failure of GH suppression to <0.4 μg/L within 1–2 h of an oral glucose load (75 g). When ultrasensitive GH assays are used, normal nadir GH levels are even lower (<0.05 μg/L). About 20% of patients exhibit a paradoxical GH rise after glucose. PRL should be measured, as it is elevated in ~25% of patients with acromegaly. Thyroid function, gonadotropins, and sex steroids may be attenuated because of tumor mass effects. Because most patients will undergo surgery with glucocorticoid coverage, tests of ACTH reserve in asymptomatic patients are more efficiently deferred until after surgery.

TREATMENT

Acromegaly

The goal of treatment is to control GH and IGF-1 hypersecretion, ablate or arrest tumor growth, ameliorate comorbidities, restore mortality rates to normal, and preserve pituitary function.

Surgical resection of GH-secreting adenomas is the initial treatment for most patients (Fig. 380-8). SRLs are used as adjuvant treatment for preoperative shrinkage of large invasive macroadenomas, immediate relief of debilitating symptoms, and reduction of GH hypersecretion; in frail patients experiencing morbidity; and in patients who decline surgery or when surgery fails to achieve biochemical control. Irradiation or repeat surgery may be required for patients who cannot tolerate or do not respond to adjunctive medical therapy. The high rate of late hypopituitarism and the slow rate (5–15 years) of biochemical response are the main disadvantages of

FIGURE 380-7 Features of acromegaly/gigantism. A 22-year-old man with gigantism due to excess growth hormone is shown to the left of his identical twin. The increased height and prognathism (***A***) and enlarged hand (***B***) and foot (***C***) of the affected twin are apparent. Their clinical features began to diverge at the age of ~13 years. *(Reproduced with permission from RF Gagel, IE McCutcheon. Images in clinical medicine. Pituitary gigantism. N Engl J Med 340:524, 1999.)*

radiotherapy. Irradiation is also relatively ineffective in normalizing IGF-1 levels. Stereotactic ablation of GH-secreting adenomas by Gamma Knife radiotherapy is promising, but long-term results and side effects appear similar to those observed with conventional radiation. SRLs may be required while awaiting the full benefits of radiotherapy. Systemic comorbid sequelae of acromegaly, including cardiovascular disease, diabetes, and arthritis, should be managed aggressively. Mandibular surgical repair may be indicated.

SURGERY

Transsphenoidal surgical resection by an experienced surgeon is the preferred primary treatment for both microadenomas (remission rate ~70%) and macroadenomas (<50% in remission). Soft tissue swelling improves immediately after tumor resection. GH levels return to normal within an hour, and IGF-1 levels are normalized within 3–4 days. In ~10% of patients, acromegaly may recur several years after apparently successful surgery; hypopituitarism develops in up to 15% of patients after surgery.

SOMATOSTATIN RECEPTOR LIGANDS

SRLs exert their therapeutic effects through SST2 and SST5 receptor subtypes, both expressed by GH-secreting tumors.

The preferred medical treatments for patients with acromegaly include long-acting injectable SRL depot formulations of octreotide and lanreotide as well as oral octreotide capsules. Although responses vary widely in individual patients, meta-analyses indicate that GH and IGF-1 levels are normalized in ~50% of patients. Octreotide acetate is an eight-amino-acid synthetic somatostatin analogue. In contrast to native somatostatin, the analogue is relatively resistant to plasma degradation. It has a 2-h serum half-life and possesses 40-fold greater potency than native somatostatin to suppress GH. *Octreotide LAR* is a sustained-release, long-acting formulation of octreotide incorporated into microspheres that sustain drug levels for several weeks after intramuscular injection. GH suppression occurs for as long as 6 weeks after a 30-mg intramuscular injection; long-term monthly treatment sustains GH and IGF-1 suppression and also reduces pituitary tumor size in ~50% of patients. *Lanreotide*, in a slow-release depot SRL preparation, is a cyclic somatostatin octapeptide analogue that suppresses GH and IGF-1 hypersecretion after a 60-mg subcutaneous injection. Long-term (every 4–6 weeks) administration controls GH hypersecretion in about two-thirds of treated patients and improves patient compliance because of the long interval required between drug injections. *Oral octreotide capsules* (40–80 mg daily) maintain biochemical control in patients previously maintained on injectable formulations. Rapid relief of headache and soft tissue swelling occurs in ~75% of patients within days to weeks of SRL initiation. Most patients report symptomatic improvement, including amelioration of headache, perspiration, obstructive apnea, and cardiac failure. *Pasireotide LAR*, a multireceptor ligand with preferential SST5 binding (see below), has been shown to exhibit efficacy in achieving biochemical control in patients resistant to octreotide or lanreotide preparations.

Side Effects SRLs are well tolerated in most patients. Adverse effects are similar for injectable octreotide and lanreotide as well as for oral octreotide formulation. They are short-lived and mostly relate to drug-induced suppression of gastrointestinal motility and secretion. Transient nausea, abdominal discomfort, fat malabsorption, diarrhea, and flatulence occur in one-third of patients, and these symptoms usually remit within 2 weeks. Gallbladder contractility and emptying are attenuated; up to 30% of patients develop long-term echogenic sludge or asymptomatic cholesterol gallstones. Other side effects include mild glucose intolerance due to transient insulin suppression, asymptomatic bradycardia, hypothyroxinemia, and local injection site discomfort. Pasireotide is associated with similar gastrointestinal side effects but with a higher prevalence of glucose intolerance and new-onset diabetes mellitus.

GH RECEPTOR ANTAGONIST

Pegvisomant antagonizes endogenous GH action by blocking peripheral GH binding to its receptor. Consequently, serum IGF-1 levels are suppressed, reducing the deleterious effects of excess endogenous GH. Pegvisomant is administered by daily

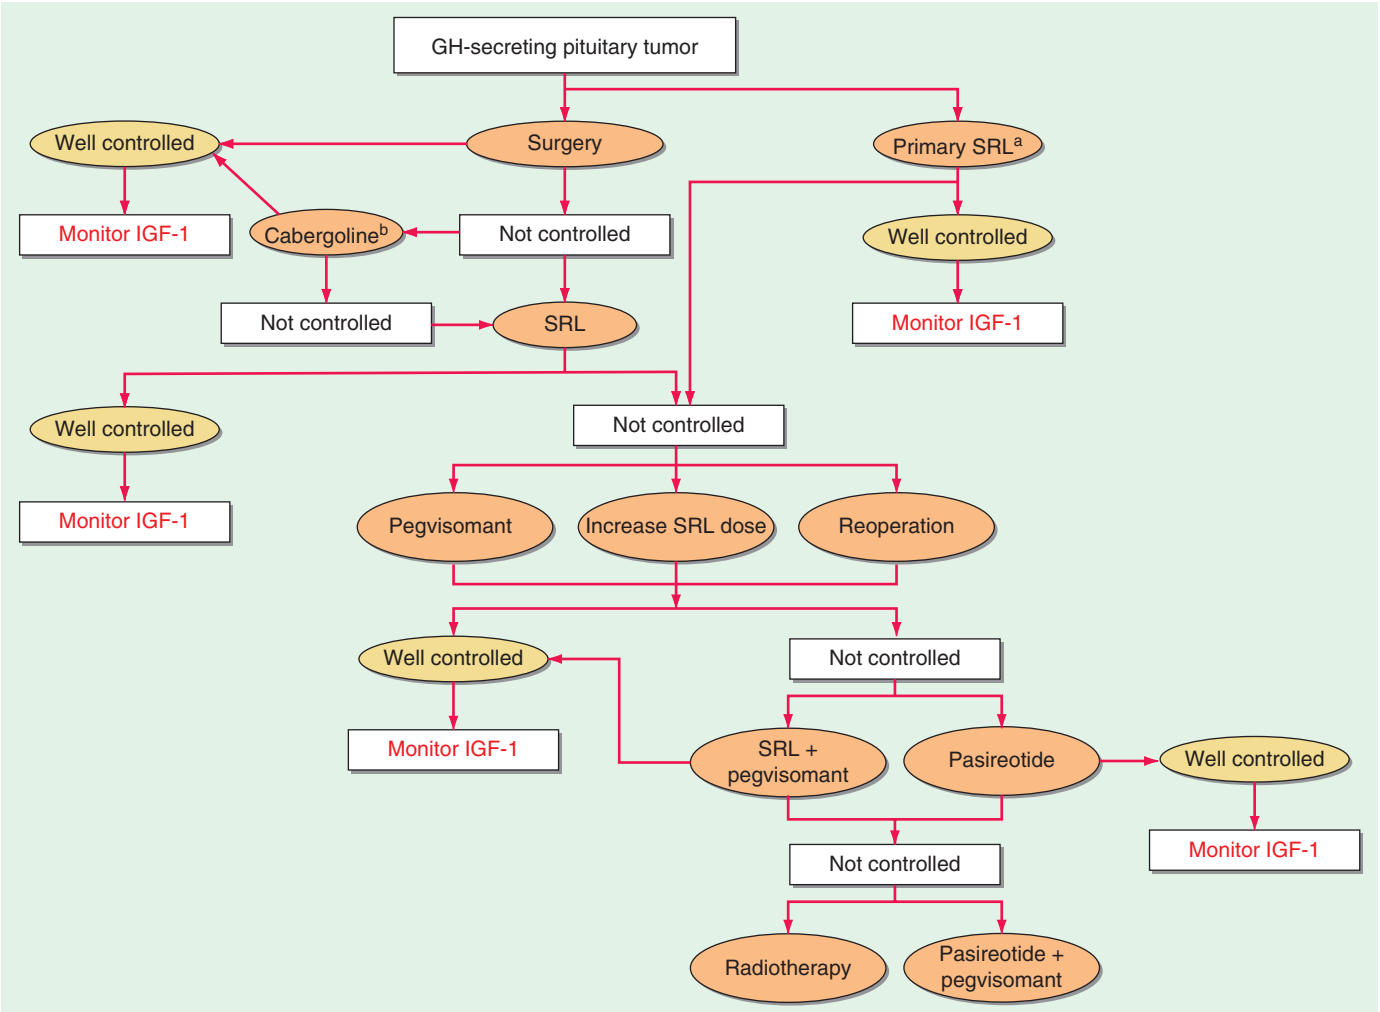

FIGURE 380-8 Management of acromegaly. [a]If curative surgery is not feasible. [b]Consider in cases of mild postoperative GH/IGF-1 elevations. GH, growth hormone; IGF, insulin-like growth factor; SRL, somatostatin receptor ligand (octreotide or lanreotide).

subcutaneous injection (10–30 mg) and normalizes IGF-1 in ~70% of patients. GH levels, however, remain elevated as the drug does not target the pituitary adenoma. Side effects include reversible liver enzyme elevation, lipodystrophy, and injection site pain. Tumor size should be monitored by MRI.

Combined treatment with monthly SRLs and weekly or biweekly pegvisomant injections has been used effectively in resistant patients.

DOPAMINE AGONISTS

Very high doses of cabergoline (0.5 mg/d) may achieve short-lived and modest GH therapeutic efficacy. Combined treatment with octreotide and cabergoline may induce additive biochemical control compared with either drug alone.

RADIATION THERAPY

External radiation therapy or high-energy stereotactic techniques are used as adjuvant therapy for acromegaly. An advantage of radiation is that patient compliance with long-term treatment is not required. Tumor mass is reduced, and GH levels are attenuated over time. However, 50% of patients require at least 8 years for GH levels to be suppressed to <5 μg/L; this level of GH reduction is achieved in ~90% of patients after 18 years but represents suboptimal GH suppression. Patients may require interim medical therapy for several years before attaining maximal radiation benefits. Most patients also experience hypothalamic-pituitary damage, leading to gonadotropin, ACTH, and/or TSH deficiency within 10 years of therapy.

SUMMARY

Surgery is the preferred primary treatment for GH-secreting microadenomas (Fig. 380-8). The high frequency of residual GH hypersecretion after macroadenoma resection usually necessitates adjuvant or primary medical therapy for these larger tumors. Patients unable to receive or respond to unimodal medical treatment may benefit from combined treatments, or they can be offered radiation. Very rarely, repeat surgery may be required.

CUSHING'S DISEASE (ACTH-PRODUCING ADENOMA)

(See also Chap. 386)

Etiology and Prevalence Pituitary corticotrope adenomas (Cushing's disease) account for 70% of patients with endogenous causes of Cushing's syndrome. However, it should be emphasized that iatrogenic hypercortisolism is the most common cause of cushingoid features. Ectopic tumor ACTH production, cortisol-producing adrenal adenomas, adrenal carcinoma, and adrenal hyperplasia account for the other causes; rarely, ectopic tumor CRH production is encountered.

ACTH-producing adenomas account for ~10–15% of all pituitary tumors. Because the clinical features of Cushing's syndrome often lead to early diagnosis, most ACTH-producing pituitary tumors are relatively small microadenomas. However, macroadenomas also are seen and some ACTH-expressing adenomas are clinically silent. Cushing's disease is 5–10 times more common in women than in men. These pituitary adenomas exhibit unrestrained ACTH secretion, with

resultant hypercortisolemia. However, they retain partial suppressibility in the presence of high doses of administered glucocorticoids, providing the basis for dynamic testing to distinguish pituitary from nonpituitary causes of Cushing's syndrome.

Presentation and Diagnosis The diagnosis of Cushing's syndrome presents two great challenges: (1) to distinguish patients with pathologic cortisol excess from those with physiologic or other disturbances of cortisol production and (2) to determine the etiology of pathologic cortisol excess.

Typical features of chronic cortisol excess include thin skin, central obesity, hypertension, plethoric moon facies, purple striae and easy bruisability, glucose intolerance or diabetes mellitus, gonadal dysfunction, osteoporosis, proximal muscle weakness, signs of hyperandrogenism (acne, hirsutism), and psychological disturbances (depression, mania, and psychoses) (Table 380-7). Hematopoietic features of hypercortisolism include leukocytosis, lymphopenia, and eosinopenia. Immune suppression includes delayed hypersensitivity and infection propensity. These protean yet commonly encountered manifestations of hypercortisolism make it challenging to decide which patients mandate formal laboratory evaluation. Certain features make pathologic causes of hypercortisolism more likely; they include characteristic central redistribution of fat, thin skin with striae and bruising, and proximal muscle weakness. In children and young females, early osteoporosis may be particularly prominent. The primary cause of death is cardiovascular disease, but life-threatening infections and risk of suicide are also increased.

Rapid development of features of hypercortisolism associated with skin hyperpigmentation and severe myopathy suggests an ectopic tumor source of ACTH. Hypertension, hypokalemic alkalosis, glucose intolerance, and edema are also more pronounced in these patients. Serum potassium levels <3.3 mmol/L are evident in ~70% of patients with ectopic ACTH secretion but are seen in <10% of patients with pituitary-dependent Cushing's syndrome.

Laboratory Investigation The diagnosis of Cushing's disease is based on laboratory documentation of endogenous hypercortisolism. Measurement of 24-h UFC is a precise and cost-effective screening test. Alternatively, the failure to suppress plasma cortisol after an overnight 1-mg dexamethasone suppression test can be used to identify patients with hypercortisolism. As nadir levels of cortisol occur at night, elevated midnight serum or salivary samples of cortisol are suggestive of Cushing's disease. Basal plasma ACTH levels often distinguish patients with ACTH-independent (adrenal or exogenous glucocorticoid) from those with ACTH-dependent (pituitary, ectopic ACTH) Cushing's syndrome. Mean basal ACTH levels are about eightfold higher in patients with ectopic ACTH secretion than in those with pituitary ACTH-secreting adenomas. However, extensive overlap of ACTH levels in these two disorders precludes using ACTH measurements to make the distinction. Preferably, dynamic testing based on differential sensitivity to glucocorticoid feedback or ACTH stimulation in response to CRH or cortisol reduction is used to distinguish ectopic from pituitary sources of excess ACTH (Table 380-8). Very rarely, circulating CRH levels are elevated, reflecting ectopic tumor-derived secretion of CRH and often ACTH. **For further discussion of dynamic testing for Cushing's syndrome, see Chap. 386.**

Most ACTH-secreting pituitary tumors are <5 mm in diameter, and about half are undetectable by sensitive MRI. The high prevalence of incidental pituitary microadenomas diminishes the ability to distinguish ACTH-secreting pituitary tumors accurately from nonsecreting incidentalomas.

Inferior Petrosal Venous Sampling Because pituitary MRI with gadolinium enhancement is insufficiently sensitive to detect small (<2 mm) pituitary ACTH-secreting adenomas, bilateral inferior petrosal sinus ACTH sampling before and after CRH administration may be required to distinguish these lesions from ectopic ACTH-secreting tumors that may have similar clinical and biochemical characteristics. Simultaneous assessment of ACTH in each inferior petrosal vein and in the peripheral circulation provides a strategy for confirming and localizing pituitary ACTH production. Sampling is performed at baseline and 2, 5, and 10 min after intravenous bovine CRH (1 μg/kg) injection.

TABLE 380-8 Differential Diagnosis of ACTH-Dependent Cushing's Syndrome[a]

	ACTH-SECRETING PITUITARY TUMOR	ECTOPIC ACTH SECRETION
Etiology	Pituitary corticotrope adenoma Plurihormonal adenoma	Bronchial, abdominal carcinoid Small-cell lung cancer Thymoma, other sources
Sex	F > M	M > F
Clinical features	Slow onset	Rapid onset Pigmentation Severe myopathy
Serum potassium <3.3 μg/L	<10%	75%
24-h UFC	High	High
Basal ACTH level	Inappropriately high	Very high
Dexamethasone suppression		
1 mg overnight		
Low-dose (0.5 mg q6h)	Cortisol >5 μg/dL	Cortisol >5 μg/dL
High-dose (2 mg q6h)	Cortisol <5 μg/dL	Cortisol >5 μg/dL
UFC >80% suppressed	Microadenomas: 90% Macroadenomas: 50%	10%
Inferior petrosal sinus sampling (IPSS)		
Basal		
IPSS: peripheral	>2	<2
CRH-induced		
IPSS: peripheral	>3	<3

[a]ACTH-independent causes of Cushing's syndrome are diagnosed by suppressed ACTH levels and an adrenal mass in the setting of hypercortisolism. Iatrogenic Cushing's syndrome is excluded by history.

Abbreviations: ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; F, female; M, male; UFC, urinary free cortisol.

An increased ratio (>2) of inferior petrosal:peripheral vein ACTH confirms pituitary Cushing's syndrome. After CRH injection, peak petrosal:peripheral ACTH ratios ≥3 confirm the presence of a pituitary ACTH-secreting tumor. The sensitivity of this test is >95%, with very rare false-positive results. False-negative results may be encountered in patients with aberrant venous drainage. Petrosal sinus catheterizations are technically difficult, and ~0.05% of patients develop neurovascular complications. The procedure should not be performed in patients with hypertension, in patients with known cerebrovascular disease, or in the presence of a well-visualized pituitary adenoma on MRI.

TREATMENT

Cushing's Disease

Selective transsphenoidal resection is the treatment of choice for Cushing's disease **(Fig. 380-9)**. The remission rate for this procedure is ~80% for microadenomas but <50% for macroadenomas. However, surgery is rarely successful when the adenoma is not visible on MRI. After successful tumor resection, most patients experience a postoperative period of symptomatic ACTH deficiency that may last up to 12 months. This usually requires low-dose cortisol replacement, as patients experience steroid withdrawal symptoms and have a suppressed hypothalamic-pituitary-adrenal axis. Biochemical recurrence occurs in ~5% of patients in whom surgery was initially successful. As persistent hypercortisolemia may cause blood clotting defects, prophylactic postoperative thromboembolic management has been advocated for vulnerable patients.

When initial surgery is unsuccessful, repeat surgery is sometimes indicated, particularly when a pituitary source for ACTH is well documented. In older patients, in whom issues of growth and fertility are less important, hemi- or total hypophysectomy may be necessary if a discrete pituitary adenoma is not recognized. Pituitary irradiation may be used after unsuccessful surgery, but it cures only ~15% of patients. Because the effects of radiation are slow and only partially effective in adults, adrenal-targeted steroidogenic inhibitors are used in combination with pituitary irradiation to block adrenal responses to persistently high ACTH levels.

Pasireotide LAR 10–40 mg intramuscularly, an SRL with high affinity for SST5 > SST2 receptor subtypes, may control hypercortisolemia in a subset of patients with ACTH-secreting pituitary tumors when surgery is not an option or has not been successful.

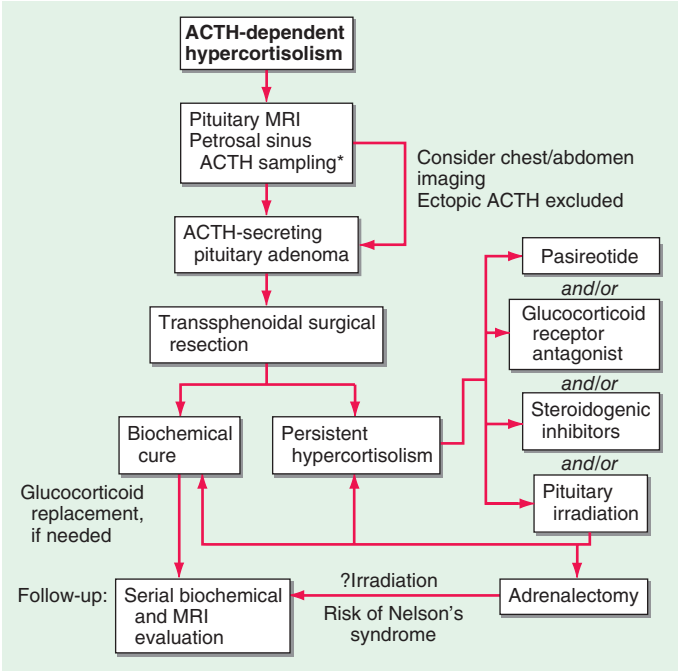

FIGURE 380-9 Management of Cushing's disease. ACTH, adrenocorticotropin hormone; MRI, magnetic resonance imaging; *, Not usually required.

The drug lowers plasma ACTH levels and normalizes 24-h UFC levels in ~20% of patients, and up to 40% of patients may experience pituitary tumor shrinkage. Side effects are similar to those encountered for other SRLs and include transient abdominal discomfort, diarrhea, nausea, and gallstones (20% of patients). Notably, hyperglycemia and new-onset diabetes develop in up to 70% of patients, likely due to suppressed pancreatic secretion of insulin and incretins. Because patients with hypercortisolism are insulin-resistant, hyperglycemia should be rigorously managed. The drug requires consistent long-term administration.

Osilodrostat (2 mg twice daily titrated up to 30 mg twice daily), an oral 11β-hydroxylase inhibitor that blocks adrenal gland cortisol biosynthesis, normalized 24-h UFC in 86% of patients. Mild, mostly transient gastrointestinal symptoms are common. Patients should be closely monitored for development of hypocortisolism and adrenal insufficiency. Elevated adrenal hormone precursors may lead to hypokalemia and hypertension. QTc prolongation and possibly increased tumor volume are also reported.

Ketoconazole, an imidazole derivative antimycotic agent, inhibits several P450 enzymes and effectively lowers cortisol in most patients with Cushing's disease when administered twice daily (600–1200 mg/d). Elevated hepatic transaminases, gynecomastia, impotence, gastrointestinal upset, and edema are common side effects.

Mifepristone (300–1200 mg/d), a glucocorticoid receptor antagonist, blocks peripheral cortisol action and is approved to treat hyperglycemia in Cushing's disease. Because the drug does not target the pituitary tumor, both ACTH and cortisol levels remain elevated, thus obviating a reliable circulating biomarker. Side effects are largely due to general antagonism of other steroid hormones and include hypokalemia, endometrial hyperplasia, hypoadrenalism, and hypertension.

Metyrapone (2–4 g/d) inhibits 11β-hydroxylase activity and normalizes plasma cortisol in up to 75% of patients. Side effects include nausea and vomiting, rash, and exacerbation of acne or hirsutism. *Mitotane* (3–6 g/d orally in four divided doses) suppresses cortisol hypersecretion by inhibiting 11β-hydroxylase and cholesterol side-chain cleavage enzymes and by destroying adrenocortical cells. Side effects of mitotane include gastrointestinal symptoms, dizziness, gynecomastia, hyperlipidemia, skin rash, and hepatic enzyme elevation. It also may lead to hypoaldosteronism. Other agents include *aminoglutethimide* (250 mg tid), *trilostane* (200–1000 mg/d), *cyproheptadine* (24 mg/d), and IV *etomidate* (0.3 mg/kg per h). Glucocorticoid insufficiency is a potential side effect of agents used to block steroidogenesis.

The use of steroidogenic inhibitors has decreased the need for bilateral adrenalectomy. Surgical removal of both adrenal glands corrects hypercortisolism but may be associated with significant morbidity rates and necessitates permanent glucocorticoid and mineralocorticoid replacement. Adrenalectomy in the setting of residual corticotrope adenoma tissue predisposes to the development of *Nelson's syndrome*, a disorder characterized by rapid pituitary tumor enlargement and increased pigmentation secondary to high ACTH levels. Prophylactic radiation therapy may be indicated to prevent the development of Nelson's syndrome after adrenalectomy.

NONFUNCTIONING AND GONADOTROPIN-PRODUCING PITUITARY ADENOMAS

Etiology and Prevalence Nonfunctioning pituitary adenomas include those that secrete little or no pituitary hormones into the systemic circulation, as well as tumors that produce too little hormone to result in recognizable clinical features. They are the most common type of pituitary adenoma and are usually macroadenomas at the time of diagnosis because clinical features are not apparent until tumor mass effects occur. Based on immunohistochemistry, most clinically nonfunctioning adenomas can be shown to originate from gonadotrope cells or from pituitary null cells. These tumors typically produce small

amounts of intact gonadotropins (usually FSH) as well as uncombined α, LH β, and FSH β subunits. Tumor secretion may lead to elevated α and FSH β subunits and, very rarely, to increased LH β subunit levels. Some adenomas express α subunits without FSH or LH. A TRH stimulation test often induces an atypical increase of tumor-derived gonadotropins or subunits.

Presentation and Diagnosis Clinically nonfunctioning tumors often present with optic chiasm pressure and other symptoms of local expansion or may be incidentally discovered on an MRI performed for another indication (incidentaloma). Rarely, menstrual disturbances or ovarian hyperstimulation occur in women with large tumors that produce FSH and LH. In these cases, ovaries may have features that resemble polycystic ovarian syndrome and may produce very high levels of estrogen. More commonly, adenoma compression of the pituitary stalk or surrounding pituitary tissue leads to attenuated LH and features of hypogonadism. PRL levels are usually slightly increased, also because of stalk compression. It is important to distinguish this circumstance from true prolactinomas, as nonfunctioning tumors do not shrink in response to treatment with dopamine agonists.

Laboratory Investigation The goal of laboratory testing in clinically nonfunctioning tumors is to classify the type of tumor, identify hormonal markers of tumor activity, and detect possible hypopituitarism. Free α subunit levels may be elevated in 10–15% of patients with nonfunctioning tumors. In female patients, peri- or postmenopausal basal FSH concentrations are difficult to distinguish from tumor-derived FSH elevation. Premenopausal women have cycling FSH levels, also preventing clear-cut diagnostic distinction from tumor-derived FSH. In men, gonadotropin-secreting tumors may be diagnosed because of slightly increased gonadotropins (FSH > LH) in the setting of a pituitary mass. Testosterone levels are usually low despite the normal or increased LH level, perhaps reflecting reduced LH bioactivity or the loss of normal LH pulsatility. Because this pattern of hormone test results is also seen in primary gonadal failure and, to some extent, with aging **(Chap. 391)**, the finding of increased gonadotropins alone is insufficient for the diagnosis of a gonadotropin-secreting tumor. In the majority of patients with gonadotrope adenomas, TRH administration stimulates LH β subunit secretion; this response is not seen in normal individuals. GnRH testing, however, is not helpful for making the diagnosis. For nonfunctioning and gonadotropin-secreting tumors, the diagnosis usually rests on immunohistochemical analyses of surgically resected tumor tissue, as the mass effects of these tumors usually necessitate resection.

Although acromegaly or Cushing's disease usually presents with unique clinical features, clinically inapparent (silent) somatotrope or corticotrope adenomas may only be diagnosed by immunostaining of resected tumor tissue. These silent tumors usually grow more aggressively and account for up to 20% of all nonfunctioning adenomas. If PRL levels are <100 μg/L in a patient harboring a pituitary mass, a nonfunctioning adenoma causing pituitary stalk compression should be considered.

TREATMENT

Nonfunctioning and Gonadotropin-Producing Pituitary Adenomas

Asymptomatic small nonfunctioning microadenomas with no threat to vision may be followed with regular MRI and visual field testing without immediate intervention. However, for macroadenomas, transsphenoidal surgery is indicated to reduce tumor size and relieve mass effects **(Fig. 380-10)**. Although it is not usually possible to remove all adenoma tissue surgically, vision improves in 70% of patients with preoperative visual field defects. Preexisting hypopituitarism that results from tumor mass effects may improve or resolve completely. Beginning ~6 months postoperatively, MRI scans should be performed yearly to detect tumor regrowth. Within 5–6 years after successful surgical resection, ~15% of nonfunctioning tumors recur. When substantial tumor remains after transsphenoidal surgery, adjuvant radiotherapy may be indicated to prevent tumor regrowth. Radiotherapy may be deferred if no postoperative residual mass is evident. Nonfunctioning pituitary tumors respond poorly to dopamine agonist treatment, and SRLs are largely ineffective for shrinking these tumors. The selective GnRH antagonist Nal-Glu GnRH suppresses FSH hypersecretion but has no effect on adenoma size.

TSH-SECRETING ADENOMAS

TSH-producing macroadenomas are very rare but are often large and locally invasive when they occur. Patients usually present with thyroid goiter and hyperthyroidism, reflecting chronic overproduction of TSH. Diagnosis is based on demonstrating elevated serum free T_4 levels, inappropriately normal or high TSH secretion, and MRI evidence of a pituitary adenoma. Elevated free glycoprotein hormone α subunits are seen in many patients.

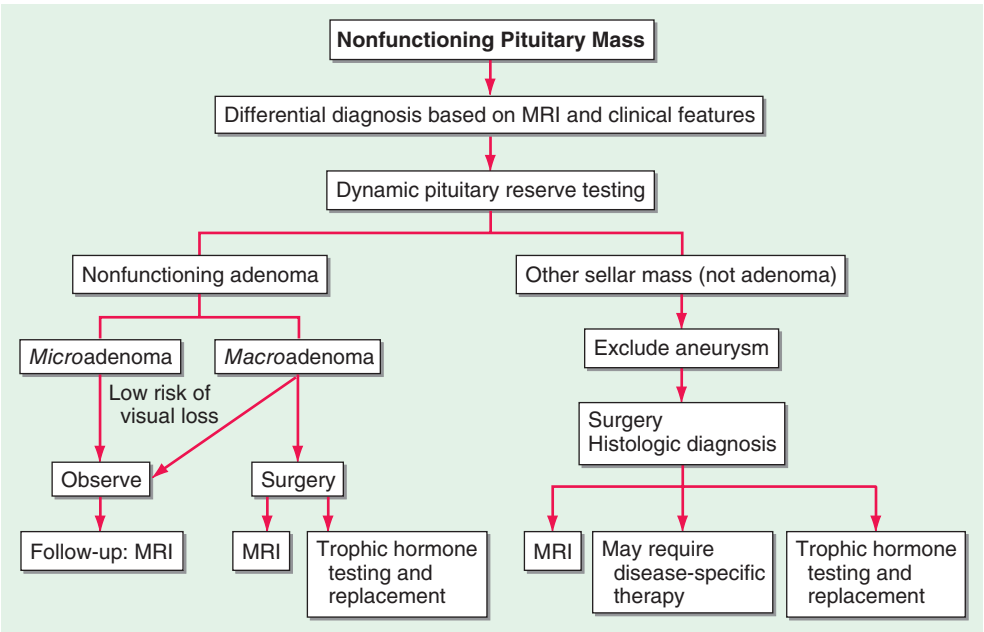

FIGURE 380-10 Management of a nonfunctioning pituitary mass. MRI, magnetic resonance imaging.

It is important to exclude other causes of inappropriate TSH secretion, such as resistance to thyroid hormone, an autosomal dominant disorder caused by mutations in the thyroid hormone β receptor (Chap. 382). The presence of a pituitary mass and elevated β subunit levels are suggestive of a TSH-secreting tumor. Dysalbuminemic hyperthyroxinemia syndromes, caused by mutations in serum thyroid hormone binding proteins, are also characterized by elevated thyroid hormone levels, but with normal rather than suppressed TSH levels. Moreover, free thyroid hormone levels are normal in these disorders, most of which are familial.

TREATMENT

TSH-Secreting Adenomas

The initial therapeutic approach is to remove or debulk the tumor mass surgically, usually using a transsphenoidal approach. Total resection is not often achieved as most of these adenomas are large and locally invasive. Normal circulating thyroid hormone levels are achieved in about two-thirds of patients after surgery. Thyroid ablation or antithyroid drugs (methimazole and propylthiouracil) can be used to reduce thyroid hormone levels. SRL treatment effectively normalizes TSH and α subunit hypersecretion, shrinks the tumor mass in 50% of patients, and improves visual fields in 75% of patients; euthyroidism is restored in most patients. Because SRLs markedly suppress TSH, biochemical hypothyroidism often requires concomitant thyroid hormone replacement, which may also further control tumor growth.

AGGRESSIVE ADENOMAS

Despite the rarity of malignant transformation and metastatic lesions, a subset of pituitary adenomas undergoes aggressive local growth and central nervous system invasion with high Ki67 levels (>4%). Silent corticotrope and somatotrope tumors, as well as prolactinomas occurring in middle-aged men, are particularly prone to aggressive growth and recurrence. Patients with these tumors usually require an integrated management approach including repeat surgeries and irradiation. Temozolomide has also been used with variable responses.

381 Disorders of the Neurohypophysis

Gary L. Robertson, Daniel G. Bichet

The neurohypophysis, or posterior pituitary, is composed of large neuronal axons that originate in cell bodies in the supraoptic and paraventricular nuclei of the hypothalamus, project through the diaphragm sella, and terminate as bulbous enlargements on a capillary plexus that drains into the superior vena cava. Some of these neurons produce arginine vasopressin (AVP), also known as antidiuretic hormone; others produce oxytocin. AVP acts on the renal tubules to reduce water loss by concentrating the urine. Oxytocin stimulates postpartum milk letdown in response to suckling. A deficiency of AVP secretion or action causes a syndrome characterized by the production of large amounts of dilute urine. Excessive or inappropriate AVP production impairs urinary water excretion and predisposes to hyponatremia if water intake is not reduced in parallel with urine output.

VASOPRESSIN

SYNTHESIS AND SECRETION

AVP is a nonapeptide composed of a six-member disulfide ring and a tripeptide tail (Fig. 381-1). It is synthesized via a polypeptide precursor that includes AVP, neurophysin, and copeptin, all encoded by a single gene on chromosome 20. After preliminary processing and folding, the precursor is packaged in neurosecretory vesicles, where it is transported down the axon; further processed to AVP, neurophysin, and copeptin; and stored in neurosecretory vesicles until released by exocytosis into peripheral blood.

In healthy individuals, AVP secretion is regulated primarily by the "effective" osmotic pressure, which is determined largely by the plasma concentration of sodium and its anions. This regulation is mediated by specialized cells in the anteromedial hypothalamus, known as *osmoreceptors*. The osmoreceptors receive blood from small perforating branches of the anterior communicating artery. They are extremely sensitive to small changes in the plasma concentration of sodium and its anions but normally are insensitive to other naturally occurring plasma solutes such as urea and glucose. This osmoregulatory system includes inhibitory as well as stimulatory components that function in concert to form a threshold, or set point, control system. Below this threshold, plasma AVP is suppressed to levels that permit the development of a maximum water diuresis. Above it, plasma AVP rises steeply in direct proportion to plasma osmolarity, quickly reaching levels sufficient to produce maximum antidiuresis. The absolute levels of plasma osmolarity/sodium at which minimally and maximally effective levels of plasma AVP occur differ from person to person, apparently due to genetic influences on the set and sensitivity of the system. However, the average threshold, or set point, for AVP release corresponds to a plasma osmolarity and sodium of ~275 mosmol/L and 135 meq/L, respectively; levels only 2–4% higher normally result in maximum antidiuresis.

The set point of the osmostat decreases ~1% during the luteal phase of the menstrual cycle and ~3% during pregnancy. It is also reduced

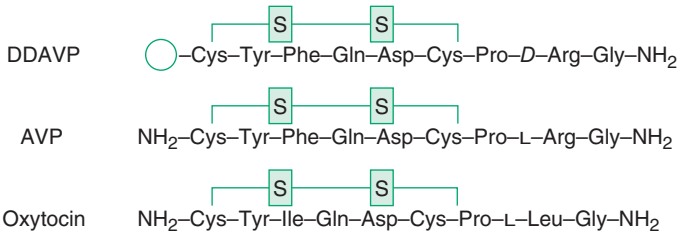

FIGURE 381-1 Primary structures of arginine vasopressin (AVP), oxytocin, and desmopressin (DDAVP).

by a decrease in blood pressure or by volume loss of >10–20%. These hemodynamic influences are mediated by neuronal afferents that originate in transmural pressure receptors of the heart and large arteries and project via the vagus and glossopharyngeal nerves to the brainstem, which sends postsynaptic projections to the hypothalamus. AVP secretion also can be stimulated by nausea, acute hypoglycemia, glucocorticoid deficiency, smoking, and, possibly, hyperangiotensinemia. Emetic stimuli are extremely potent since they typically elicit immediate, 50- to 100-fold increases in plasma AVP even when the nausea is transient and is not associated with vomiting or other symptoms. They appear to act via the emetic center in the medulla and can be blocked completely by treatment with antiemetics such as fluphenazine. There is no evidence that pain or other noxious stresses have any effect on AVP unless they elicit a vasovagal reaction with its associated nausea and hypotension.

ACTION

The most important, if not the only, physiologic action of AVP is to reduce water excretion by promoting concentration of urine. This antidiuretic effect is achieved primarily by increasing the hydroosmotic permeability of principal cells that line the distal tubule and medullary collecting ducts of the kidney **(Fig. 381-2)**. In the absence of AVP, these cells are impermeable to water and reabsorb little, if any, of the relatively large volume of dilute filtrate that enters from the proximal nephron. In this condition, the rate of urine output can be as high as 0.2 mL/kg per min and the specific gravity and osmolarity as low as ~1.000 and 50 mosmol/L, respectively. When AVP is secreted, it binds to V_2 receptors on the basal surface of principal cells causing water channels composed of aquaporin-2 to be inserted into the apical surface of the cell. These channels allow water to flow passively from the lumen through the cell down the osmotic gradient created by the hypertonicity of the renal medulla. The magnitude of this antidiuretic effect varies in direct proportion to plasma AVP, the rate of solute excretion, and the level of hypertonicity in the renal medulla. The maximum antidiuresis achievable in healthy humans occurs at plasma AVP levels in the range of 1 to 3 pg/mL and results in a urine osmolarity as high as 1200 mosmol/L and a rate of output as low as 0.35 mL/min. However, maximum concentrating capacity varies considerably depending on the level of hypertonicity in the renal medulla and that, in turn, is a function of the level and duration of AVP receptor 2 (AVPR2)–stimulated readsorption of urea in the distal nephron. Hence, if basal AVP stimulation of AVPR2 is low for any reason (e.g., a high basal fluid intake), the rise in urine osmolarity that occurs immediately after an increase in hormone levels may be so blunted as to suggest a defect in antidiuretic function. This probably accounts for the shortcomings of the traditional indirect methods for the differential diagnosis of diabetes insipidus (see below).

At high concentrations, AVP also causes contraction of smooth muscle in blood vessels in the skin and gastrointestinal tract, induces glycogenolysis in the liver, and potentiates adrenocorticotropic hormone (ACTH) release by corticotropin-releasing factor. These effects are mediated by V_{1a} or V_{1b} receptors that are coupled to phospholipase C. They may also affect the sensitivity of the baroreceptor and influence sympathetic and parasympathetic outflows to a variety of target organs, including the heart, the peripheral vasculature, and the kidneys. Their role, if any, in human physiology/pathophysiology remains to be determined.

METABOLISM

AVP distributes rapidly into a space roughly equal to the extracellular fluid volume. It is cleared irreversibly with a half-life ($t_{1/2}$) of 10–30 min. Most AVP clearance is due to degradation in the liver and kidneys. During pregnancy, the metabolic clearance of AVP is increased three- to fourfold due to placental production of an N-terminal peptidase.

THIRST

Because AVP cannot reduce water loss below a certain minimum level obligated by urinary solute load and evaporation from skin and lungs, a mechanism for ensuring adequate intake is essential for preventing dehydration. This vital function is performed by the thirst mechanism. Like AVP, thirst and fluid intake are regulated primarily by an osmostat that is situated in the anteromedial hypothalamus and is able to detect very small changes in the plasma concentration of sodium and its anions. The thirst osmostat appears to be "set" about 3% higher than the AVP osmostat. This arrangement ensures that thirst, polydipsia, and dilution of body fluids do not occur until plasma osmolarity/sodium exceeds the defensive capacity of the antidiuretic mechanism. Defects in this mechanism result in hypodipsia, diverse abnormalities in AVP secretion, and a variety of clinical disorders of water balance (see below). The gastrointestinal tract also has a mechanism that detects fluid intake and inhibits thirst and AVP secretion before water is absorbed sufficiently to lower plasma osmolarity/sodium. However, the resultant inhibition of thirst and AVP is transient unless plasma

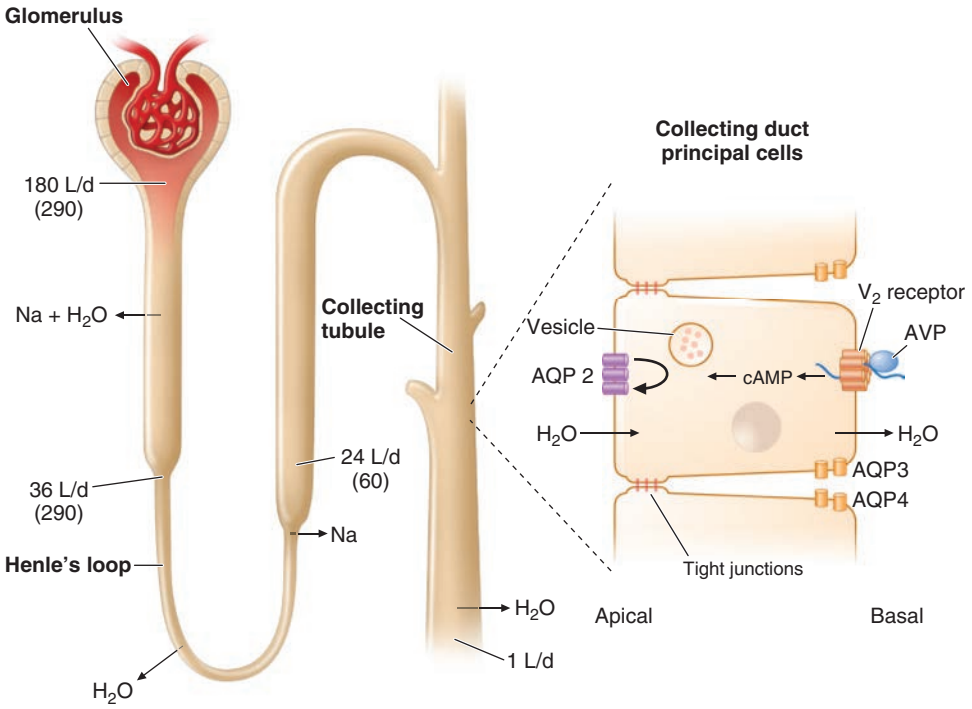

FIGURE 381-2 Antidiuretic effect of arginine vasopressin (AVP) in the regulation of urine volume. In a typical 70-kg adult, the kidney filters ~180 L/d of plasma. Of this, ~144 L (80%) is reabsorbed isosmotically in the proximal tubule and another 8 L (4–5%) is reabsorbed without solute in the descending limb of Henle's loop. The remainder is diluted to an osmolarity of ~60 mmol/kg by selective reabsorption of sodium and chloride in the ascending limb. In the absence of AVP, the urine issuing from the loop passes largely unmodified through the distal tubules and collecting ducts, resulting in a maximum water diuresis. In the presence of AVP, solute-free water is reabsorbed osmotically through the principal cells of the collecting ducts, resulting in the excretion of a much smaller volume of concentrated urine. This antidiuretic effect is mediated via a G protein–coupled V_2 receptor that increases intracellular cyclic AMP, thereby inducing translocation of aquaporin 2 (AQP 2) water channels into the apical membrane. The resultant increase in permeability permits an influx of water that diffuses out of the cell through AQP 3 and AQP 4 water channels on the basal-lateral surface. The net rate of flux across the cell is determined by the number of AQP 2 water channels in the apical membrane and the strength of the osmotic gradient between tubular fluid and the renal medulla. Tight junctions on the lateral surface of the cells serve to prevent unregulated water flow. The V_2 receptors and AQP 2 are encoded by genes on chromosome Xq28 and 12q13, respectively.

osmolarity/sodium is reduced, and the role of this system in clinical disorders of water balance has not been determined.

OXYTOCIN

Oxytocin is also a nonapeptide that differs from AVP only at positions 3 and 8 (Fig. 381-1). However, it has relatively little antidiuretic effect and seems to act mainly on mammary ducts to facilitate milk letdown during nursing. It also may help initiate or facilitate labor by stimulating contraction of uterine smooth muscle, but it is not clear if this action is physiologic or necessary for normal delivery.

DEFICIENCIES OF AVP SECRETION AND ACTION

DIABETES INSIPIDUS

Clinical Characteristics Diabetes insipidus (DI) is a syndrome characterized by the excretion of abnormally large volumes of dilute urine. The 24-h urine volume exceeds 40 mL/kg body weight, and the 24-h urine osmolarity is <280 mosm/L. The polyuria produces symptoms of urinary frequency, enuresis, and/or nocturia. It also results in a slight rise in plasma osmolarity/sodium that stimulates thirst and a commensurate increase in fluid intake (polydipsia). Hence, clinical symptoms and signs of dehydration are uncommon unless thirst and/or water intake are also impaired.

Etiology DI is divided into four different types based on the etiology. The most common is due to a primary deficiency of AVP secretion. It is referred to variously as *neurohypophyseal*, *neurogenic*, *pituitary*, *cranial*, or *central DI*. It can be caused by a variety of congenital, acquired, or genetic disorders but is often idiopathic (Table 381-1). Six genetic forms of pituitary DI are now known. By far, the most common is transmitted in an autosomal dominant mode and is caused by diverse mutations in the coding region of one allele of the AVP–neurophysin II (or *AVP-NPII*) gene. All the mutations alter one or more amino acids known to be critical for correct processing and/or folding of the prohormone, thus interfering with its trafficking through the endoplasmic reticulum. Presumably, the misfolded mutant precursor accumulates and interferes with the production of AVP by the normal allele. Eventually, it destroys the magnocellular neurons in which it is produced since histologic studies in a few patients show fibrosis and a lack of AVP-containing neurons in the posterior pituitary. The AVP deficiency usually is not present at birth but develops gradually over a period of months to years, progressing from partial to severe at different rates depending on the mutation and other unknown variables. Once established, the deficiency of AVP is permanent, but for unknown reasons, the DI occasionally improves or remits completely in late middle age. The parvocellular neurons that make AVP and the magnocellular neurons that make oxytocin appear to be unaffected. There are also rare autosomal recessive forms of pituitary DI. One is due to an inactivating mutation in the AVP portion of the gene that results in production of a biologically inactive form of AVP. Another is due to a large deletion that involves the majority of the AVP gene and regulatory sequences in the intergenic region. A third is caused by mutations of the *WFS1* gene responsible for Wolfram's syndrome (DI, diabetes mellitus, optic atrophy, and neural deafness [DIDMOAD]). An X-linked recessive form pituitary DI linked to Xq28 also has been reported, but the causative gene has not yet been identified. Finally, mutations in the *PCSK1* gene have been associated with severe early malabsorptive diarrhea and an undefined polyuria-polydipsia syndrome developing before 5 years of age.

The second type of DI is due to a suppression of AVP secretion by excessive intake of fluids. It is commonly referred to as *primary polydipsia* and can be subdivided into three subcategories. In one, called *dipsogenic DI*, the excessive fluid intake appears to be caused by inappropriate thirst. It can occur following head trauma or in association with multifocal diseases of the brain such as neurosarcoid, tuberculous meningitis, and multiple sclerosis, but like pituitary DI, it is often idiopathic. The second subcategory, *psychogenic polydipsia*, is not associated with thirst, and the polydipsia seems to be a feature of psychosis or obsessive-compulsive disorder. The third subcategory, *iatrogenic polydipsia*, is due to an increase in water intake motivated by a belief in its health benefits.

The third type of DI is also due to a deficiency of AVP caused by an increased rate of degradation by an N-terminal aminopeptidase produced in the placenta. It is referred to as *gestational DI* because the signs and symptoms manifest during pregnancy and usually remit several weeks after delivery. The fourth type of DI is caused by renal insensitivity to the antidiuretic action of AVP. It is called *nephrogenic* DI and can be caused by a drug such as lithium, a disorder such as

TABLE 381-1 Causes of Diabetes Insipidus

- **Pituitary diabetes insipidus**
  - Acquired
    - Head trauma (closed and penetrating) including pituitary surgery
    - Neoplasms
      - Primary
        - Craniopharyngioma
        - Pituitary adenoma (suprasellar)
        - Dysgerminoma
        - Meningioma
      - Metastatic (lung, breast)
      - Hematologic (lymphoma, leukemia)
    - Granulomas
      - Sarcoidosis
      - Histiocytosis
      - Xanthoma disseminatum
    - Infectious
      - Chronic meningitis
      - Viral encephalitis
      - Toxoplasmosis
    - Inflammatory
      - Lymphocytic infundibuloneurohypophysitis
      - Granulomatosis with polyangiitis (Wegener's)
      - Lupus erythematosus
      - Scleroderma
    - Chemical toxins
      - Tetrodotoxin
      - Snake venom
    - Vascular
      - Sheehan's syndrome
      - Aneurysm (internal carotid)
      - Aortocoronary bypass
      - Hypoxic encephalopathy
    - Idiopathic
  - Congenital malformations
    - Septo-optic dysplasia
    - Midline craniofacial defects
    - Holoprosencephaly
    - Hypogenesis, ectopia of pituitary
  - Genetic
    - Autosomal dominant (*AVP-neurophysin* gene)
    - Autosomal recessive
      - Type A (*AVP-neurophysin* gene)
      - Type B (*AVP-neurophysin* gene)
      - Type C (*Wolfram's [4p-WFS1]* gene)
    - X-linked recessive (Xq28)
- **Gestational diabetes insipidus**
  - Pregnancy (second and third trimesters)
- **Nephrogenic diabetes insipidus**
  - Acquired
    - Drugs
      - Lithium
      - Demeclocycline
      - Methoxyflurane
      - Amphotericin B
      - Aminoglycosides
      - Cisplatin
      - Rifampin
      - Foscarnet
    - Metabolic
      - Hypercalcemia, hypercalciuria
      - Hypokalemia
    - Obstruction (ureter or urethra)
    - Vascular
      - Sickle cell disease and trait
      - Ischemia (acute tubular necrosis)
    - Granulomas

hypokalemia, or a genetic mutation (Table 381-1). The most common genetic form is transmitted in a semirecessive X-linked manner and is due to mutations in the gene on chromosome Xq28 that encodes the V_2 receptor. There are also autosomal recessive or dominant forms of nephrogenic DI. They are caused by mutations of the gene on chromosome 20 that encodes the aquaporin-2 water channels necessary for readsorption of water from dilute urine in the renal collecting ducts.

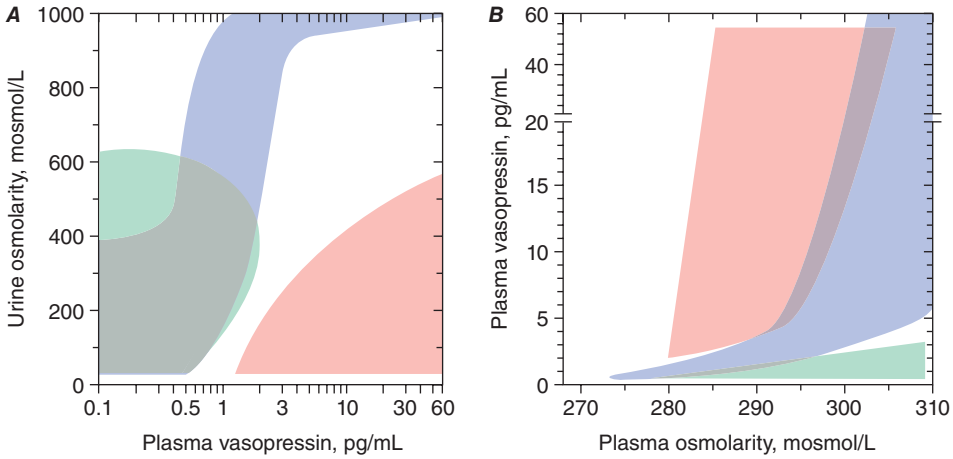

FIGURE 381-3 Relationship of plasma arginine vasopressin (AVP) to urine osmolarity (*A*) and plasma osmolarity (*B*) before and during fluid deprivation–hypertonic saline infusion test in patients who are normal or have primary polydipsia (*blue zones*), pituitary diabetes insipidus (*green zones*), or nephrogenic diabetes insipidus (*pink zones*).

Pathophysiology In pituitary and nephrogenic DI, the defect in urine concentration results in a rise in the rate of water excretion, a small (1–2%) decrease in body water, and a commensurate increase in plasma osmolarity/sodium, which stimulates thirst and a compensatory increase in water intake. The severity of the defect in antidiuretic function varies significantly from patient to patient. In some, it is nearly complete and cannot be overcome by even an intense stimulus such as nausea or severe dehydration. In others, the defect in AVP secretion or action is incomplete, and a modest stimulus such as a few hours of fluid deprivation, smoking, or a vasovagal reaction is sufficient to concentrate the urine. However, even in patients with a partial defect, the *maximum* level of urine osmolarity produced by these stimuli is usually less than normal partly because the prior deficiency in basal AVP stimulation temporarily diminishes renal concentrating capacity. Nevertheless, the underlying cause of the DI can be determined by analyzing the relationship of urine osmolarity to plasma AVP **(Fig. 381-3*A*)** and of plasma AVP to plasma osmolarity/sodium **(Fig. 381-3*B*)**.

The pathophysiology of primary polydipsia is the reverse of that in pituitary and nephrogenic DI. The increase in fluid intake reduces plasma osmolarity/sodium and AVP secretion. The resultant urinary dilution produces a compensatory increase in urinary free-water excretion that usually offsets the increase in intake and stabilizes plasma osmolarity/sodium at a level below basal. Thus, hyponatremia is uncommon unless the polydipsia is very severe or the compensatory water diuresis is impaired. Fluid deprivation or hypertonic saline infusion produces a normal rise in plasma AVP, but the resultant increase in urine concentration is usually subnormal because the capacity of the kidney to concentrate the urine is temporarily diminished by the prior lack of AVP stimulation. Thus, the *maximum* level of urine osmolarity achieved is often indistinguishable from that produced by fluid deprivation and/or administration of antidiuretic hormone in partial pituitary or partial nephrogenic DI. However, unlike the other two types of DI, the *relationships* of the rise in plasma AVP to the rise in plasma and urine osmolarity are both normal in primary polydipsia (Fig. 381-3).

Differential Diagnosis If symptoms of urinary frequency, enuresis, nocturia, and/or persistent thirst are present in the absence of glucosuria, the possibility of DI should be evaluated by collecting a 24-h urine on unrestricted fluid intake. If the osmolarity is <280 mosm/L and the volume >50 mL/kg per day, the patient has DI and should be evaluated further to determine the type. Sometimes the type can be inferred from the clinical setting. Often, however, this information is lacking, ambiguous, or even misleading, and other approaches to differential diagnosis are needed. In the few patients in whom basal plasma osmolarity and/or sodium are above the normal range, a fluid deprivation test is unnecessary and potentially hazardous because primary polydipsia can be excluded. Therefore, an injection of AVP (0.5 IU) or desmopressin (2 μg) followed by a repeat measurement of urine osmolarity will suffice to determine if the DI is due to a severe defect in the secretion or action of AVP. However, if basal plasma osmolarity and sodium are within normal limits, as they usually are, some other method is needed to determine the type of DI. The traditional approach is to stop all fluid intake for 4–6 h and closely monitor the changes in body weight, plasma osmolarity/sodium, and urine osmolarity. If plasma osmolarity and sodium rise above the normal range *without* concentrating the urine, primary polydipsia is excluded, and the effect on urine osmolarity of injecting AVP or desmopressin will determine if the patient has severe pituitary or severe nephrogenic DI. If, however, fluid deprivation results in concentration of the urine, the effect on urine osmolarity of injecting AVP or desmopressin does *not* distinguish reliably between *partial* pituitary DI, *partial* nephrogenic DI, and primary polydipsia because all three disorders temporarily diminish renal concentrating capacity to a variable extent depending on the severity of the basal polyuria.

The ambiguities inherent in the indirect method of differential diagnosis usually can be avoided by measuring plasma AVP before and during 4–6 h of complete fluid deprivation and relating these values to the concurrent level of plasma and urine osmolarity (Fig. 381-3). This approach distinguishes reliably between pituitary and nephrogenic DI even when the defect in AVP secretion or action is partial. It also differentiates partial pituitary DI from primary polydipsia if plasma osmolarity and sodium rise above the normal range. However, this level of dehydration is difficult to achieve by fluid deprivation alone when urinary concentration occurs. Therefore, it is usually necessary to add a short infusion of 3% saline (0.1 mL/kg body weight per minute for 60–90 min) and repeat the measurements of plasma AVP when plasma osmolarity and sodium rise above the normal range. This approach differentiates reliably between partial pituitary DI and primary polydipsia as evidenced by other findings, including MRI of the posterior pituitary and a properly dosed and closely monitored trial of antidiuretic therapy.

A simpler and less stressful but equally reliable way to differentiate among pituitary DI, nephrogenic DI, and primary polydipsia is to start by measuring basal plasma AVP and urine osmolarity under conditions of unrestricted fluid intake **(Fig. 381-4)**. If AVP is normal or elevated (>1 pg/mL) and the concurrent urine osmolarity is low (<280 mosm/L), the patient has nephrogenic DI and the only additional evaluation required is to determine the cause. If, however, basal plasma AVP is low or undetectable (<1 pg/mL), nephrogenic DI is very unlikely, and a brain MRI can be performed to determine if the hyperintense signal normally emitted by the posterior pituitary on T1-weighted images is present. Because this "bright spot" is a function of pituitary stores of AVP, it is almost always present in primary polydipsia but is abnormally small or absent in pituitary DI even when the deficiency in AVP is partial or due to production of a biologically inactive form of the hormone. The bright spot is also faint or absent in nephrogenic DI presumably because the chronic stimulus to AVP secretion depletes pituitary stores of the hormone. Therefore, MRI does not differentiate between pituitary and nephrogenic DI unless it reveals other pathology involving the gland. The other caveat is that the pituitary bright spot is

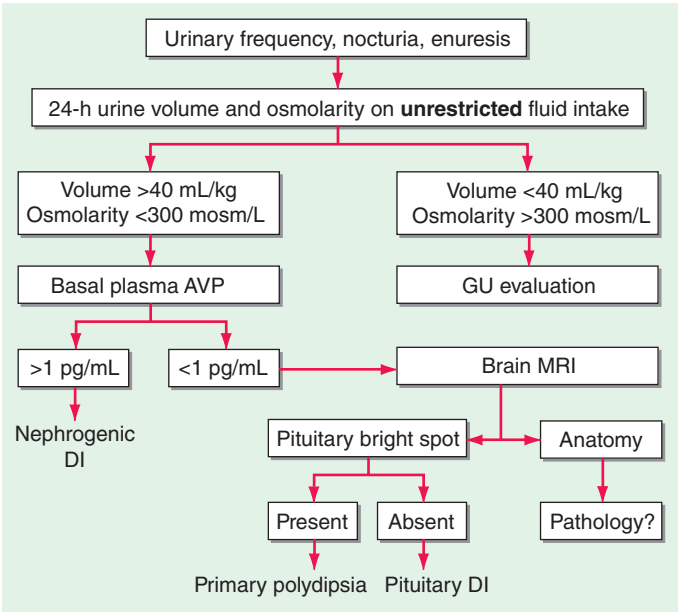

FIGURE 381-4 Simplified approach to the differential diagnosis of diabetes insipidus. When symptoms suggest diabetes insipidus (DI), the syndrome should be differentiated from a genitourinary (GU) abnormality by measuring the 24-h urine volume and osmolarity on unrestricted fluid intake. If DI is confirmed, basal plasma arginine vasopressin (AVP) should be measured on unrestricted fluid intake. If AVP is normal or elevated (>1 pg/mL), the patient probably has nephrogenic DI. However, if plasma AVP is low or undetectable, the patient has either pituitary DI or primary polydipsia. In that case, magnetic resonance imaging (MRI) of the brain can be performed to differentiate between these two conditions by determining whether or not the normal posterior pituitary bright spot is visible on T1-weighted midsagittal images. In addition, the MRI anatomy of the pituitary hypothalamic area can be examined to look for evidence of pathology that sometimes causes pituitary DI or the dipsogenic form of primary polydipsia. MRI is not reliable for differential diagnosis unless nephrogenic DI has been excluded because the bright spot is also absent, small, or faint in this condition.

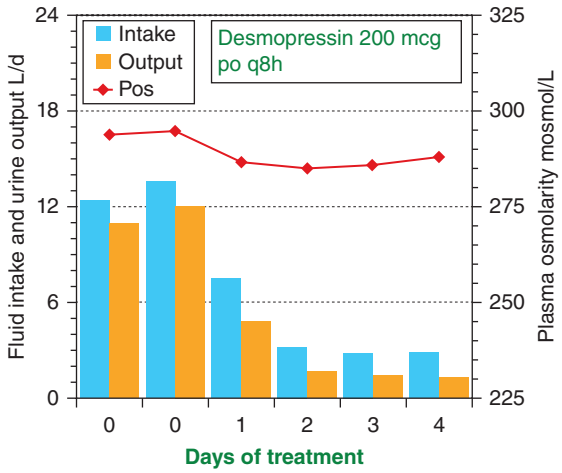

FIGURE 381-5 Effect of desmopressin therapy on fluid intake (*blue bars*), urine output (*orange bars*), and plasma osmolarity (*red line*) in a patient with uncomplicated pituitary diabetes insipidus. Note that treatment rapidly reduces fluid intake and urine output to normal, with only a slight increase in body water as evidenced by the slight decrease in plasma osmolarity.

also absent in patients with empty sella even in the absence of any type of DI and is sometimes present in infants in the early stages of familial pituitary DI.

If MRI and/or AVP assays with the requisite sensitivity and specificity are unavailable and a fluid deprivation test is impractical or undesirable, a third way to differentiate among pituitary DI, nephrogenic DI, and primary polydipsia is a properly dosed and closely monitored trial of desmopressin therapy (see below). In nephrogenic DI, this treatment has no effect on urine output, fluid intake, or plasma osmolarity/sodium. In pituitary DI, it abolishes the polyuria and polydipsia and reduces plasma osmolarity/sodium by 1–2%. However, in primary polydipsia, antidiuretic therapy eliminates the polyuria but not the polydipsia and, as a consequence, produces moderate to severe hyponatremia within 8–24 h.

The measurement of plasma copeptin has also been advocated for the differential diagnosis of DI since it is synthesized and co-secreted with AVP. However, because copeptin is cleared from plasma more slowly than AVP, its relationship to plasma and urine osmolarity is not diagnostic, and another approach based on the *change* in plasma copeptin after an infusion of hypertonic saline has been reported. However, unlike the measurement of plasma AVP, the diagnoses obtained by the copeptin method do not correlate well with the MRI findings or the response to antidiuretic therapy. The reason for these disparities remains to be determined.

TREATMENT

Diabetes Insipidus

The signs and symptoms of uncomplicated pituitary DI can be eliminated by treatment with desmopressin (DDAVP), a synthetic analogue of AVP (Fig. 381-1). DDAVP acts selectively at V_2 receptors to increase urine concentration and decrease urine flow in a dose-dependent manner. It is also more resistant to degradation than is AVP and has a three- to fourfold longer duration of action. DDAVP can be given by IV or SC injection, nasal inhalation, or orally by means of a tablet or melt. The doses required to control pituitary DI vary depending on the patient and the route of administration. However, among adults, they usually range from 1–2 μg qd or bid by injection, 10–20 μg bid or tid by nasal spray, or 100–400 μg bid or tid orally. The onset of antidiuresis is rapid, ranging from as little as 15 min after injection to 60 min after oral administration. When given in a dose that normalizes 24-h urinary osmolarity (400–800 mosmol/L) and volume (15–30 mL/kg body weight), DDAVP produces a slight increase in total body water and a (1–2%) decrease in plasma osmolarity/sodium that rapidly eliminates thirst and polydipsia **(Fig. 381-5)**. Consequently, water balance is maintained within the normal range. Hyponatremia rarely develops unless urine volume is reduced to <10 mL/kg per day or fluid intake is excessive due to an associated abnormality in thirst or cognition. Fortunately, thirst abnormalities are rare, and if the patient learns to drink only when truly thirsty, DDAVP can be given safely in doses sufficient to normalize urine output without the need for allowing intermittent escape to prevent water intoxication.

Primary polydipsia cannot be treated safely with DDAVP or any other antidiuretic drug because eliminating the polyuria does not eliminate the urge to drink. Therefore, it invariably produces hyponatremia and/or other signs of water intoxication, usually within 8–24 h if urine output is normalized completely. There is no consistently effective way to correct dipsogenic or psychogenic polydipsia, but the iatrogenic form may respond to patient education. To minimize the risk of water intoxication, all patients should be warned about the use of other drugs such as thiazide diuretics or carbamazepine (Tegretol) that can impair urinary free-water excretion directly or indirectly.

The polyuria and polydipsia of nephrogenic DI are not affected by treatment with standard doses of DDAVP. If resistance is partial, it may be overcome by tenfold higher doses, but this treatment is too expensive and inconvenient for long-term use. However, treatment with conventional doses of a thiazide diuretic and/or amiloride in conjunction with a low-sodium diet and a prostaglandin synthesis inhibitor (e.g., indomethacin) usually reduces the polyuria and polydipsia by 30–70% and may eliminate them completely. Side effects such as hypokalemia and gastric irritation can be minimized by the use of amiloride or potassium supplements and by taking medications with meals.

HYPODIPSIC HYPERNATREMIA

An increase in plasma osmolarity/sodium above the normal range (hypertonic hypernatremia) can be due to a decrease in total body water or an increase in total body sodium. The former results from a failure to drink enough water to replace normal or increased urinary and insensible loss due either to water deprivation or a lack of thirst (hypodipsia). This chapter focuses on hypodipsic hypernatremia, the form of hypernatremia due to a primary defect in the thirst mechanism. Hypernatremia caused by an increase in total body sodium is described elsewhere **(Chap. 386)**.

Clinical Characteristics Hypodipsic hypernatremia is a syndrome characterized by chronic or recurrent hypertonic dehydration. The hypernatremia varies widely in severity and is often associated with signs of hypovolemia such as tachycardia, postural hypotension, azotemia, hyperuricemia, and hypokalemia due to secondary hyperaldosteronism. Muscle weakness, pain, rhabdomyolysis, hyperglycemia, hyperlipidemia, and acute renal failure may also occur. Obtundation or coma may be present. At presentation, plasma AVP is usually but not always subnormal relative to the concurrent hypernatremia/hyperosmolemia. DI is usually absent but may develop during rehydration as blood volume, blood pressure, and plasma osmolarity/sodium return toward normal.

Etiology Hypodipsia is usually due to hypogenesis or destruction of the osmoreceptors in the anterior hypothalamus that regulate thirst. The defect can result from various congenital malformations of midline brain structures or may be acquired due to diseases such as surgery or aneurysms of the anterior communicating artery, primary or metastatic tumors in the hypothalamus, head trauma, granulomatous diseases such as sarcoidosis and histiocytosis, AIDS, and cytomegalovirus encephalitis. Adipsic hypernatremia without demonstrable hypothalamic lesions has also been associated with autoantibodies directed against the subfornical organ. Episodes of transient hypodipsic hypernatremia have also been reported in association with depression or other psychological disorders, suggesting that reversible neurochemical defects in the osmoregulation of thirst can also occur.

Pathophysiology A deficiency in osmotically induced thirst results in a failure to drink enough water to replenish obligatory renal and extrarenal losses. Consequently, plasma osmolarity and sodium rise often to extremely high levels before the disorder is recognized. In most cases, plasma AVP is subnormal relative to the hyperosmolarity/hypernatremia, but it is still adequate to prevent DI. However, during rehydration, plasma AVP sometimes falls to levels that result in DI before the dehydration is fully corrected **(Fig. 381-6)**. In other cases, plasma AVP does not decline even when the patient is overhydrated and a hyponatremic syndrome indistinguishable from inappropriate antidiuresis develops. This suggests that the AVP osmoreceptors normally provide inhibitory as well as stimulatory input to the neurohypophysis. In both situations, AVP secretion responds normally to nonosmotic stimuli such as nausea, hypovolemia, or hypotension, indicating that the neurohypophysis is intact. In a few patients, however, the neurohypophysis is also destroyed, resulting in a combination of chronic pituitary DI and hypodipsia, a life-threatening disorder that can be very difficult to manage. Rarely, the regulation of AVP secretion is completely normal, suggesting that the lack of thirst is due to a defect in post-osmoreceptor neural pathways to higher cognitive centers.

Differential Diagnosis Hypodipsic hypernatremia usually can be distinguished from other causes of inadequate fluid intake (e.g., coma, paralysis, restraints, absence of fresh water) by the clinical history and setting. Previous episodes and/or denial of thirst and failure to drink spontaneously when the patient is conscious, unrestrained, and hypernatremic are virtually diagnostic. The hypernatremia caused by excessive retention or intake of sodium can be distinguished by the presence of thirst as well as the physical and laboratory signs of hypervolemia rather than hypovolemia.

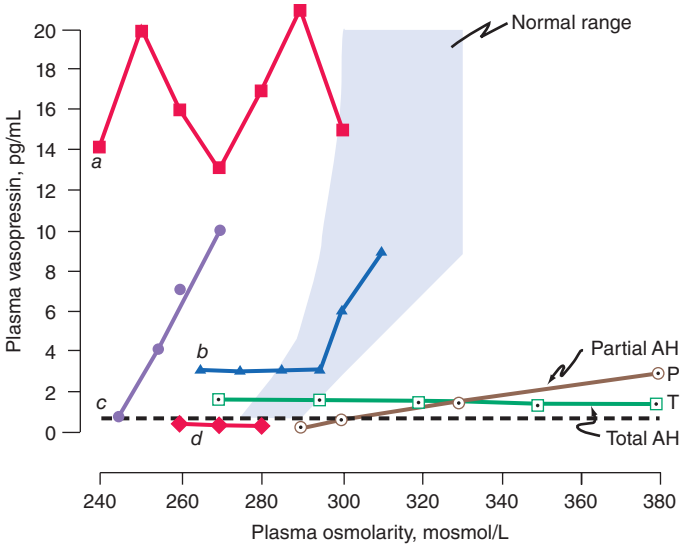

FIGURE 381-6 Heterogeneity of osmoregulatory dysfunction in adipsic hypernatremia (AH) and the syndrome of inappropriate antidiuresis (SIAD). Each line depicts schematically the relationship of plasma arginine vasopressin (AVP) to plasma osmolarity during water loading and/or infusion of 3% saline in a patient with either AH (*open symbols*) or SIAD (*closed symbols*). The shaded area indicates the normal range of the relationship. The horizontal broken line indicates the plasma AVP level below which the hormone is undetectable and urinary concentration usually does not occur. Lines P and T represent patients with a selective deficiency in the osmoregulation of thirst and AVP that is either partial (⊙) or total (⊡). In the latter, plasma AVP does not change in response to increases or decreases in plasma osmolarity but remains within a range sufficient to concentrate the urine even if overhydration produces hypotonic hyponatremia. In contrast, if the osmoregulatory deficiency is partial (⊙), rehydration of the patient suppresses plasma AVP to levels that result in urinary dilution and polyuria before plasma osmolarity and sodium are reduced to normal. Lines *a*–*d* represent different defects in the osmoregulation of plasma AVP observed in patients with SIADH or SIAD. In *a* (■), plasma AVP is markedly elevated and fluctuates widely without relation to changes in plasma osmolarity, indicating complete loss of osmoregulation. In *b* (▲), plasma AVP remains fixed at a slightly elevated level until plasma osmolarity reaches the normal range, at which point it begins to rise appropriately, indicating a selective defect in the inhibitory component of the osmoregulatory mechanism. In *c* (●), plasma AVP rises in close correlation with plasma osmolarity before the latter reaches the normal range, indicating downward resetting of the osmostat. In *d* (◆), plasma AVP appears to be osmoregulated normally, suggesting that the inappropriate antidiuresis is caused by some other abnormality.

TREATMENT

Hypodipsic Hypernatremia

Hypodipsic hypernatremia can be corrected by administering water orally if the patient is alert and cooperative or by infusing hypotonic fluids (0.45% saline or 5% dextrose and water) if the patient is not. The amount of free water in liters required to correct the deficit (ΔFW) can be estimated from body weight in kg (BW) and the serum sodium concentration in mmol/L (S_{Na}) by the formula $\Delta FW = 0.5BW \times ([S_{Na} - 140]/140)$. If serum glucose ($S_{Glu}$) is elevated, the measured S_{Na} should be corrected (S_{Na}^*) by the formula $S_{Na}^* = S_{Na} + ([S_{Glu} - 90]/36)$. This amount plus an allowance for continuing insensible and urinary losses should be given over a 24- to 48-h period. Close monitoring of serum sodium as well as fluid intake and urinary output is essential because, depending on the extent of osmoreceptor deficiency, some patients will develop AVP-deficient DI, requiring DDAVP therapy to complete rehydration; others will develop hyponatremia and a syndrome of inappropriate antidiuresis (SIAD)-like picture if overhydrated. If hyperglycemia and/or hypokalemia are present, insulin and/or potassium supplements should be given with the expectation that both can be discontinued when rehydration is complete. Plasma urea/creatinine should be monitored closely for signs of acute renal failure caused by rhabdomyolysis, hypovolemia, and hypotension.

Once the patient has been rehydrated, an MRI of the brain and tests of anterior pituitary function should be performed to look for

the cause and collateral defects in other hypothalamic functions. A long-term management plan to prevent or minimize recurrence of the fluid and electrolyte imbalance also should be developed. This should include a practical method to regulate fluid intake in accordance with variations in water balance as indicated by changes in body weight or serum sodium determined by home monitoring analyzers. Prescribing a fixed fluid intake is often problematic and potentially dangerous because insensible as well as urinary loss varies significantly over time due to changes in ambient temperature and physical activity as well as diet and antidiuresis.

INAPPROPRIATE ANTIDIURESIS (SEE ALSO CHAP. 53)

Clinical Characteristics SIAD is characterized by hypo-osmolemic hyponatremia and impaired urinary dilution in the absence of hypovolemia, hypotension, or other nonosmotic stimuli to AVP secretion. If the hyponatremia develops gradually or exists for more than a few days, it may be largely asymptomatic. However, if the hyponatremia is severe or develops acutely, it can cause a variety of adverse symptoms and signs ranging from headache, confusion, and anorexia to nausea, vomiting, coma, and convulsions. SIAD occurs in many diverse clinical settings (Table 381-2).

Etiology The cause of SIAD is a failure to maximally dilute the urine and mount a water diuresis when total water intake exceeds urinary and insensible water loss. In most cases, the defect in urinary dilution is due to an abnormality in AVP secretion and is commonly referred to as the syndrome of inappropriate antidiuretic hormone (SIADH). The defect in the osmoregulation of AVP secretion can take any of several different forms (Fig. 381-6). The most common is one in which the AVP secretion responds normally to osmotic stimulation and suppression but the threshold or set point of the system is lower than normal. These patients are able to dilute their urine if plasma osmolarity/sodium is reduced below the abnormal set point. In others, the secretion of AVP appears to be fixed or totally erratic. In ~10% of cases, there is no demonstrable defect in the osmoregulation of AVP secretion, and the failure to maximally dilute the urine may be due to an abnormality in the kidney. This form may be referred to as nephrogenic SIAD (NSIAD). In some of these patients, the inappropriate antidiuresis has been traced to a constitutive activating mutation of the V_2 receptor gene or the stimulatory G alpha protein GNAS. This form of inappropriate antidiuresis may be referred to as familial NSIAD.

TABLE 381-2 Causes of Syndrome of Inappropriate Antidiuresis

Neoplasms	Neurologic
Carcinomas	Guillain-Barré syndrome
Lung	Multiple sclerosis
Duodenum	Delirium tremens
Pancreas	Amyotrophic lateral sclerosis
Ovary	Hydrocephalus
Bladder, ureter	Psychosis
Other neoplasms	Peripheral neuropathy
Thymoma	Congenital malformations
Mesothelioma	Agenesis corpus callosum
Bronchial adenoma	Cleft lip/palate
Carcinoid	Other midline defects
Gangliocytoma	Metabolic
Ewing's sarcoma	Acute intermittent porphyria
Genetic	Pulmonary
AVP receptor-2	Asthma
Head trauma (closed and penetrating)	Pneumothorax
Infections	Positive-pressure respiration
Pneumonia, bacterial or viral	Drugs
Abscess, lung or brain	Vasopressin or desmopressin
Cavitation (aspergillosis)	Serotonin reuptake inhibitors
Tuberculosis, lung or brain	Oxytocin, high dose
Meningitis, bacterial or viral	Vincristine
Encephalitis	Carbamazepine
AIDS	Nicotine
Vascular	Phenothiazines
Cerebrovascular occlusions, hemorrhage	Cyclophosphamide
Cavernous sinus thrombosis	Tricyclic antidepressants
	Monoamine oxidase inhibitors

Abbreviation: AVP, arginine vasopressin.

Pathophysiology In SIADH and NSIAD, the failure to mount a water diuresis when intake exceeds urinary and insensible loss results in a slight expansion of total body water followed by a modest increase in urinary sodium excretion due at least in part to suppression of plasma renin activity and aldosterone secretion. As a result, expansion of extracellular volume is minimal, and clinically detectable edema does not develop. However, intracellular volume increases in proportion to the severity and rapidity of the change in plasma sodium. In the brain, this cellular swelling causes an increase in pressure that triggers a variety of symptoms. After several days, the swelling and symptoms may subside due to inactivation of some intracellular solutes and resultant decrease in cellular volume.

Differential Diagnosis SIADH and NSIAD must be differentiated from other types of hypo-osmolemic hyponatremia associated with impaired urinary dilution. This is usually possible from the history, physical examination, and basic laboratory findings (Table 381-3). Hypervolemic hyponatremia (type I) typically occurs in patients with generalized edema due to severe congestive heart failure or cirrhosis. Plasma renin activity (PRA) and aldosterone are elevated. Hypovolemic hyponatremia (type II) occurs in patients with loss of sodium and water due to severe vomiting, diarrhea, or primary adrenal insufficiency. It is usually associated with hypotension in the recumbent or upright position and an elevation in PRA. Euvolemic hyponatremia (type III) is divisible into two groups, which need to be managed differently. In one group, the cause is a severe deficiency in cortisol or thyroxine and should be treated accordingly. The other group is composed of patients with SIADH and NSIAD. In both, edema and a history or signs of sodium and water loss are absent, urinary sodium may be slightly elevated, and PRA is often low. Measurement of plasma AVP is usually of little diagnostic value except to differentiate SIADH from NSIAD in children or families with two or more affected members. If it is undetectable, sequencing of the *AVPR2* gene is indicated.

TREATMENT

Inappropriate Antidiuresis

The management of hyponatremia differs depending on the type as well as the severity and duration of symptoms. In hypervolemic hyponatremia, the objective should be to reduce total body sodium and water. If the hyponatremia is mild and symptomatic, restricting daily fluid intake to less than total urinary and insensible water loss usually suffices to prevent progression and gradually correct the defect. However, if basal urine output is very low or the hyponatremia is severe and/or symptomatic, an AVP antagonist such as tolvaptan or conivaptan can be given to increase the rate of urinary water excretion (see below). Their use should be limited to 30 days at a time because longer periods may cause or worsen abnormal liver chemistries. Infusion of hypertonic saline is absolutely contraindicated in hypervolemic hyponatremia because it further increases total body sodium and water, worsens the edema, and may precipitate cardiovascular decompensation.

In hypovolemic hyponatremia, fluid restriction and inhibitors of AVP action are absolutely contraindicated because they aggravate the hypovolemia and could precipitate hemodynamic collapse. Instead, an effort should be made to stop the loss of sodium and water and replace the deficits by mouth or infusion of isotonic or hypertonic saline. As in the treatment of other forms of

TABLE 381-3 Differential Diagnosis of Hyponatremia Based on Clinical Assessment of Extracellular Fluid Volume (ECFV)

CLINICAL FINDINGS	TYPE I, HYPERVOLEMIC	TYPE II, HYPOVOLEMIC	TYPE III, EUVOLEMIC	SIADH AND SIAD EUVOLEMIC
History				
CHF, cirrhosis, or nephrosis	Yes	No	No	No
Salt and water loss	No	Yes	No	No
ACTH-cortisol deficiency and/or nausea and vomiting	No	No	Yes	No
Physical examination				
Generalized edema, ascites	Yes	No	No	No
Postural hypotension	Maybe	Maybe	Maybe[a]	No
Laboratory				
BUN, creatinine	High-normal	High-normal	Low-normal	Low-normal
Uric acid	High-normal	High-normal	Low-normal	Low-normal
Serum potassium	Low-normal	Low-normal[b]	Normal[c]	Normal
Serum urate	High	High	Low	Low
Serum albumin	Low-normal	High-normal	Normal	Normal
Serum cortisol	Normal-high	Normal-high[d]	Low[e]	Normal
Plasma renin activity	High	High	Low[f]	Low
Urinary sodium (meq per unit of time)[g]	Low	Low[h]	High[i]	High[i]

[a]Postural hypotension may occur in secondary (ACTH-dependent) adrenal insufficiency even though extracellular fluid volume and aldosterone are usually normal. [b]Serum potassium may be high if hypovolemia is due to aldosterone deficiency. [c]Serum potassium may be low if vomiting causes alkalosis. [d]Serum cortisol is low if hypovolemia is due to primary adrenal insufficiency (Addison's disease). [e]Serum cortisol will be normal or high if the cause is nausea and vomiting rather than secondary (ACTH-dependent) adrenal insufficiency. [f]Plasma renin activity may be high if the cause is secondary (ACTH) adrenal insufficiency. [g]Urinary sodium should be expressed as the *rate of excretion* rather than the concentration. In a hyponatremic adult, an excretion rate >25 meq/d (or 25 μeq/mg of creatinine) could be considered high. [h]The rate of urinary sodium excretion may be high if the hypovolemia is due to diuretic abuse, primary adrenal insufficiency, or other causes of renal sodium wasting. [i]The rate of urinary sodium excretion may be low if intake is curtailed by symptoms or treatment.

Abbreviations: ACTH, adrenocorticotropic hormone; BUN, blood urea nitrogen; CHF, congestive heart failure; SIAD, syndrome of inappropriate antidiuresis; SIADH, syndrome of inappropriate antidiuretic hormone.

hyponatremia, care must be taken to ensure that plasma sodium does not increase too rapidly or too far since doing so may produce osmotic demyelination in the brain.

In euvolemic hyponatremia, the treatment of choice depends on the cause. If it is a deficiency in cortisol or thyroxine, gradual replacement usually suffices to eliminate all signs and symptoms, including the hyponatremia. In SIADH, the excess body water should be eliminated. If the hyponatremia is mild and largely asymptomatic, restricting total water intake to ~30 mL/kg per day less than urine output for several days or until the syndrome remits spontaneously will usually suffice. If, however, the hyponatremia is severe and symptomatic, the goal should be to partially correct it by intravenous infusion of hypertonic (3%) saline or administration of an AVP antagonist such as tolvaptan or conivaptan (Fig. 381-7). Infusion of 3% saline at a rate of ~0.05 mL/kg body weight per min raises serum sodium at a rate of ~1–2 meq/L per h, not only by replacing the slight sodium deficit but also by promoting a solute diuresis, which reduces total body water. Alternatively, a vaptan can be used to reduce body water by increasing urine output. Tolvaptan should be started at a dose of 15 mg PO qd and increased to 30 mg and 60 mg as needed to produce a brisk water diuresis. Conivaptan can be given intravenously starting with a loading dose of 20 mg over 30 min followed by another 20 mg IV over 24 h. With either vaptan, fluid intake should be monitored and restricted so as to underreplace urine output by ~5 mL/kg body weight per h. With hypertonic saline or vaptan therapy, plasma osmolarity and/or sodium should be checked every 1–2 h, and water intake or the treatment should be adjusted to keep the rate of rise at ~1% an hour until the values reach ~270 mosm/L or 130 meq/L, at which point the treatment should be discontinued. Raising the plasma sodium faster or farther may increase the risk of central pontine myelinolysis, an acute, potentially fatal neurologic syndrome characterized by quadriparesis, ataxia, and abnormal extraocular movements.

In SIAD due to an activating mutation of the V_2 receptor, the V_2 antagonists may not block the antidiuresis or raise plasma osmolarity/sodium. In that condition, use of an osmotic diuretic such as urea is reported to be effective in long-term prevention or correction of hyponatremia. However, some vaptans may be effective in patients with a different type of activating mutation of the V_2 receptor, so the response to this therapy may be neither predictable nor diagnostic.

GLOBAL PERSPECTIVES

The incidence, clinical characteristics, etiology, pathophysiology, differential diagnosis, and treatments of fluid and electrolyte disorders in tropical and nonindustrialized countries differ in some respects from those in the United States and other industrialized parts of the world.

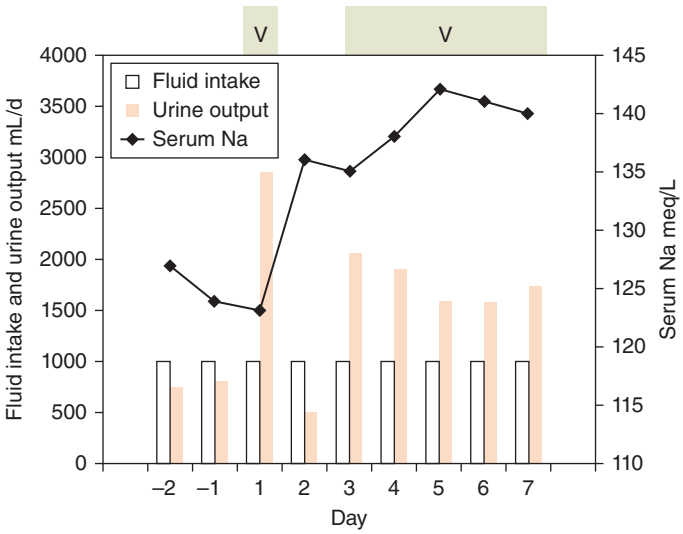

FIGURE 381-7 The effect of vaptan therapy on water balance in a patient with chronic syndrome of inappropriate antidiuretic hormone (SIADH). The periods of vaptan (V) therapy are indicated by the green shaded boxes at the top. Urine output is indicated by orange bars. Fluid intake is shown by the open bars. Intake was restricted to 1 L/d throughout. Serum sodium is indicated by the black line. Note that sodium increased progressively when vaptan increased urine output to levels that clearly exceeded fluid intake.

Hyponatremia, for example, appears to be more common and is more likely to be due to infectious diseases such as cholera, shigellosis, and other diarrheal disorders. In these circumstances, hyponatremia is probably due to gastrointestinal losses of salt and water (hypovolemia type II), but other abnormalities, including undefined infectious toxins, also may contribute. The causes of DI are similar worldwide except that malaria and venoms from snake or insect bites are much more common in some tropical climates.

382 Thyroid Gland Physiology and Testing

J. Larry Jameson, Susan J. Mandel, Anthony P. Weetman

The thyroid gland produces two related hormones, thyroxine (T_4) and triiodothyronine (T_3) **(Fig. 382-1)**. Acting through thyroid hormone receptors (TR) α and β, these hormones play a critical role in cell differentiation and organogenesis during development and help maintain thermogenic and metabolic homeostasis in the adult. Autoimmune disorders of the thyroid gland can stimulate overproduction of thyroid hormones (*thyrotoxicosis*) or cause glandular destruction and hormone deficiency (*hypothyroidism*). Benign nodules and various forms of thyroid cancer are relatively common and amenable to detection by physical examination, ultrasound, and other imaging techniques.

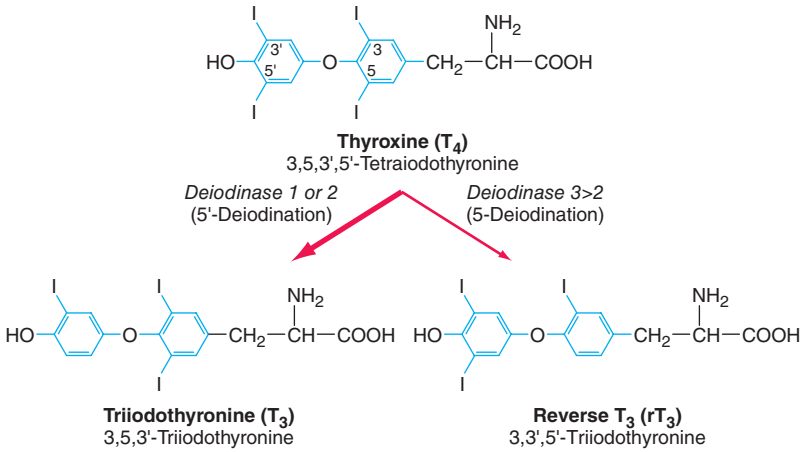

FIGURE 382-1 Structures of thyroid hormones. Thyroxine (T_4) contains four iodine atoms. Deiodination leads to production of the potent hormone triiodothyronine (T_3) or the inactive hormone reverse T_3.

ANATOMY AND DEVELOPMENT

The thyroid (Greek *thyreos*, shield, plus *eidos*, form) consists of two lobes connected by an isthmus. It is located anterior to the trachea between the cricoid cartilage and the suprasternal notch. The normal thyroid is 12–20 g in size, highly vascular, and soft in consistency. Four parathyroid glands, which produce parathyroid hormone **(Chap. 410)**, are located posterior to each pole of the thyroid. The recurrent laryngeal nerves traverse the lateral borders of the thyroid gland and must be identified during thyroid surgery to avoid injury and vocal cord paralysis.

The thyroid gland develops from the floor of the primitive pharynx during the third week of gestation. The developing gland migrates along the thyroglossal duct to reach its final location in the neck. This feature accounts for the rare ectopic location of thyroid tissue at the base of the tongue (lingual thyroid) as well as the occurrence of thyroglossal duct cysts along this developmental tract. Thyroid hormone synthesis begins at about 11 weeks' gestation.

Neural crest derivatives from the ultimobranchial body give rise to thyroid medullary C cells that produce calcitonin, a calcium-lowering hormone. The C cells are interspersed throughout the thyroid gland, although their density is greatest in the juncture of the upper one-third and lower two-thirds of the gland. Calcitonin plays a minimal role in calcium homeostasis in humans, but the C cells are important because of their involvement in medullary thyroid cancer.

Thyroid gland development is orchestrated by the coordinated expression of several developmental transcription factors. Thyroid transcription factor (TTF)-1, TTF-2, NKX2-1, and paired homeobox-8 (PAX-8) are expressed selectively, but not exclusively, in the thyroid gland. In combination, they dictate thyroid cell development and the induction of thyroid-specific genes such as thyroglobulin (Tg), thyroid peroxidase (TPO), the sodium iodide symporter (Na^+/I^-, NIS), and the thyroid-stimulating hormone (TSH) receptor (TSH-R). Mutations in these developmental transcription factors or their downstream target genes are rare causes of thyroid agenesis or dyshormonogenesis, although the causes of most forms of congenital hypothyroidism remain unknown **(see Chap. 383, Table 383-1)**. Because congenital hypothyroidism occurs in ~1 in 4000 newborns, neonatal screening is now performed in most industrialized countries. Transplacental passage of maternal thyroid hormone occurs before the fetal thyroid gland begins to function and provides significant hormone support to a fetus with congenital hypothyroidism. Early thyroid hormone replacement in newborns with congenital hypothyroidism prevents potentially severe developmental abnormalities.

The thyroid gland consists of numerous spherical follicles composed of thyroid follicular cells that surround secreted colloid, a proteinaceous fluid containing large amounts of thyroglobulin, the protein precursor of thyroid hormones **(Fig. 382-2)**. The thyroid follicular cells are polarized—the basolateral surface is apposed to the bloodstream and an apical surface faces the follicular lumen. Increased demand for thyroid hormone is regulated by TSH, which binds to its receptor on the basolateral surface of the follicular cells. This binding leads to Tg reabsorption from the follicular lumen and proteolysis within the cytoplasm, yielding thyroid hormones for secretion into the bloodstream.

REGULATION OF THE THYROID AXIS

TSH, secreted by the thyrotrope cells of the anterior pituitary, plays a pivotal role in control of the thyroid axis and serves as the most useful physiologic marker of thyroid hormone action. TSH is a 31-kDa hormone composed of α and β subunits; the α subunit is common to the other glycoprotein hormones (luteinizing hormone, follicle-stimulating hormone, human chorionic gonadotropin [hCG]), whereas the TSH β subunit is unique to TSH. The extent and nature of carbohydrate modification are modulated by thyrotropin-releasing hormone (TRH) and influence the biologic activity of the hormone.

The thyroid axis is a classic example of an endocrine feedback loop **(Chap. 377)**. Hypothalamic TRH stimulates pituitary production of TSH, which, in turn, stimulates

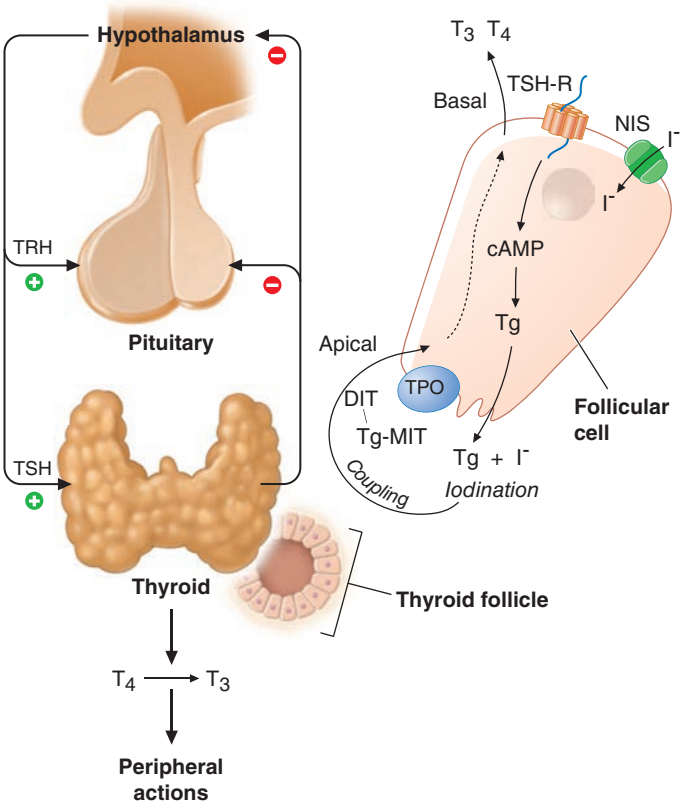

FIGURE 382-2 Regulation of thyroid hormone synthesis. ***Left.*** Thyroid hormones T_4 and T_3 feed back to inhibit hypothalamic production of thyrotropin-releasing hormone (TRH) and pituitary production of thyroid-stimulating hormone (TSH). TSH stimulates thyroid gland production of T_4 and T_3. ***Right.*** Thyroid follicles are formed by thyroid epithelial cells surrounding proteinaceous colloid, which contains thyroglobulin. Follicular cells, which are polarized, synthesize thyroglobulin and carry out thyroid hormone biosynthesis (see text for details). DIT, diiodotyrosine; MIT, monoiodotyrosine; NIS, sodium iodide symporter; Tg, thyroglobulin; TPO, thyroid peroxidase; TSH-R, thyroid-stimulating hormone receptor.

thyroid hormone synthesis and secretion. Thyroid hormones act via negative feedback predominantly through thyroid hormone receptor β2 (TRβ2) to inhibit TRH and TSH production (Fig. 382-2). The "set point" in this axis is established by TSH. TRH is the major positive regulator of TSH synthesis and secretion. Peak TSH secretion occurs ~15 min after administration of exogenous TRH. Dopamine, glucocorticoids, and somatostatin suppress TSH but are not of major physiologic importance except when these agents are administered in pharmacologic doses. Reduced levels of thyroid hormone increase basal TSH production and enhance TRH-mediated stimulation of TSH. High thyroid hormone levels rapidly and directly suppress TSH gene expression and inhibit TRH stimulation of TSH secretion, indicating that thyroid hormones are the dominant regulator of TSH production. Like other pituitary hormones, TSH is released in a pulsatile manner and exhibits a diurnal rhythm; its highest levels occur at night. However, these TSH excursions are modest in comparison to those of other pituitary hormones, in part, because TSH has a relatively long plasma half-life (50 min). Consequently, single measurements of TSH are adequate for assessing its circulating level. TSH is measured using immunoradiometric assays that are highly sensitive and specific. These assays readily distinguish between normal and suppressed TSH values; thus, TSH can be used for the diagnosis of primary hyperthyroidism (low TSH) or primary hypothyroidism (high TSH).

THYROID HORMONE SYNTHESIS, METABOLISM, AND ACTION

THYROID HORMONE SYNTHESIS

Thyroid hormones are derived from Tg, a large iodinated glycoprotein. After secretion into the thyroid follicle, Tg is iodinated on tyrosine residues that are subsequently coupled via an ether linkage. Reuptake of Tg into the thyroid follicular cell allows proteolysis and the release of newly synthesized T_4 and T_3.

Iodine Metabolism and Transport Iodide uptake is a critical first step in thyroid hormone synthesis. Ingested iodine is bound to serum proteins, particularly albumin. Unbound iodine is excreted in the urine. The thyroid gland extracts iodine from the circulation in a highly efficient manner. For example, 10–25% of radioactive tracer (e.g., ^{123}I) is taken up by the normal thyroid gland over 24 h in an iodine-replete state; this value can rise to 70–90% in Graves' disease. Iodide uptake is mediated by NIS, which is expressed at the basolateral membrane of thyroid follicular cells. NIS is most highly expressed in the thyroid gland, but low levels are present in the salivary glands, lactating breast, and placenta. The iodide transport mechanism is highly regulated, allowing adaptation to variations in dietary supply. Low iodine levels increase the amount of NIS and stimulate uptake, whereas high iodine levels suppress NIS expression and uptake. The selective expression of NIS in the thyroid allows isotopic scanning, treatment of hyperthyroidism, and ablation of thyroid cancer with radioisotopes of iodine, without significant effects on other organs. Mutation of the *NIS* gene is a rare cause of congenital hypothyroidism, underscoring its importance in thyroid hormone synthesis. Another iodine transporter, pendrin, is located on the apical surface of thyroid cells and mediates iodine efflux into the lumen. Mutation of the *pendrin* gene causes *Pendred syndrome*, a disorder characterized by defective organification of iodine, goiter, and sensorineural deafness.

Iodine deficiency is prevalent in many mountainous regions and in central Africa, central South America, and northern Asia **(Fig. 382-3)**. Europe remains mildly iodine-deficient, and health surveys indicate that iodine intake has been falling in the United States and Australia. The World Health Organization (WHO) estimates that about 2 billion people are iodine-deficient, based on urinary excretion data. In areas of relative iodine deficiency, there is an increased prevalence of goiter and, when deficiency is severe, hypothyroidism and cretinism. *Cretinism* is characterized by intellectual disability and growth retardation and occurs when children who live in iodine-deficient regions are not treated with iodine or thyroid hormone to restore normal thyroid hormone levels during early life. These children are often born to mothers with iodine deficiency, and it is likely that maternal thyroid hormone deficiency worsens the condition. Concomitant selenium deficiency may also contribute to the neurologic manifestations of cretinism. Iodine supplementation of salt, bread, and other food substances has markedly reduced the prevalence of cretinism. Unfortunately, however, iodine deficiency remains the most common cause of preventable intellectual disability, often because of societal resistance to food additives or the cost of supplementation. In addition to overt cretinism, mild iodine deficiency can lead to subtle reduction of IQ. Oversupply of iodine, through supplements or foods enriched in iodine (e.g., shellfish, kelp), is associated with an increased incidence of autoimmune thyroid disease. The Recommended Dietary Allowance (RDA) is 220 μg iodine per day for pregnant women and 290 μg iodine per day for breastfeeding women. Because the effects of iodine deficiency are most severe in pregnant women and their babies, the American Thyroid Association has recommended that all pregnant and breastfeeding women in the United States and Canada take a prenatal multivitamin containing 150 μg iodine per day. Urinary iodine is >100 μg/L in iodine-sufficient populations.

Organification, Coupling, Storage, and Release After iodide enters the thyroid, it is trapped and transported to the apical membrane of thyroid follicular cells, where it is oxidized in an organification reaction that involves TPO and hydrogen peroxide produced by dual oxidase (DUOX) and DUOX maturation factor (DUOXA). The reactive iodine atom is added to specific tyrosyl residues within Tg, a large (660 kDa) dimeric protein that consists of 2769 amino acids. The iodotyrosines in Tg are then coupled via an ether linkage in a reaction that is also catalyzed by TPO. Either T_4 or T_3 can be produced by this reaction, depending on the number of iodine atoms present in the iodotyrosines. After coupling, Tg is taken back into the thyroid cell,

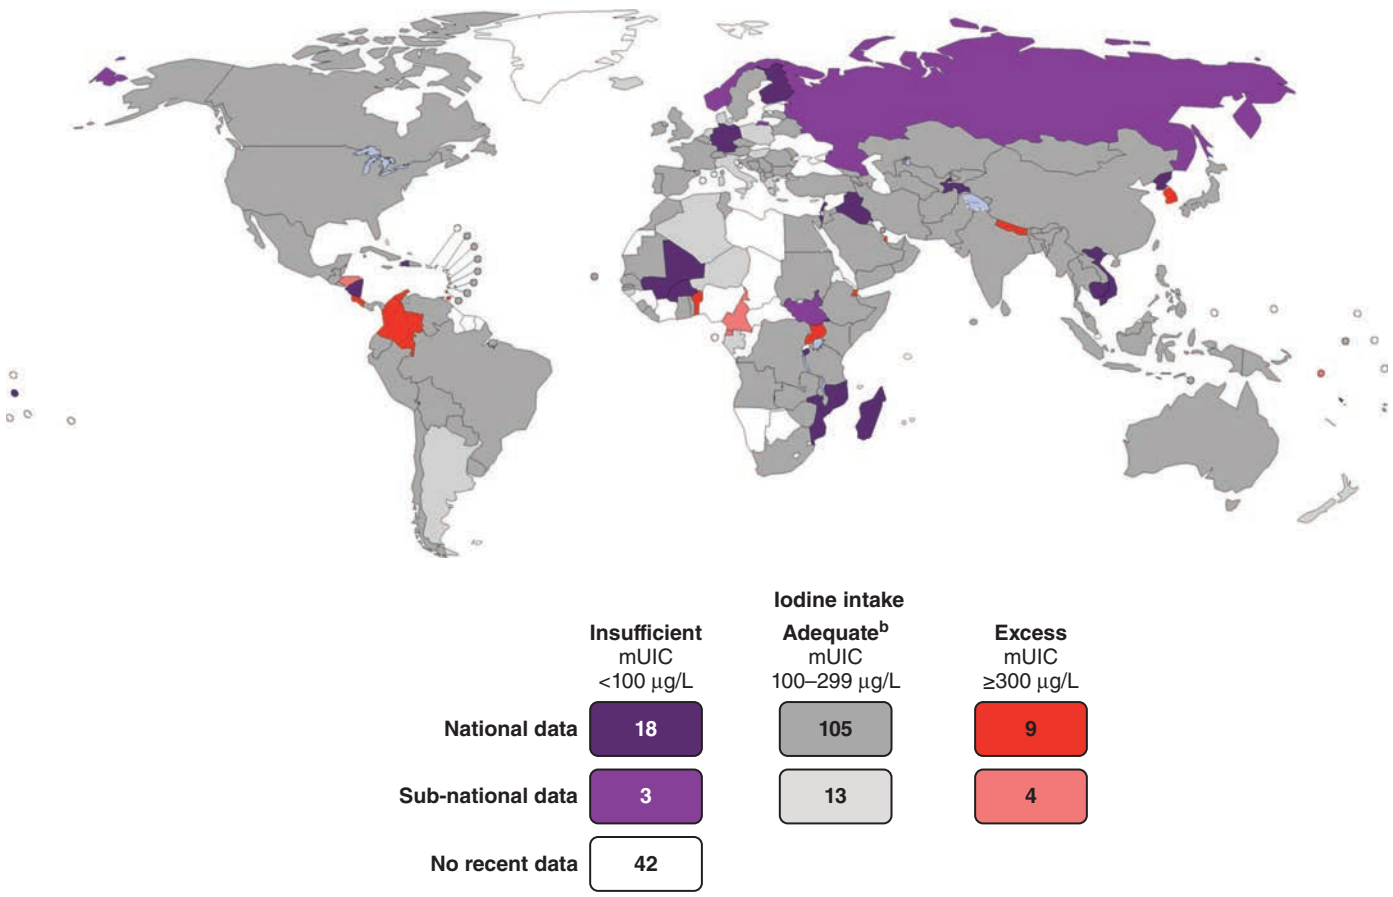

FIGURE 382-3 Worldwide iodine nutrition. [a]In population monitoring of iodine status using urinary iodine concentration (UIC), school-age children (SAC) serve as a proxy for the general population; therefore, preference has been given to studies carried out in SAC. The UIC data have been selected for each country in the following order of priority: data from the most recent known nationally representative survey carried out between 2005 and 2020 in (i) SAC, (ii) SAC and adolescents, (iii) adolescents, (iv) women of reproductive age, (v) other adults (excluding pregnant or lactating women), and (vi) other eligible populations. In the absence of recent national surveys, subnational data were used in the same order of priority. Subnational UIC surveys are commonly carried out to provide a rapid assessment of population iodine status, but due to a lack of sampling rigor, they may over- or underestimate the iodine status at the national level and should be interpreted with caution. [b]Adequate iodine intake in school-age children corresponds to median UIC values in the range 100-299 µg/L, and includes categories previously referred to as "Adequate" (100-199 µg/L) and "More than adequate" (200-299 µg/L). *(Reproduced with permission from The Iodine Global Network. Global scorecard of iodine nutrition in 2021 in the general population based on data in school-age children (SAC). IGN: Ottawa, Canada. 2021.)*

where it is processed in lysosomes to release T_4 and T_3. Uncoupled mono- and diiodotyrosines (MIT, DIT) can be deiodinated by the enzyme dehalogenase, thereby recycling any iodide that is not converted into thyroid hormones.

Disorders of thyroid hormone synthesis are rare causes of congenital hypothyroidism (Chap. 383). The vast majority of these disorders are due to recessive mutations in TPO or Tg, but defects have also been identified in the TSH-R, NIS, pendrin, hydrogen peroxide generation, and dehalogenase, as well as genes involved in thyroid gland development. In the case of biosynthetic defects, the gland is incapable of synthesizing adequate amounts of hormone, leading to increased TSH and a large goiter.

TSH Action TSH regulates thyroid gland function through the TSH-R, a seven-transmembrane G protein–coupled receptor (GPCR). The TSH-R is coupled to the α subunit of stimulatory G protein ($G_s\alpha$), which activates adenylyl cyclase, leading to increased production of cyclic adenosine monophosphate (cAMP). TSH also stimulates phosphatidylinositol turnover by activating phospholipase C. Recessive loss-of-function TSH-R mutations cause thyroid hypoplasia and congenital hypothyroidism. Dominant gain-of-function mutations cause sporadic or familial hyperthyroidism that is characterized by goiter, thyroid cell hyperplasia, and autonomous function (Chap. 384). Most of these activating mutations occur in the transmembrane domain of the receptor. They mimic the conformational changes induced by TSH binding or the interactions of thyroid-stimulating immunoglobulins (TSIs) in Graves' disease. Activating TSH-R mutations also occur as somatic events, leading to clonal selection and expansion of the affected thyroid follicular cell and autonomously functioning thyroid nodules.

Other Factors That Influence Hormone Synthesis and Release Although TSH is the dominant hormonal regulator of thyroid gland growth and function, a variety of growth factors, most produced locally in the thyroid gland, also influence thyroid hormone synthesis. These include insulin-like growth factor 1 (IGF-1), epidermal growth factor, transforming growth factor β (TGF-β), endothelins, and various cytokines. The quantitative roles of these factors are not well understood, but they are important in selected disease states. In acromegaly, for example, increased levels of growth hormone and IGF-1 are associated with goiter and predisposition to multinodular goiter (MNG). Certain cytokines and interleukins (ILs) produced in association with autoimmune thyroid disease induce thyroid growth, whereas others lead to apoptosis. Iodine deficiency increases thyroid blood flow and upregulates the NIS, stimulating more efficient iodine uptake. Excess iodide transiently inhibits thyroid iodide organification, a phenomenon known as the *Wolff-Chaikoff effect*. In individuals with a normal thyroid, the gland escapes from this inhibitory effect and iodide organification resumes; the suppressive action of high iodide

may persist, however, in patients with underlying autoimmune thyroid disease.

THYROID FUNCTION IN PREGNANCY

Five factors alter thyroid function in pregnancy: (1) the transient increase in hCG during the first trimester, which weakly stimulates the TSH-R; (2) the estrogen-induced rise in TBG during the first trimester, which is sustained during pregnancy; (3) alterations in the immune system, leading to the onset, exacerbation, or amelioration of an underlying autoimmune thyroid disease; (4) increased thyroid hormone metabolism by the placental type III deiodinase; and (5) increased urinary iodide excretion, which can cause impaired thyroid hormone production in areas of marginal iodine sufficiency. Women with a precarious iodine intake (<50 μg/d) are most at risk of developing a goiter during pregnancy or giving birth to an infant with a goiter and hypothyroidism. The World Health Organization recommends a daily iodine intake of 250 μg during pregnancy and lactation, and prenatal vitamins should contain 150 μg per tablet.

The rise in circulating hCG levels during the first trimester is accompanied by a reciprocal fall in TSH that persists into the middle of pregnancy. This reflects the weak binding of hCG, which is present at very high levels, to the TSH-R. Rare individuals have variant TSH-R sequences that enhance hCG binding and TSH-R activation. hCG-induced changes in thyroid function can result in transient gestational hyperthyroidism that may be associated with *hyperemesis gravidarum*, a condition characterized by severe nausea and vomiting and risk of volume depletion. However, since the hyperthyroidism is not causal, antithyroid drugs are not indicated unless concomitant Graves' disease is suspected. Parenteral fluid replacement usually suffices until the condition resolves.

Normative values for most thyroid function tests differ during pregnancy and, if available, trimester-specific reference ranges should be used when diagnosing thyroid dysfunction during pregnancy. TSH levels decrease at the end of the first trimester and then rise as gestation progresses so that the nonpregnant reference ranges can be used from mid-gestation to delivery. Total T_4 and T_3 levels are ~1.5× higher throughout pregnancy, but the free T_4, which is the same or slightly higher at the end of the 1st trimester, then progressively decreases so that third-trimester values in healthy pregnancies are often below the nonpregnant lower reference cutoff.

During pregnancy, subclinical hypothyroidism occurs in 2% of women, but overt hypothyroidism is present in only 1 in 500. Prospective randomized controlled trials have not shown a benefit for universal thyroid disease screening in pregnancy. Targeted TSH testing for hypothyroidism is recommended for women planning a pregnancy if they have a strong family history of autoimmune thyroid disease, other autoimmune disorders (e.g., type 1 diabetes), infertility, prior preterm delivery or recurrent miscarriage, or signs or symptoms of thyroid disease, or are older than 30 years. Thyroid hormone requirements are increased by up to 45% during pregnancy in levothyroxine-treated hypothyroid women.

THYROID HORMONE TRANSPORT AND METABOLISM

Serum-Binding Proteins T_4 is secreted from the thyroid gland in about twentyfold excess over T_3 **(Table 382-1)**. Both hormones are bound to plasma proteins, including thyroxine-binding globulin (TBG), transthyretin (TTR, formerly known as thyroxine-binding prealbumin [TBPA]), and albumin. The plasma-binding proteins increase the pool of circulating hormone, delay hormone clearance, and may modulate hormone delivery to selected tissue sites. The concentration of TBG is relatively low (1–2 mg/dL), but because of its high affinity for thyroid hormones ($T_4 > T_3$), it carries ~80% of the bound hormones. Albumin has relatively low affinity for thyroid hormones but has a high plasma concentration (~3.5 g/dL), and it binds up to 10% of T_4 and 30% of T_3. TTR carries ~10% of T_4 but little T_3.

When the effects of the various binding proteins are combined, ~99.98% of T_4 and 99.7% of T_3 are protein-bound. Because T_3 is less tightly bound than T_4, the fraction of unbound T_3 is greater than unbound T_4, but there is less unbound T_3 in the circulation because it is produced in smaller amounts and cleared more rapidly than T_4. The unbound or "free" concentrations of the hormones are ~2×10^{-11} *M* for T_4 and ~6×10^{-12} *M* for T_3, which roughly correspond to the thyroid hormone receptor–binding constants for these hormones (see below). The unbound hormone is thought to be biologically available to tissues. The homeostatic mechanisms that regulate the thyroid axis are directed toward maintenance of normal concentrations of unbound hormones.

TABLE 382-1 Characteristics of Circulating T_4 and T_3

HORMONE PROPERTY	T_4	T_3
Serum concentrations		
Total hormone	8 μg/dL	0.14 μg/dL
Fraction of total hormone in the unbound form	0.02%	0.3%
Unbound (free) hormone	21×10^{-12} *M*	6×10^{-12} *M*
Serum half-life	7 d	2 d
Fraction directly from the thyroid	100%	20%
Production rate, including peripheral conversion	90 μg/d	32 μg/d
Intracellular hormone fraction	~20%	~70%
Relative metabolic potency	0.3	1
Receptor binding	10^{-10} *M*	10^{-11} *M*

Abnormalities of Thyroid Hormone–Binding Proteins A number of inherited and acquired abnormalities affect thyroid hormone–binding proteins. X-linked TBG deficiency is associated with very low levels of total T_4 and T_3. However, because unbound hormone levels are normal, patients are euthyroid and TSH levels are normal. It is important to recognize this disorder to avoid efforts to normalize total T_4 levels, because this leads to thyrotoxicosis and is futile because of rapid hormone clearance in the absence of TBG. TBG levels are elevated by estrogen, which increases sialylation and delays TBG clearance. Consequently, in women who are pregnant or taking estrogen-containing contraceptives, elevated TBG increases total T_4 and T_3 levels; however, unbound T_4 and T_3 levels are normal. These features are part of the explanation for why women with hypothyroidism require increased amounts of L-thyroxine replacement as TBG levels are increased by pregnancy or estrogen treatment. Mutations in TBG, TTR, and albumin may increase the binding affinity for T_4 and/or T_3 and cause disorders known as *euthyroid hyperthyroxinemia* or *familial dysalbuminemic hyperthyroxinemia* (FDH) **(Table 382-2)**. These disorders result in increased total T_4 and/or T_3, but unbound hormone levels are normal. The familial nature of the disorders, and the fact that TSH levels are normal rather than suppressed, should suggest this diagnosis. Unbound hormone levels (ideally measured by dialysis) are normal in FDH. The diagnosis can be confirmed by using tests that measure the affinities of radiolabeled hormone binding to specific transport proteins or by performing DNA sequence analyses of the abnormal transport protein genes.

Certain medications, such as salicylates and salsalate, can displace thyroid hormones from circulating binding proteins. Although these drugs transiently perturb the thyroid axis by increasing free thyroid hormone levels, TSH is suppressed until a new steady state is reached, thereby restoring euthyroidism. Circulating factors associated with acute illness may also displace thyroid hormone from binding proteins **(Chap. 384)**.

Deiodinases T_4 may be thought of as a precursor for the more potent T_3. T_4 is converted to T_3 by the deiodinase enzymes (Fig. 382-1). Type I deiodinase, which is located primarily in thyroid, liver, and kidneys, has a relatively low affinity for T_4. Type II deiodinase has a higher affinity for T_4 and is found primarily in the pituitary gland, brain, brown fat, and thyroid gland. Expression of type II deiodinase allows it to regulate T_3 concentrations locally, a property that may be important in the context of levothyroxine (T_4) replacement. Type II deiodinase

TABLE 382-2 Conditions Associated with Euthyroid Hyperthyroxinemia

DISORDER	CAUSE	TRANSMISSION	CHARACTERISTICS
Familial dysalbuminemic hyperthyroxinemia (FDH)	Albumin mutations, usually R218H	AD	Increased T_4 Normal unbound T_4 Rarely increased T_3
TBG			
Familial excess	Increased TBG production	XL	Increased total T_4, T_3 Normal unbound T_4, T_3
Acquired excess	Medications (estrogen), pregnancy, cirrhosis, hepatitis	Acquired	Increased total T_4, T_3 Normal unbound T_4, T_3
Transthyretin[a]			
Excess	Islet tumors	Acquired	Usually normal T_4, T_3
Mutations	Increased affinity for T_4 or T_3	AD	Increased total T_4, T_3 Normal unbound T_4, T_3
Medications: propranolol, ipodate, iopanoic acid, amiodarone	Decreased $T_4 \rightarrow T_3$ conversion	Acquired	Increased T_4 Decreased T_3 Normal or increased TSH
Resistance to thyroid hormone (RTH)	Thyroid hormone receptor β mutations	AD	Increased unbound T_4, T_3 Normal or increased TSH Some patients clinically thyrotoxic

[a]Also known as thyroxine-binding prealbumin (TBPA).

Abbreviations: AD, autosomal dominant; TBG, thyroxine-binding globulin; TSH, thyroid-stimulating hormone; XL, X-linked.

is also regulated by thyroid hormone; hypothyroidism induces the enzyme, resulting in enhanced $T_4 \rightarrow T_3$ conversion in tissues such as brain and pituitary. $T_4 \rightarrow T_3$ conversion is impaired by fasting, systemic illness or acute trauma, oral contrast agents, and a variety of medications (e.g., propylthiouracil, propranolol, amiodarone, glucocorticoids). Type III deiodinase inactivates T_4 and T_3 and is the most important source of reverse T_3 (rT_3), including in the sick euthyroid syndrome. This enzyme is expressed in the human placenta but is not active in healthy individuals. In the sick euthyroid syndrome, especially with hypoperfusion, the type III deiodinase is activated in muscle and liver. Massive hemangiomas and other tumors that express type III deiodinase are a rare cause of consumptive hypothyroidism.

THYROID HORMONE ACTION

Thyroid Hormone Transport Circulating thyroid hormones enter cells by passive diffusion and via specific transporters such as the monocarboxylate 8 transporter (MCT8), MCT10, and organic anion-transporting polypeptide 1C1. Mutations in the *MCT8* gene have been identified in patients with X-linked psychomotor retardation and thyroid function abnormalities (low T_4, high T_3, and high TSH). After entering cells, thyroid hormones act primarily through nuclear receptors, although they also have nongenomic actions through stimulating mitochondrial enzymatic responses and may act directly on blood vessels and the heart through integrin receptors.

Nuclear Thyroid Hormone Receptors Thyroid hormones bind with high affinity to nuclear TRs α and β. Both TRα and TRβ are expressed in most tissues, but their relative expression levels vary among organs; TRα is particularly abundant in brain, kidneys, gonads, muscle, and heart, whereas TRβ expression is relatively high in the pituitary and liver. Both receptors are variably spliced to form unique isoforms. The TRβ2 isoform, which has a unique amino terminus, is selectively expressed in the hypothalamus and pituitary, where it plays a role in feedback control of the thyroid axis (see above). The TRα2 isoform contains a unique carboxy terminus that precludes thyroid hormone binding; it may function to inhibit the action of other TR isoforms.

The TRs contain a central DNA-binding domain and a C-terminal ligand-binding domain. They bind to specific DNA sequences, termed *thyroid response elements* (TREs), in target genes (Fig. 382-4). The receptors bind as homodimers or, more commonly, as heterodimers with retinoic acid X receptors (RXRs) (Chap. 377). The activated receptor can either stimulate gene transcription (e.g., myosin heavy chain α) or inhibit transcription (e.g., TSH β-subunit gene), depending on the nature of the regulatory elements in the target gene.

Thyroid hormones (T_3 and T_4) bind with similar affinities to TRα and TRβ. However, structural differences in the ligand-binding domains provide the potential for developing receptor-selective agonists or antagonists, and these are under investigation. T_3 is bound with 10–15 times greater affinity than T_4, which explains its increased potency. Although T_4 is produced in excess of T_3, receptors are occupied mainly by T_3, reflecting $T_4 \rightarrow T_3$ conversion by peripheral tissues, T_3 bioavailability in the plasma, and the greater affinity of receptors for T_3. After binding to TRs, thyroid hormone induces conformational changes in the receptors that modify its interactions with accessory transcription factors. Importantly, in the absence of thyroid hormone binding, the aporeceptors bind to co-repressor proteins that inhibit gene transcription. Hormone binding dissociates the co-repressors and allows the recruitment of co-activators that enhance transcription. The discovery of TR interactions with co-repressors explains the fact that TR silences gene expression in the absence of hormone binding. Consequently, hormone deficiency has a profound effect on gene expression because it causes gene repression as well as loss of hormone-induced stimulation. This concept has been corroborated by the finding that targeted deletion of the TR genes in mice has a less pronounced phenotypic effect than hormone deficiency.

Thyroid Hormone Resistance Resistance to thyroid hormone (RTH) is an autosomal dominant disorder characterized by elevated thyroid hormone levels and inappropriately normal or elevated TSH.

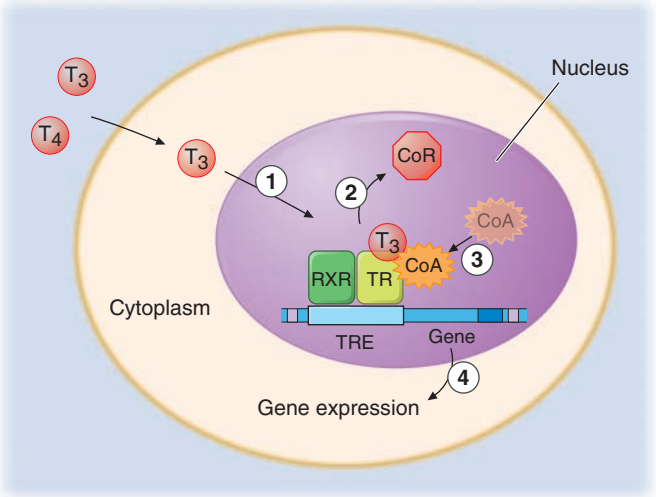

FIGURE 382-4 Mechanism of thyroid hormone receptor action. The thyroid hormone receptor (TR) and retinoid X receptor (RXR) form heterodimers that bind specifically to thyroid hormone response elements (TRE) in the promoter regions of target genes. In the absence of hormone, TR binds co-repressor (CoR) proteins that silence gene expression. The numbers refer to a series of ordered reactions that occur in response to thyroid hormone: (1) T_4 or T_3 enters the nucleus; (2) T_3 binding dissociates CoR from TR; (3) co-activators (CoA) are recruited to the T_3-bound receptor; and (4) gene expression is altered.

Individuals with RTH do not, in general, exhibit signs and symptoms that are typical of hypothyroidism because hormone resistance is partial and is compensated by increased levels of thyroid hormone. The clinical features of RTH can include goiter, attention deficit disorder, mild reduction in IQ, delayed skeletal maturation, tachycardia, and impaired metabolic responses to thyroid hormone.

Classical forms of RTH are caused by mutations in the TRβ gene. These mutations, located in restricted regions of the ligand-binding domain, cause loss of receptor function. However, because the mutant receptors retain the capacity to dimerize with RXRs, bind to DNA, and recruit co-repressor proteins, they function as antagonists of the remaining normal TRβ and TRα receptors. This property, referred to as "dominant negative" activity, explains the autosomal dominant mode of transmission. The diagnosis is suspected when unbound thyroid hormone levels are increased without suppression of TSH. Similar hormonal abnormalities are found in other affected family members, although the TRβ mutation arises de novo in ~20% of patients. DNA sequence analysis of the TRβ gene provides a definitive diagnosis. RTH must be distinguished from other causes of euthyroid hyperthyroxinemia (e.g., FDH) and inappropriate secretion of TSH by TSH-secreting pituitary adenomas **(Chap. 380)**. In most patients, no treatment is indicated; the importance of making the diagnosis is to avoid inappropriate treatment of mistaken hyperthyroidism and to provide genetic counseling.

A distinct form of RTH is caused by mutations in the TRα gene. Affected patients have many clinical features of congenital hypothyroidism including growth retardation, skeletal dysplasia, and severe constipation. In contrast to RTH caused by mutations in TRβ, thyroid function tests include normal TSH, low or normal T_4, and normal or elevated T_3 levels. These distinct clinical and laboratory features underscore the different tissue distribution and functional roles of TRβ and TRα. Thyroxine treatment appears to alleviate some of the clinical manifestations of patients with RTH caused by TRα mutations.

PHYSICAL EXAMINATION

In addition to the examination of the thyroid itself, the physical examination should include a search for signs of abnormal thyroid function and the extrathyroidal features of ophthalmopathy and dermopathy **(Chap. 384)**. Examination of the neck begins by inspecting the seated patient from the front and side and noting any surgical scars, obvious masses, or distended veins. The thyroid can be palpated with both hands from behind or while facing the patient, using the thumbs to palpate each lobe. It is best to use a combination of these methods, especially when nodules are small. The patient's neck should be slightly flexed to relax the neck muscles. After locating the cricoid cartilage, the isthmus, which is attached to the lower one-third of the thyroid lobes, can be identified and then followed laterally to locate either lobe (normally, the right lobe is slightly larger than the left). By asking the patient to swallow sips of water, thyroid consistency can be better appreciated as the gland moves beneath the examiner's fingers.

Features to be noted include thyroid size, consistency, nodularity, and any tenderness or fixation. An estimate of thyroid size (normally 12–20 g) should be made, and a drawing is often the best way to record findings. Ultrasound imaging provides the most accurate measurement of thyroid volume and nodularity and is useful for assessment of goiter prevalence in iodine-deficient regions. However, ultrasound is not indicated if the thyroid physical examination is normal. The size, location, and consistency of any nodules should also be defined. A bruit or thrill over the gland, located over the insertion of the superior and inferior thyroid arteries (supero- or inferolaterally), indicates increased vascularity, associated with turbulent rather than laminar blood flow, as occurs in hyperthyroidism. If the lower borders of the thyroid lobes are not clearly felt, a goiter may be retrosternal. Large retrosternal goiters can cause venous distention over the neck and difficulty breathing, especially when the arms are raised (Pemberton's sign). With any central mass above the thyroid, the tongue should be extended, as thyroglossal cysts then move upward. The thyroid examination is not complete without assessment for lymphadenopathy in the supraclavicular and cervical regions of the neck.

LABORATORY EVALUATION

Measurement of Thyroid Hormones The enhanced sensitivity and specificity of *TSH assays* have greatly improved laboratory assessment of thyroid function. Because TSH levels change dynamically in response to alterations of T_4 and T_3, a logical approach to thyroid testing is to first determine whether TSH is suppressed, normal, or elevated. With rare exceptions (see below), a normal TSH level excludes a primary abnormality of thyroid function. This strategy depends on the use of immunochemiluminometric assays (ICMAs) for TSH that are sensitive enough to discriminate between the lower limit of the reference interval and the suppressed values that occur with thyrotoxicosis. Extremely sensitive assays can detect TSH levels ≤0.004 mIU/L, but, for practical purposes, assays sensitive to ≤0.1 mIU/L are sufficient. The widespread availability of the TSH ICMA has rendered the TRH stimulation test obsolete, because the failure of TSH to rise after an intravenous bolus of 200–400 μg TRH has the same implications as a suppressed basal TSH measured by ICMA. Because the antibodies used in the ICMA are biotinylated, biotin supplements, including biotin in multivitamins, can interfere with TSH measurement, resulting in falsely low TSH values and falsely high T_4 or T_3 levels. Therefore, patients should be advised to stop taking biotin for at least 2 days prior to thyroid function testing.

The finding of an abnormal TSH level must be followed by measurements of circulating thyroid hormone levels to confirm the diagnosis of hyperthyroidism (suppressed TSH) or hypothyroidism (elevated TSH). Automated immunoassays are widely available for serum *total* T_4 and *total* T_3. T_4 and T_3 are highly protein-bound, and numerous factors (illness, medications, genetic factors) can influence protein binding. It is useful, therefore, to measure the free, or unbound, hormone levels, which correspond to the biologically available hormone pool. Two direct methods are used to measure *unbound thyroid hormones*: (1) unbound thyroid hormone competition with radiolabeled T_4 (or an analogue) for binding to a solid-phase antibody, and (2) physical separation of the unbound hormone fraction by ultracentrifugation or equilibrium dialysis. Although early unbound hormone immunoassays suffered from artifacts, newer assays correlate well with the results of the more technically demanding and expensive physical separation methods. An indirect method that is now less commonly used to estimate unbound thyroid hormone levels is to calculate the free T_3 or free T_4 index from the total T_4 or T_3 concentration and the *thyroid hormone binding ratio* (THBR). The latter is derived from the *T_3-resin uptake test*, which determines the distribution of radiolabeled T_3 between an absorbent resin and the unoccupied thyroid hormone–binding proteins in the sample. The binding of the labeled T_3 to the resin is increased when there is reduced unoccupied protein binding sites (e.g., TBG deficiency) or increased total thyroid hormone in the sample; it is decreased under the opposite circumstances. The product of THBR and total T_3 or T_4 provides the *free T_3 or T_4 index*. In effect, the index corrects for anomalous total hormone values caused by variations in hormone-protein binding.

Total thyroid hormone levels are *elevated* when TBG is increased due to estrogens (pregnancy, oral contraceptives, hormone therapy, tamoxifen, selective estrogen receptor modulators, inflammatory liver disease) and *decreased* when TBG binding is reduced (androgens, nephrotic syndrome). Genetic disorders and acute illness can also cause abnormalities in thyroid hormone–binding proteins, and various drugs (phenytoin, carbamazepine, salicylates, and nonsteroidal anti-inflammatory drugs [NSAIDs]) can interfere with thyroid hormone binding. Because unbound thyroid hormone levels are normal and the patient is euthyroid in all of these circumstances, assays that measure unbound hormone are preferable to those for total thyroid hormones.

For most purposes, the unbound T_4 level is sufficient to confirm thyrotoxicosis, but 2–5% of patients have only an elevated T_3 level (T_3 toxicosis). Thus, unbound T_3 levels should be measured in patients with a suppressed TSH but normal unbound T_4 levels.

There are several clinical conditions in which the use of TSH as a screening test may be misleading, particularly without simultaneous unbound T_4 determinations. Any severe nonthyroidal illness can cause abnormal TSH levels. Although hypothyroidism is the most common cause of an elevated TSH level, rare causes include a TSH-secreting

pituitary tumor (Chap. 380), thyroid hormone resistance, and assay artifact. Conversely, a suppressed TSH level, particularly <0.01 mIU/L, usually indicates thyrotoxicosis. However, subnormal TSH levels between 0.01 and 0.1 mIU/L may be seen during the first trimester of pregnancy (due to hCG secretion), after treatment of hyperthyroidism (because TSH can remain suppressed for several months), and in response to certain medications (e.g., high doses of glucocorticoids or dopamine). TSH levels measured by immunoassay may also be suppressed in patients ingesting biotin supplements <18 h prior to a blood draw because the TSH capture antibodies are biotinylated and the exogenous biotin can interfere with the subsequent streptavidin capture. Importantly, secondary hypothyroidism, caused by hypothalamic-pituitary disease, is associated with a variable (low to high-normal) TSH level, which is inappropriate for the low T_4 level. Thus, *TSH should not be used as an isolated laboratory test to assess thyroid function in patients with suspected or known hypothalamic or pituitary disease.*

Tests for the end-organ effects of thyroid hormone excess or depletion, such as estimation of basal metabolic rate, tendon reflex relaxation rates, or serum cholesterol, are relatively insensitive and are not useful as clinical determinants of thyroid function.

Tests to Determine the Etiology of Thyroid Dysfunction Autoimmune thyroid disease is detected most easily by measuring circulating antibodies against TPO and Tg. Because antibodies to Tg alone are less common, it is reasonable to measure only TPO antibodies. About 5–15% of euthyroid women and up to 2% of euthyroid men have thyroid antibodies; such individuals are at increased risk of developing thyroid dysfunction. Almost all patients with autoimmune hypothyroidism, and up to 80% of those with Graves' disease, have TPO antibodies, usually at high levels.

TSIs are antibodies that stimulate the TSH-R in Graves' disease. They are most commonly measured by commercially available tracer displacement assays called TRAb (TSH receptor antibody) with the assumption that elevated levels in the setting of clinical hyperthyroidism reflect stimulatory effects on the TSH receptor. A bioassay is less commonly used. Remission rates in patients with Graves' disease after antithyroid drug cessation are higher with disappearance rather than persistence of TRAb. Furthermore, the TRAb assay is used to predict both fetal and neonatal thyrotoxicosis caused by transplacental passage of high maternal levels of TRAb or TSI (>3× upper limit of normal) in the last trimester of pregnancy.

Serum Tg levels are increased in all types of thyrotoxicosis except *thyrotoxicosis factitia* caused by self-administration of thyroid hormone. Tg levels are particularly increased in thyroiditis, reflecting thyroid tissue destruction and release of Tg. The main role for Tg measurement, however, is in the follow-up of thyroid cancer patients. After total thyroidectomy and radioablation, Tg levels should be <0.2 ng/mL in the absence of anti-Tg antibodies; measurable levels indicate incomplete ablation or recurrent cancer.

Radioiodine Uptake and Thyroid Scanning The thyroid gland selectively transports radioisotopes of iodine (^{123}I, ^{125}I, ^{131}I) and ^{99m}Tc pertechnetate, allowing thyroid imaging and quantitation of radioactive tracer fractional uptake.

Nuclear imaging of Graves' disease is characterized by an enlarged gland and increased tracer uptake that is distributed homogeneously. Toxic adenomas appear as focal areas of increased uptake, with suppressed tracer uptake in the remainder of the gland (reflecting suppressed TSH). In toxic MNG, the gland is enlarged—often with distorted architecture—and there are multiple areas of relatively increased (functioning nodules) or decreased tracer uptake (suppressed thyroid parenchyma or nonfunctioning nodules). Subacute, viral, and postpartum thyroiditis are associated with very low uptake because of follicular cell damage and TSH suppression. Thyrotoxicosis factitia is also associated with low uptake because exogenous hormone suppresses TSH. In addition, if there is excessive circulating exogenous iodine (e.g., from dietary sources of iodinated contrast dye), the radionuclide uptake is low even in the presence of increased thyroid hormone production.

Thyroid scintigraphy is not used in the routine evaluation of patients with thyroid nodules but should be performed if the serum TSH level is subnormal to determine if functioning thyroid nodules are present. Functioning or "hot" nodules are almost never malignant, and fine-needle aspiration (FNA) biopsy is not indicated. The vast majority of thyroid nodules do not produce thyroid hormone ("cold" nodules), and these are more likely to be malignant (~5–10%). Whole-body and thyroid scanning is also used in the treatment and, now less frequently, in the surveillance of thyroid cancer. After thyroidectomy for thyroid cancer, the TSH level is raised by either using a thyroid hormone withdrawal protocol or recombinant human TSH injection (Chap. 385). Administration of either ^{131}I or ^{123}I (in higher activities than used to image the thyroid gland alone) allows whole-body scanning (WBS) to detect the thyroid remnant. WBS imaging is also performed after therapeutic administration of ^{131}I, which confirms remnant ablation and may reveal iodine-avid metastases.

Thyroid Ultrasound Ultrasonography is the most valuable tool for the diagnosis and evaluation of patients with nodular thyroid disease (Chap. 385). Evidence-based guidelines recommend thyroid ultrasonography for all patients suspected of having thyroid nodules by either physical examination or another imaging study. Using 10- to 12-MHz linear transducers, resolution and image quality are excellent, allowing the characterization of nodules and cysts >3 mm. Sonographic patterns that combine suspicious sonographic features are highly suggestive of malignancy (e.g., hypoechoic solid nodules with infiltrative borders and microcalcifications, >90% cancer risk), whereas other patterns correlate with a lower likelihood of cancer (isoechoic solid nodules, 5–10% cancer risk). Some patterns suggest benignity (e.g., spongiform nodules, defined as those with multiple small internal cystic areas, or simple cysts, <3% cancer risk) (see Chap. 385, Fig. 385-2). These patterns have been incorporated into validated risk stratification systems (RSSs) for sonographic imaging of thyroid nodules (American College of Radiology [ACR] Thyroid Imaging Reporting and Data System [TI-RADS], American Thyroid Association, European Thyroid Association [EU-TIRADS] and others) (see Chap. 385, Fig. 385-1). These systems are relatively concordant in the classification of thyroid nodules; they differ in size cutoff recommendations for FNA. Not surprisingly, the RSSs with lower size cutoffs have higher sensitivity and lower specificity for thyroid cancer diagnosis than those with higher cutoffs. Nevertheless, all have been shown to reduce unnecessary FNAs by at least 45%, in part due to the recommendation not to perform FNA of spongiform nodules.

In addition to evaluating thyroid nodules, ultrasound is useful for monitoring nodule size and for the aspiration of nodules or cystic lesions. Ultrasound-guided FNA biopsy of thyroid lesions lowers the rate of inadequate sampling and decreases sample error, thereby reducing both the nondiagnostic and false-negative rates of FNA cytology. Ultrasonography of the central and lateral cervical lymph node compartments is indispensable in the evaluation of thyroid cancer patients, preoperatively and during follow-up. In addition, the ACR recommends a survey of the cervical lymph nodes as part of every diagnostic thyroid sonographic examination.

383 Hypothyroidism

J. Larry Jameson, Susan J. Mandel, Anthony P. Weetman

HYPOTHYROIDISM

Iodine deficiency remains a common cause of hypothyroidism worldwide. In areas of iodine sufficiency, autoimmune disease (Hashimoto's thyroiditis) and iatrogenic causes (treatment of hyperthyroidism) are most common (Table 383-1).

CONGENITAL HYPOTHYROIDISM

Prevalence Hypothyroidism occurs in about 1 in 2000–4000 newborns, and neonatal screening is performed in most industrialized countries. It may be transient, especially if the mother has thyroid-stimulating hormone (TSH) receptor (TSH-R)–blocking antibodies or has received antithyroid drugs, but permanent hypothyroidism occurs in the majority. The causes of neonatal hypothyroidism include thyroid gland dysgenesis in 65%, inborn errors of thyroid hormone synthesis in 30%, and TSH-R antibody mediated in 5% of affected newborns. The developmental abnormalities are twice as common in girls. Mutations that cause congenital hypothyroidism are being increasingly identified, but most remain idiopathic. These can be broadly categorized as mutations causing (1) central hypothyroidism because of abnormal hypothalamic-pituitary development or the loss of specific components of the thyrotropin-releasing hormone (TRH)/TSH hormonal pathways; (2) abnormal thyroid gland development or dysgenesis; or (3) abnormal thyroid hormone synthesis and processing, or dyshormonogenesis (Table 383-2). Transplacental passage of maternal thyroid hormone occurs before the fetal thyroid gland begins to function and provides partial hormone support to a fetus with congenital hypothyroidism.

TABLE 383-1 Causes of Hypothyroidism

Primary
Autoimmune hypothyroidism: Hashimoto's thyroiditis, atrophic thyroiditis
Iatrogenic: ^{131}I treatment, subtotal or total thyroidectomy, external irradiation of neck for lymphoma or cancer
Drugs: iodine excess (including iodine-containing contrast media), amiodarone, lithium, antithyroid drugs, *p*-aminosalicylic acid, interferon α and other cytokines, aminoglutethimide, tyrosine kinase inhibitors (e.g., sunitinib), immune checkpoint inhibitors (e.g., ipilimumab, nivolumab, pembrolizumab)
Congenital hypothyroidism: absent or ectopic thyroid gland, dyshormonogenesis, TSH-R mutation
Iodine deficiency
Infiltrative disorders: amyloidosis, sarcoidosis, hemochromatosis, scleroderma, cystinosis, Riedel's thyroiditis
Overexpression of type 3 deiodinase in infantile hemangioma and other tumors
Transient
Silent thyroiditis, including postpartum thyroiditis
Subacute thyroiditis
Withdrawal of supraphysiologic thyroxine treatment in individuals with an intact thyroid
After ^{131}I treatment or subtotal thyroidectomy for Graves' disease
Secondary
Hypopituitarism: tumors, pituitary surgery or irradiation, infiltrative disorders, Sheehan's syndrome, trauma, genetic forms of combined pituitary hormone deficiencies
Isolated TSH deficiency or inactivity
Bexarotene treatment
Hypothalamic disease: tumors, trauma, infiltrative disorders, idiopathic

Abbreviations: TSH, thyroid-stimulating hormone; TSH-R, TSH receptor.

Clinical Manifestations The majority of infants appear normal at birth, and with the use of biochemical screening, few cases are now diagnosed based on clinical features, which include prolonged jaundice, feeding problems, hypotonia, enlarged tongue, delayed bone maturation, and umbilical hernia. Importantly, permanent neurologic damage results if treatment is delayed. Typical features of adult hypothyroidism may also be present (Table 383-3). Other congenital malformations, especially cardiac, are four times more common in congenital hypothyroidism.

Diagnosis and Treatment Because of the severe neurologic consequences of untreated congenital hypothyroidism, neonatal screening programs have been established. These are generally based on measurement of TSH or T_4 levels in heel-prick blood specimens. When the diagnosis is confirmed, T_4 is instituted at a dose of 10–15 μg/kg per d, and the dose is adjusted by close monitoring of TSH levels. T_4 requirements are relatively great during the first year of life, and a high circulating T_4 level is usually needed to normalize TSH. Early treatment with T_4 results in normal IQ levels, but subtle neurodevelopmental abnormalities may occur in those with the most severe hypothyroidism at diagnosis or when treatment is delayed or suboptimal. If transient hypothyroidism is suspected, or the diagnosis is unclear, treatment can be stopped safely after the age of 3 years followed by further evaluation.

AUTOIMMUNE HYPOTHYROIDISM

Classification Autoimmune hypothyroidism may be associated with a goiter (*Hashimoto's, or goitrous thyroiditis*) or minimal residual thyroid tissue (*atrophic thyroiditis*). Because the autoimmune process gradually reduces thyroid function, there is a phase of compensation when normal thyroid hormone levels are maintained by a rise in TSH. Although some patients may have minor symptoms, this state is called *subclinical hypothyroidism*. Later, unbound T_4 levels fall and TSH levels rise further; symptoms become more readily apparent at this stage (usually TSH >10 mIU/L), which is referred to as *clinical hypothyroidism* or *overt hypothyroidism*.

Prevalence The mean annual incidence rate of autoimmune hypothyroidism is up to 4 per 1000 women and 1 per 1000 men. It is more common in certain populations, such as the Japanese, probably because of genetic factors and chronic exposure to a high-iodine diet. The mean age at diagnosis is 60 years, and the prevalence of overt hypothyroidism increases with age. Subclinical hypothyroidism is found in 6–8% of women (10% over the age of 60) and 3% of men. The annual risk of developing clinical hypothyroidism is ~4% when subclinical hypothyroidism is associated with positive thyroid peroxidase (TPO) antibodies.

Pathogenesis In Hashimoto's thyroiditis, there is a marked lymphocytic infiltration of the thyroid with germinal center formation, atrophy of the thyroid follicles accompanied by oxyphil metaplasia, absence of colloid, and mild to moderate fibrosis. In atrophic thyroiditis, the fibrosis is much more extensive, lymphocyte infiltration is less pronounced, and thyroid follicles are almost completely absent. Atrophic thyroiditis usually represents the end stage of Hashimoto's thyroiditis rather than a separate disorder, although a distinct form of marked fibrosis occurs in which the gland is infiltrated with IgG4-positive plasma cells.

As with most autoimmune disorders, susceptibility to autoimmune hypothyroidism is determined by a combination of genetic and environmental factors, and the risk of either autoimmune hypothyroidism or Graves' disease is increased among siblings. HLA-DR polymorphisms are the best documented genetic risk factors for autoimmune hypothyroidism, especially HLA-DR3, DR4, and DR5 in Caucasians. A weak association also exists between polymorphisms in *CTLA-4*, a T cell–regulatory gene, and autoimmune hypothyroidism. Both of these genetic associations are shared by other autoimmune diseases, which may explain the relationship between autoimmune hypothyroidism and other autoimmune diseases, especially type 1 diabetes mellitus, Addison's disease, pernicious anemia, and vitiligo. HLA-DR and *CTLA-4* polymorphisms account for approximately half of the

TABLE 383-2 Examples of Genetic Causes of Congenital Hypothyroidism

DEFECTIVE GENE PROTEIN	TYPE OF HYPOTHYROIDISM	INHERITANCE	CONSEQUENCES
PROP-1	Central, hypothyroidism	Homozygous recessive	Combined pituitary hormone deficiencies, including thyroid-stimulating hormone (TSH), with preservation of adrenocorticotropic hormone
PIT-1	Central, hypothyroidism	Homozygous or Heterozygous loss of function	Combined deficiencies of growth hormone, prolactin, TSH
IGSF1	Central, hypothyroidism	X-linked loss of function	Loss of TSH receptor (TSH-R) expression, testicular enlargement
TSHβ	Central, hypothyroidism	Heterozygous loss of function	TSH deficiency
TTF-1 (TITF-1)	Primary, thyroid dysgenesis	Heterozygous loss of function	Variable thyroid hypoplasia, choreoathetosis, pulmonary problems
TTF-2 (FOXE-1)	Primary, thyroid dysgenesis	Homozygous recessive	Thyroid agenesis, choanal atresia, spiky hair
PAX-8	Primary, thyroid dysgenesis	Heterozygous loss of function	Thyroid dysgenesis, kidney abnormalities
NKX2-1	Primary, thyroid dysgenesis	Heterozygous loss of function	Thyroid dysgenesis, brain, lung abnormalities
NKX2-5	Primary, thyroid dysgenesis	Heterozygous loss of function	Thyroid dysgenesis, heart abnormalities
GLIS3	Primary, thyroid dysgenesis	Homozygous recessive	Thyroid dysgenesis, neonatal diabetes, facial abnormalities
JAG-1	Primary, thyroid dysgenesis	Heterozygous loss of function	Thyroid dysgenesis, Alagille syndrome type 1, heart abnormalities
TSH receptor	Primary, thyroid dysgenesis and dyshormonogenesis	Homozygous recessive	Resistance to TSH
$G_s\alpha$ (Albright hereditary osteodystrophy)	Primary, thyroid dyshormonogenesis	Heterozygous loss of function, imprinting	Resistance to TSH
Na^+/I^- symporter (SLC5A5)	Primary, thyroid dyshormonogenesis	Homozygous recessive	Inability to transport iodide
DUOX2 (THOX2)	Primary, thyroid dyshormonogenesis	Heterozygous loss of function	Organification defect
DUOXA2	Primary, thyroid dyshormonogenesis	Homozygous recessive	Organification defect
Thyroid peroxidase	Primary, thyroid dyshormonogenesis	Homozygous recessive	Defective organification of iodide
Thyroglobulin	Primary, thyroid dyshormonogenesis	Homozygous recessive	Defective synthesis of thyroid hormone
Pendrin (SLC26A4)	Primary, thyroid dyshormonogenesis	Homozygous recessive	Pendred syndrome: sensorineural deafness and partial organification defect in thyroid
Dehalogenase 1 (IYD)	Primary, thyroid dyshormonogenesis	Homozygous recessive	Loss of iodide reutilization

genetic susceptibility to autoimmune hypothyroidism, and the role of other contributory loci remains to be clarified. A gene on chromosome 21 may be responsible for the association between autoimmune hypothyroidism and Down's syndrome. The female preponderance of thyroid autoimmunity is most likely due to sex steroid effects on the immune response, but an X chromosome–related genetic factor is also possible and may account for the high frequency of autoimmune hypothyroidism in Turner's syndrome. Environmental susceptibility factors are poorly defined at present. A high iodine or low selenium intake and decreased exposure to microorganisms in childhood increase the risk of autoimmune hypothyroidism. Smoking cessation transiently increases incidence, whereas alcohol intake seems protective. These factors may account for the increase in prevalence over the past two to three decades.

TABLE 383-3 Signs and Symptoms of Hypothyroidism (Descending Order of Frequency)

SYMPTOMS	SIGNS
Tiredness, weakness	Dry coarse skin; cool peripheral extremities
Dry skin	Puffy face, hands, and feet (myxedema)
Feeling cold	Diffuse alopecia
Hair loss	Bradycardia
Difficulty concentrating and poor memory	Peripheral edema
Constipation	Delayed tendon reflex relaxation
Weight gain with poor appetite	Carpal tunnel syndrome
Dyspnea	Serous cavity effusions
Hoarse voice	
Menorrhagia (later oligomenorrhea or amenorrhea)	
Paresthesia	
Impaired hearing	

The thyroid lymphocytic infiltrate in autoimmune hypothyroidism is composed of activated T cells as well as B cells. Thyroid cell destruction is primarily mediated by the CD8+ cytotoxic T cells, but local production of cytokines, such as tumor necrosis factor (TNF), interleukin-1 (IL-1), and interferon γ (IFN-γ), derived from the inflammatory infiltrate may render thyroid cells more susceptible to apoptosis mediated by death receptors, such as Fas, and by oxidative stress. These cytokines also impair thyroid cell function directly and induce the expression of other proinflammatory molecules by the thyroid cells themselves, such as cytokines, HLA class I and class II molecules, adhesion molecules, CD40, and nitric oxide. Administration of high concentrations of cytokines for therapeutic purposes (especially IFN-α) is associated with increased autoimmune thyroid disease, possibly through mechanisms similar to those in sporadic disease. Novel anticancer and immunomodulatory treatments, such as tyrosine kinase inhibitors, immune checkpoint inhibitors, and alemtuzumab, can also induce thyroiditis via their effects on T-cell regulation.

Antibodies to TPO and thyroglobulin (Tg) are clinically useful markers of thyroid autoimmunity, but any pathogenic effect is restricted to a secondary role in amplifying an ongoing autoimmune response. TPO antibodies fix complement, and complement membrane-attack complexes are present in the thyroid in autoimmune hypothyroidism. However, transplacental passage of Tg or TPO antibodies has no effect on the fetal thyroid, which suggests that T cell–mediated injury is required to initiate autoimmune damage to the thyroid.

Up to 20% of patients with autoimmune hypothyroidism have antibodies against the TSH-R, which, in contrast to thyroid-stimulating immunoglobulin (TSI), do not stimulate the receptor but prevent the

binding of TSH. These TSH-R-blocking antibodies, therefore, cause hypothyroidism and, especially in Asian patients, thyroid atrophy. Their transplacental passage may induce transient neonatal hypothyroidism. Rarely, patients have a mixture of TSI and TSH-R-blocking antibodies, and thyroid function can oscillate between hyperthyroidism and hypothyroidism as one or the other antibody becomes dominant. Predicting the course of disease in such individuals is difficult, and they require close monitoring of thyroid function. Bioassays can be used to document that TSH-R-blocking antibodies reduce the cyclic AMP–inducing effect of TSH on cultured TSH-R-expressing cells, but these assays are difficult to perform. Thyrotropin-binding inhibitory immunoglobulin (TBII) assays that measure the binding of antibodies to the receptor by competition with labeled TSH do not distinguish between TSI and TSH-R-blocking antibodies, but a positive result in a patient with spontaneous hypothyroidism is strong evidence for the presence of blocking antibodies. The use of these assays does not generally alter clinical management, although it may be useful to confirm the cause of transient neonatal hypothyroidism.

Clinical Manifestations The main clinical features of hypothyroidism are summarized in Table 383-3. The onset is usually insidious, and the patient may become aware of symptoms only when euthyroidism is restored. Patients with Hashimoto's thyroiditis may present because of goiter rather than symptoms of hypothyroidism. The goiter may not be large, but it is usually irregular and firm in consistency. Rarely, uncomplicated Hashimoto's thyroiditis is associated with pain.

Patients with atrophic thyroiditis or the later stage of Hashimoto's thyroiditis present with symptoms and signs of hypothyroidism. The skin is dry, and there is decreased sweating, thinning of the epidermis, and hyperkeratosis of the stratum corneum. Increased dermal glycosaminoglycan content traps water, giving rise to skin thickening without pitting (*myxedema*). Typical features include a puffy face with edematous eyelids and nonpitting pretibial edema **(Fig. 383-1)**. There is pallor, often with a yellow tinge to the skin due to carotene accumulation. Nail growth is retarded, and hair is dry, brittle, difficult to manage, and falls out easily. In addition to diffuse alopecia, there is thinning of the outer third of the eyebrows, although this is not a specific sign of hypothyroidism.

FIGURE 383-1 Facial appearance in hypothyroidism. Note puffy eyes and thickened skin.

Other common features include constipation and weight gain (despite a poor appetite). In contrast to popular perception, the weight gain is usually modest and due mainly to fluid retention in the myxedematous tissues. Libido is decreased in both sexes, and there may be oligomenorrhea or amenorrhea in long-standing disease, but menorrhagia may occur at an early stage. Fertility is reduced, and the incidence of miscarriage is increased. Prolactin levels are often modestly increased **(Chap. 380)** and may contribute to alterations in libido and fertility and cause galactorrhea.

Myocardial contractility and pulse rate are reduced, leading to a reduced stroke volume and bradycardia. Increased peripheral resistance may be accompanied by hypertension, particularly diastolic. Blood flow is diverted from the skin, producing cool extremities. Pericardial effusions occur in up to 30% of patients but rarely compromise cardiac function. Although alterations in myosin heavy chain isoform expression have been documented, cardiomyopathy is rare. Fluid may also accumulate in other serous cavities and in the middle ear, giving rise to conductive deafness; sensorineural deafness may also occur. Pulmonary function is generally normal, but dyspnea may be caused by pleural effusion, impaired respiratory muscle function, diminished ventilatory drive, or sleep apnea.

Carpal tunnel and other entrapment syndromes are common, as is impairment of muscle function with stiffness, cramps, and pain. On examination, there may be slow relaxation of tendon reflexes and pseudomyotonia. Memory and concentration are impaired. Experimentally, positron emission tomography (PET) scans examining glucose metabolism in hypothyroid subjects show lower regional activity in the amygdala, hippocampus, and perigenual anterior cingulate cortex, among other regions, and this activity corrects after thyroxine replacement. Rare neurologic problems include reversible cerebellar ataxia, dementia, psychosis, and myxedema coma. *Hashimoto's encephalopathy* has been defined as a steroid-responsive syndrome associated with TPO antibodies, myoclonus, and slow-wave activity on electroencephalography, but the relationship with thyroid autoimmunity or hypothyroidism is not established, and if a patient is euthyroid, levothyroxine (LT4) therapy has not been shown to be efficacious in treatment. The hoarse voice and occasionally clumsy speech of hypothyroidism reflect fluid accumulation in the vocal cords and tongue.

The features described above are the consequence of thyroid hormone deficiency. However, autoimmune hypothyroidism may be associated with signs or symptoms of other autoimmune diseases, particularly vitiligo, pernicious anemia, Addison's disease (Schmidt's syndrome), alopecia areata, and type 1 diabetes mellitus (T1DM). In the polygenic disorder autoimmune polyendocrine syndrome type 2, autoimmune thyroid disease is present in 70–75%, T1DM in 40–60%, and Addison's disease in 40–50%. Less common associations include celiac disease, dermatitis herpetiformis, chronic active hepatitis, rheumatoid arthritis, systemic lupus erythematosus (SLE), myasthenia gravis, autoimmune hypoparathyroidism, primary hypogonadism, and Sjögren's syndrome. Thyroid-associated ophthalmopathy usually occurs in Graves' disease (see below), but in ~5% of patients, it is associated with autoimmune hypothyroidism.

Autoimmune hypothyroidism is uncommon in children and usually presents with slow growth and delayed facial and dental maturation. The pituitary may be enlarged due to thyrotroph hyperplasia. Myopathy, with muscle swelling, is more common in children than in adults. In most cases, puberty is delayed, but precocious puberty sometimes occurs. There may be intellectual impairment if the onset is before 3 years and the hormone deficiency is severe.

Laboratory Evaluation A summary of the investigations used to determine the existence and cause of hypothyroidism is provided in **Fig. 383-2**. A normal TSH level excludes primary (but not secondary) hypothyroidism. If the TSH is elevated, a free or unbound T_4 level (FT_4) is needed to confirm the presence of clinical hypothyroidism, but T_4 is inferior to TSH when used as a screening test because it will not detect subclinical hypothyroidism. Circulating unbound T_3 levels are normal in ~25% of patients, reflecting adaptive deiodinase responses to hypothyroidism. T_3 measurements are, therefore, not indicated.

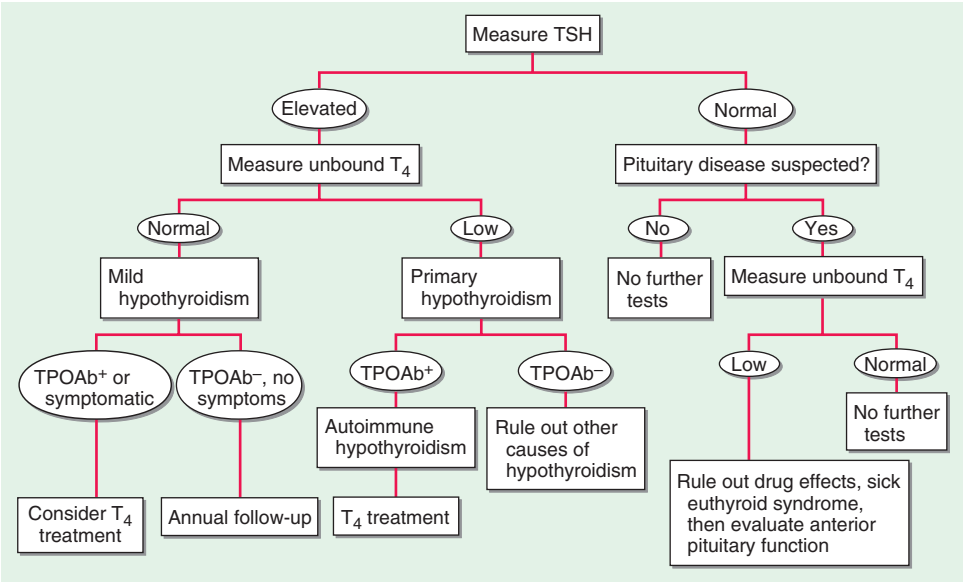

FIGURE 383-2 Evaluation of hypothyroidism. TPOAb⁺, thyroid peroxidase antibodies present; TPOAb⁻, thyroid peroxidase antibodies not present; TSH, thyroid-stimulating hormone.

Once clinical or subclinical hypothyroidism is confirmed, the etiology is usually easily established by demonstrating the presence of TPO and Tg antibodies, which are present in >95% of patients with autoimmune hypothyroidism. TBII can be found in 10–20% of patients, but measurement is not needed routinely. Other abnormal laboratory findings in hypothyroidism may include increased creatine phosphokinase, elevated cholesterol and triglycerides, and anemia (usually normocytic or macrocytic). Except when accompanied by iron deficiency, the anemia and other abnormalities gradually resolve with thyroxine replacement.

Differential Diagnosis An asymmetric goiter in Hashimoto's thyroiditis may be confused with a multinodular goiter (MNG) or thyroid carcinoma, in which thyroid antibodies may also be present. Ultrasound can be used to show the presence of a solitary lesion or an MNG rather than the thyroid enlargement with heterogeneous echogenicity typical of Hashimoto's thyroiditis. Fine-needle aspiration biopsy is useful in the investigation of focal nodules. Other causes of hypothyroidism are discussed below and in Table 383-1 but rarely cause diagnostic confusion.

OTHER CAUSES OF HYPOTHYROIDISM

Iatrogenic hypothyroidism is a common cause of hypothyroidism and can often be detected by screening before symptoms develop. In the first 3–4 months after radioiodine treatment for Graves' disease, transient hypothyroidism may occur due to reversible radiation damage. Low-dose thyroxine treatment can be withdrawn if recovery occurs. Because TSH levels are suppressed by hyperthyroidism, unbound T_4 levels are a better measure of thyroid function than TSH in the months following radioiodine treatment. Mild hypothyroidism after subtotal thyroidectomy may also resolve after several months, as the gland remnant is stimulated by increased TSH levels.

Iodine deficiency is responsible for endemic goiter and cretinism but is an uncommon cause of adult hypothyroidism unless the iodine intake is very low or there are complicating factors, such as the consumption of thiocyanates in cassava or selenium deficiency. Although hypothyroidism due to iodine deficiency can be treated with thyroxine, public health measures to improve iodine intake should be advocated to eliminate this problem. Iodized salt or bread or a single bolus of oral or intramuscular iodized oil have all been used successfully.

Paradoxically, chronic iodine excess can also induce goiter and hypothyroidism. The intracellular events that account for this effect are unclear, but individuals with autoimmune thyroiditis are especially susceptible. Iodine excess is responsible for the hypothyroidism that occurs in patients treated with amiodarone (Chap. 384). Other drugs, particularly lithium, may also cause hypothyroidism. Transient hypothyroidism caused by thyroiditis is discussed below.

Secondary or central hypothyroidism is usually diagnosed in the context of other anterior pituitary hormone deficiencies; isolated TSH deficiency is very rare (Chap. 379). TSH levels may be low, normal, or even slightly increased in secondary hypothyroidism; the latter is due to secretion of immunoactive but bioinactive forms of TSH. The diagnosis is confirmed by detecting a low unbound T_4 level. The goal of treatment is to maintain T_4 levels in the upper half of the reference interval because TSH levels cannot be used to monitor therapy.

TREATMENT

Hypothyroidism

CLINICAL HYPOTHYROIDISM

If there is no residual thyroid function, the daily replacement dose of LT4 is usually 1.6 μg/kg body weight (typically 100–150 μg), ideally taken at least 30 min before breakfast. In many patients, however, lower doses suffice until residual thyroid tissue is destroyed. In patients who develop hypothyroidism after the treatment of Graves' disease, there is often underlying autonomous function, necessitating lower replacement doses (typically 75–125 μg/d).

Adult patients under 60 years old without evidence of heart disease may be started on 50–100 μg of LT4 daily. The dose is adjusted on the basis of TSH levels, with the goal of treatment being a normal TSH, ideally in the lower half of the reference range. TSH responses are gradual and should be measured about 2 months after instituting treatment or after any subsequent change in LT4 dosage. The clinical effects of LT4 replacement are slow to appear. Patients may not experience full relief from symptoms until 3–6 months after normal TSH levels are restored. Adjustment of LT4 dosage is made in 12.5- or 25-μg increments if the TSH is high; decrements of the same magnitude should be made if the TSH is suppressed. Patients with a suppressed TSH of any cause, including LT4 overtreatment, have an increased risk of atrial fibrillation and reduced bone density.

About 10–15% of patients may have persistent symptoms despite restoration of euthyroidism with LT4 for reasons that remain unclear. Although desiccated animal thyroid preparations (thyroid extract USP) are available, they are not recommended because the

ratio of T_3 to T_4 is nonphysiologic. The use of LT4 combined with liothyronine (triiodothyronine, T_3) has been investigated, but benefit has not been confirmed in prospective studies. There is no place for liothyronine alone as long-term replacement, because the short half-life necessitates three or four daily doses and is associated with fluctuating T_3 levels.

Once full replacement is achieved and TSH levels are stable, follow-up measurement of TSH is recommended at annual intervals. It is important to ensure ongoing adherence as patients do not feel any symptomatic difference after missing a few doses of LT4, and this sometimes leads to self-discontinuation.

In patients of normal body weight who are taking ≥200 μg of LT4 per d, an elevated TSH level is often a sign of poor adherence to treatment. This is also the likely explanation for fluctuating TSH levels, despite a constant LT4 dosage. Such patients often have normal or high unbound T_4 levels, despite an elevated TSH, because they remember to take medication for a few days before testing; this is sufficient to normalize T_4, but not TSH levels. It is important to consider variable adherence, because this pattern of thyroid function tests is otherwise suggestive of disorders associated with inappropriate TSH secretion **(Chap. 382)**. Because T_4 has a long half-life (7 days), patients who miss a dose can be advised to take two doses of the skipped tablets at once. Other causes of increased LT4 requirements must be excluded, particularly malabsorption (e.g., celiac disease, small-bowel surgery, atrophic or *Helicobacter pylori*–related gastritis), oral estrogen-containing medications or selective estrogen receptor modulator therapy, ingestion with a meal, and drugs that interfere with T_4 absorption or metabolism such as bile acid sequestrants, ferrous sulfate, calcium supplements, sevelamer, sucralfate, proton pump inhibitors, lovastatin, aluminum hydroxide, rifampicin, amiodarone, carbamazepine, phenytoin, and tyrosine kinase inhibitors.

SUBCLINICAL HYPOTHYROIDISM

By definition, subclinical hypothyroidism refers to biochemical evidence of thyroid hormone deficiency in patients who have few or no apparent clinical features of hypothyroidism. There are no universally accepted recommendations for the management of subclinical hypothyroidism, but LT4 is recommended if the patient is a woman who wishes to conceive or is pregnant or when TSH levels are >10 mIU/L. Most other patients can simply be monitored annually. A trial of treatment may be considered when young or middle-aged patients have symptoms of hypothyroidism or risk of heart disease. It is important to confirm that any elevation of TSH is sustained over a 3-month period before treatment is given. Treatment is administered by starting with a low dose of LT4 (25–50 μg/d) with the goal of normalizing TSH.

SPECIAL TREATMENT CONSIDERATIONS

Rarely, LT4 replacement is associated with pseudotumor cerebri in children. Presentation appears to be idiosyncratic and occurs months after treatment has begun.

Because maternal hypothyroidism may both adversely affect fetal neural development and be associated with adverse gestational outcomes (miscarriage, preterm delivery), thyroid function should be monitored to preserve euthyroidism in women with a history or high risk of hypothyroidism. Although epidemiologic studies have demonstrated the association of miscarriage and preterm delivery with the presence of thyroid autoantibodies detected either during or prior to gestation, randomized controlled trails evaluating LT4 therapy in this population have not demonstrated benefit. Because of the known increase in thyroid hormone requirements during pregnancy in hypothyroid women, LT4 therapy should be targeted to maintain a serum TSH in the normal range but <2.5 mIU/L prior to conception. Subsequently, thyroid function should be evaluated immediately after pregnancy is confirmed and every 4 weeks during the first half of the pregnancy, with less frequent testing after 20 weeks' gestation (every 6–8 weeks depending on whether LT4 dose adjustment is ongoing). The increment of LT4 dosage increase depends upon the etiology of hypothyroidism, with athyreotic women requiring more (~45%) than those with Hashimoto's who may have some residual thyroid function. Women should increase LT4 from once-daily dosing to nine doses per week as soon as pregnancy is confirmed to anticipate this change. Thereafter dosage should be closely monitored with a goal TSH in the lower half of the trimester-specific normative range, if available, or <2.5 mIU/L which allows for reserve if additional LT4 dosage increases are required as pregnancy progresses. However, it is important to recognize that the normal TSH range in pregnancy for the second and third trimesters is not significantly different from the nonpregnancy reference range. However, serum TSH decreases in the late first trimester, and if trimester-specific ranges are not available, an appropriate range for 7–12 weeks' gestation can be approximated by decreasing the upper limit of the nonpregnant reference range by 0.5 mIU/L (~4.0 mIU/L) and the lower limit by 0.4 mIU/L (~0.1 mIU/L).

After delivery, LT4 doses typically return to prepregnancy levels. Pregnant women should be counseled to separate ingestion of prenatal vitamins and iron supplements from LT4.

Elderly patients may require 20% less thyroxine than younger patients. In the elderly, especially patients with known coronary artery disease, the starting dose of LT4 is 12.5–25 μg/d with similar increments every 2–3 months until TSH is normalized. In some patients, it may be impossible to achieve full replacement despite optimal antianginal treatment. *Emergency surgery* is generally safe in patients with untreated hypothyroidism, although routine surgery in a hypothyroid patient should be deferred until euthyroidism is achieved.

Myxedema coma still has a 20–40% mortality rate, despite intensive treatment, and outcomes are independent of the T_4 and TSH levels. Clinical manifestations include reduced level of consciousness, sometimes associated with seizures, as well as the other features of hypothyroidism (Table 383-3). Hypothermia can reach 23°C (74°F). There may be a history of treated hypothyroidism with poor compliance, or the patient may be previously undiagnosed. Myxedema coma almost always occurs in the elderly and is usually precipitated by factors that impair respiration, such as drugs (especially sedatives, anesthetics, and antidepressants), pneumonia, congestive heart failure, myocardial infarction, gastrointestinal bleeding, or cerebrovascular accidents. Sepsis should also be suspected. Exposure to cold may also be a risk factor. Hypoventilation, leading to hypoxia and hypercapnia, plays a major role in pathogenesis; hypoglycemia and dilutional hyponatremia also contribute to the development of myxedema coma.

LT4 can initially be administered as a single IV bolus of 200–400 μg, which serves as a loading dose, followed by a daily oral dose of 1.6 μg/kg per d, reduced by 25% if administered IV. If suitable IV preparation is not available, the same initial dose of LT4 can be given by nasogastric tube (although absorption may be impaired in myxedema). Because $T_4 \rightarrow T_3$ conversion is impaired in myxedema coma, there is a rationale for adding liothyronine (T_3) intravenously or via nasogastric tube to LT4 treatment, although excess liothyronine has the potential to provoke arrhythmias. An initial loading dose of 5–20 μg liothyronine should be followed by 2.5–10 μg every 8 h, with lower doses chosen for smaller or older patients and those at cardiovascular risk.

Supportive therapy should be provided to correct any associated metabolic disturbances. External warming is indicated only if the temperature is <30°C, as it can result in cardiovascular collapse **(Chap. 464)**. Space blankets should be used to prevent further heat loss. Parenteral hydrocortisone (50 mg every 6 h) should be administered because there is impaired adrenal reserve in profound hypothyroidism. Any precipitating factors should be treated, including the early use of broad-spectrum antibiotics, pending the exclusion of infection. Ventilatory support with regular blood gas analysis is usually needed during the first 48 h. Hypertonic saline or IV glucose may be needed if there is severe hyponatremia or hypoglycemia; hypotonic IV fluids should be avoided because they

may exacerbate water retention secondary to reduced renal perfusion and inappropriate vasopressin secretion. The metabolism of most medications is impaired, and sedatives should be avoided if possible or used in reduced doses. Medication blood levels should be monitored, when available, to guide dosage.

384 Hyperthyroidism and Other Causes of Thyrotoxicosis

J. Larry Jameson, Susan J. Mandel, Anthony P. Weetman

THYROTOXICOSIS

Thyrotoxicosis is defined as the state of thyroid hormone excess and is not synonymous with *hyperthyroidism*, which is the result of excessive thyroid function. However, the major etiologies of thyrotoxicosis are hyperthyroidism caused by Graves' disease, toxic multinodular goiter (MNG), and toxic adenomas. Other causes are listed in Table 384-1.

TABLE 384-1 Causes of Thyrotoxicosis

Primary Hyperthyroidism
Graves' disease
Toxic multinodular goiter
Toxic adenoma
Functioning thyroid carcinoma metastases
Activating mutation of the TSH receptor
Activating mutation of $G_s\alpha$ (McCune-Albright syndrome)
Struma ovarii
Drugs: iodine excess (Jod-Basedow phenomenon)
Thyrotoxicosis without Hyperthyroidism
Subacute thyroiditis
Silent thyroiditis
Other causes of thyroid destruction: amiodarone, radiation, infarction of adenoma
Ingestion of excess thyroid hormone (thyrotoxicosis factitia) or thyroid tissue
Secondary Hyperthyroidism
TSH-secreting pituitary adenoma
Thyroid hormone resistance syndrome: occasional patients may have features of thyrotoxicosis
Chorionic gonadotropin-secreting tumors[a]
Gestational thyrotoxicosis[a]

[a]Circulating TSH levels are low in these forms of secondary hyperthyroidism.

Abbreviation: TSH, thyroid-stimulating hormone.

GRAVES' DISEASE

Epidemiology Graves' disease accounts for 60–80% of thyrotoxicosis. The prevalence varies among populations, reflecting genetic factors and iodine intake (high iodine intake is associated with an increased prevalence of Graves' disease). Graves' disease occurs in up to 2% of women but is one-tenth as frequent in men. The disorder rarely begins before adolescence and typically occurs between 20 and 50 years of age; it also occurs in the elderly.

Pathogenesis As in autoimmune hypothyroidism, a combination of environmental and genetic factors, including polymorphisms in HLA-DR, the immunoregulatory genes *CTLA-4*, *CD25*, *PTPN22*, *FCRL3*, and *CD226*, as well as the gene encoding the thyroid-stimulating hormone (TSH) receptor (TSH-R), contributes to Graves' disease susceptibility. The concordance for Graves' disease in monozygotic twins is 20–30%, compared to <5% in dizygotic twins. Indirect evidence suggests that stress is an important environmental factor, presumably operating through neuroendocrine effects on the immune system. Smoking is a minor risk factor for Graves' disease and a major risk factor for the development of ophthalmopathy. Sudden increases in iodine intake may precipitate Graves' disease, and there is a threefold increase in the occurrence of Graves' disease in the postpartum period. Graves' disease may occur during the immune reconstitution phase after highly active antiretroviral therapy (HAART) or alemtuzumab treatment and following treatment with immune checkpoint inhibitors (e.g., nivolumab, pembrolizumab).

The hyperthyroidism of Graves' disease is caused by thyroid-stimulating immunoglobulins (TSIs) that are synthesized by lymphocytes in the thyroid gland as well as in bone marrow and lymph nodes. Such antibodies can be detected by bioassays or by using the more widely available immunoassays (TSH receptor antibody [TRAb]) that measure whether the patient's serum contains an antibody that can displace either labeled TSH or a monoclonal TSH receptor antibody from the TSH receptor. The presence of TRAb in a patient with thyrotoxicosis implies the existence of TSI, and these assays are useful in monitoring pregnant Graves' patients in whom high levels of TSI can cross the placenta and cause neonatal thyrotoxicosis. Other thyroid autoimmune responses, similar to those in autoimmune hypothyroidism (see above), occur concurrently in patients with Graves' disease. In particular, thyroid peroxidase (TPO) and thyroglobulin (Tg) antibodies occur in up to 80% of cases. Because the coexisting thyroiditis can also affect thyroid function, there is no direct correlation between the level of TSI and thyroid hormone levels in Graves' disease.

Cytokines appear to play a major role in thyroid-associated ophthalmopathy. There is infiltration of the extraocular muscles by activated T cells; the release of cytokines such as interferon γ (IFN-γ), tumor necrosis factor (TNF), and interleukin 1 (IL-1) results in fibroblast activation and increased synthesis of glycosaminoglycans that trap water, thereby leading to characteristic muscle swelling. Late in the disease, there is irreversible fibrosis of the muscles. Increased fat is an additional cause of retrobulbar tissue expansion. The increase in intraorbital pressure can lead to proptosis, diplopia, and optic neuropathy. Although the pathogenesis of thyroid-associated ophthalmopathy is incompletely understood, the TSH-R is a thyroid autoantigen and is expressed in orbital tissues. In addition, aberrant signaling via insulin-like growth factor 1 receptors (IGF-1R) on orbital fibroblasts has also been implicated. These mechanisms are the basis for new monoclonal antibody treatments (e.g., teprotumumab) that reduce the levels of TSH-R/IGF-1R complexes and attenuate signaling.

Clinical Manifestations Signs and symptoms include features that are common to any cause of thyrotoxicosis (Table 384-2) as well as those specific for Graves' disease. The clinical presentation depends on the severity of thyrotoxicosis, the duration of disease, individual susceptibility to excess thyroid hormone, and the patient's age. In the

TABLE 384-2 Signs and Symptoms of Thyrotoxicosis (Descending Order of Frequency)

SYMPTOMS	SIGNS[a]
Hyperactivity, irritability, dysphoria	Tachycardia; atrial fibrillation in the elderly
Heat intolerance and sweating	Tremor
Palpitations	Goiter
Fatigue and weakness	Warm, moist skin
Weight loss with increased appetite	Muscle weakness, proximal myopathy
Diarrhea	Lid retraction or lag
Polyuria	Gynecomastia
Oligomenorrhea, loss of libido	

[a]Excludes the signs of ophthalmopathy and dermopathy specific for Graves' disease.

FIGURE 384-1 Features of Graves' disease. ***A.*** Ophthalmopathy in Graves' disease; lid retraction, periorbital edema, conjunctival injection, and proptosis are marked. ***B.*** Thyroid dermopathy over the lateral aspects of the shins. ***C.*** Thyroid acropachy.

elderly, features of thyrotoxicosis may be subtle or masked, and patients may present mainly with fatigue and weight loss, a condition known as *apathetic thyrotoxicosis*.

Thyrotoxicosis may cause unexplained weight loss, despite an enhanced appetite, due to the increased metabolic rate. Weight gain occurs in 5% of patients, however, because of increased food intake. Other prominent features include hyperactivity, nervousness, and irritability, ultimately leading to a sense of easy fatigability in some patients. Insomnia and impaired concentration are common; apathetic thyrotoxicosis may be mistaken for depression in the elderly. Fine tremor is a frequent finding, best elicited by having patients stretch out their fingers while feeling the fingertips with the palm. Common neurologic manifestations include hyperreflexia, muscle wasting, and proximal myopathy without fasciculation. Chorea is rare. Thyrotoxicosis is sometimes associated with a form of hypokalemic periodic paralysis; this disorder is particularly common in Asian males with thyrotoxicosis, but it occurs in other ethnic groups as well.

The most common cardiovascular manifestation is sinus tachycardia, often associated with palpitations, occasionally caused by supraventricular tachycardia. The high cardiac output produces a bounding pulse, widened pulse pressure, and an aortic systolic murmur and can lead to worsening of angina or heart failure in the elderly or those with preexisting heart disease. Atrial fibrillation is more common in patients >50 years of age. Treatment of the thyrotoxic state alone converts atrial fibrillation to normal sinus rhythm in about half of patients, suggesting the existence of an underlying cardiac problem in the remainder.

The skin is usually warm and moist, and the patient may complain of sweating and heat intolerance, particularly during warm weather. Palmar erythema, onycholysis, and, less commonly, pruritus, urticaria, and diffuse hyperpigmentation may be evident. Hair texture may become fine, and a diffuse alopecia occurs in up to 40% of patients, persisting for months after restoration of euthyroidism. Gastrointestinal transit time is decreased, leading to increased stool frequency, often with diarrhea and occasionally mild steatorrhea. Women frequently experience oligomenorrhea or amenorrhea; in men, there may be impaired sexual function and, rarely, gynecomastia. The direct effect of thyroid hormones on bone resorption leads to osteopenia in long-standing thyrotoxicosis; mild hypercalcemia occurs in up to 20% of patients, but hypercalciuria is more common. There is a small increase in fracture rate in patients with a previous history of thyrotoxicosis.

In Graves' disease, the thyroid is usually diffusely enlarged to two to three times its normal size. The consistency is firm, but not nodular. There may be a thrill or bruit, best detected at the inferolateral margins of the thyroid lobes, due to the increased vascularity of the gland and the hyperdynamic circulation.

Lid retraction, causing a staring appearance, can occur in any form of thyrotoxicosis and is the result of sympathetic overactivity. However, Graves' disease is associated with specific eye signs that comprise *Graves' ophthalmopathy* **(Fig. 384-1*A*)**. This condition is also called *thyroid-associated ophthalmopathy*, because it occurs in the absence of hyperthyroidism in 10% of patients. Most of these individuals have autoimmune hypothyroidism or thyroid antibodies. The onset of Graves' ophthalmopathy occurs within the year before or after the diagnosis of thyrotoxicosis in 75% of patients but can sometimes precede or follow thyrotoxicosis by several years, accounting for some cases of euthyroid ophthalmopathy.

About one-third of patients with Graves' disease have clinical evidence of ophthalmopathy. However, the enlarged extraocular muscles typical of the disease, and other subtle features, can be detected in most patients when investigated by ultrasound or computed tomography (CT) imaging of the orbits. Unilateral signs are found in up to 10% of ophthalmopathy patients. The earliest manifestations of ophthalmopathy are usually a sensation of grittiness, eye discomfort, and excess tearing. About one-third of patients have proptosis, best detected by visualization of the sclera between the lower border of the iris and the lower eyelid, with the eyes in the primary position. Proptosis can be measured using an exophthalmometer. In severe cases, proptosis may cause corneal exposure and damage, especially if the lids fail to close during sleep. Periorbital edema, scleral injection, and chemosis are also frequent. In 5–10% of patients, the muscle swelling is so severe that diplopia results, typically, but not exclusively, when the patient looks up and laterally. The most serious manifestation is compression of the optic nerve at the apex of the orbit, leading to papilledema; peripheral field defects; and, if left untreated, permanent loss of vision.

The "NO SPECS" scoring system to evaluate ophthalmopathy is an acronym derived from the following changes:

0 = **N**o signs or symptoms
1 = **O**nly signs (lid retraction or lag), no symptoms
2 = **S**oft tissue involvement (periorbital edema)
3 = **P**roptosis (>22 mm)
4 = **E**xtraocular muscle involvement (diplopia)
5 = **C**orneal involvement
6 = **S**ight loss

Although useful as a mnemonic, the NO SPECS scheme is inadequate to describe the eye disease fully, and patients do not necessarily progress from one class to another; alternative scoring systems (e.g., the EUGOGO system developed by the European Group on Graves' Orbitopathy) that assess disease activity are preferable for monitoring and treatment purposes. When Graves' eye disease is active and severe, referral to an ophthalmologist is indicated and objective measurements are needed, such as lid-fissure width; corneal staining with fluorescein;

and evaluation of extraocular muscle function (e.g., Hess chart), intraocular pressure and visual fields, acuity, and color vision.

Thyroid dermopathy occurs in <5% of patients with Graves' disease (**Fig. 384-1*B***), almost always in the presence of moderate or severe ophthalmopathy. Although most frequent over the anterior and lateral aspects of the lower leg (hence the term *pretibial myxedema*), skin changes can occur at other sites, particularly after trauma. The typical lesion is a noninflamed, indurated plaque with a deep pink or purple color and an "orange skin" appearance. Nodular involvement can occur, and the condition can rarely extend over the whole lower leg and foot, mimicking elephantiasis. *Thyroid acropachy* refers to a form of clubbing found in <1% of patients with Graves' disease (**Fig. 384-1*C***). It is so strongly associated with thyroid dermopathy that an alternative cause of clubbing should be sought in a Graves' patient without coincident skin and orbital involvement. Ophthalmopathy, dermopathy, and acropachy have declined in incidence, probably due to better recognition and prompt treatment of the underlying thyroid disease.

Laboratory Evaluation Investigations used to determine the existence and cause of thyrotoxicosis are summarized in Fig. 384-2. In Graves' disease, the TSH level is suppressed, and total and unbound thyroid hormone levels are increased. In 2–5% of patients (and more in areas of borderline iodine intake), only T_3 is increased (T_3 toxicosis). The converse state of T_4 toxicosis, with elevated total and unbound T_4 and normal T_3 levels, is occasionally seen when hyperthyroidism is induced by excess iodine, providing surplus substrate for thyroid hormone synthesis. Measurement of TPO antibodies or TRAb may be useful if the diagnosis is unclear clinically but is not needed routinely. Associated abnormalities that may cause diagnostic confusion in thyrotoxicosis include elevation of bilirubin, liver enzymes, and ferritin. Microcytic anemia and thrombocytopenia may occur.

Differential Diagnosis Diagnosis of Graves' disease is straightforward in a patient with biochemically confirmed thyrotoxicosis, diffuse goiter on palpation, ophthalmopathy, and often a personal or family history of autoimmune disorders. For patients with thyrotoxicosis who lack these features, the diagnosis can be established by a radionuclide (^{99m}Tc, ^{123}I, or ^{131}I) scan and uptake of the thyroid, which will distinguish the diffuse, high uptake of Graves' disease from destructive thyroiditis, ectopic thyroid tissue, and factitious thyrotoxicosis, as well as diagnose a toxic adenoma or toxic MNG. Increasingly, because of the rapidity of laboratory test results, TRAb measurement is used instead of radionuclide scanning to confirm the diagnosis of Graves' disease. Color-flow Doppler ultrasonography may distinguish between hyperthyroidism (with increased blood flow) and destructive thyroiditis. In secondary hyperthyroidism due to a TSH-secreting pituitary tumor, there is also a diffuse goiter. The presence of a nonsuppressed TSH level and the finding of a pituitary tumor on CT or magnetic resonance imaging (MRI) scan suggest this diagnosis.

Clinical features of thyrotoxicosis can mimic certain aspects of other disorders, including panic attacks, mania, pheochromocytoma, and weight loss associated with malignancy. The diagnosis of thyrotoxicosis can be easily excluded if the TSH and unbound T_4 and T_3 levels are normal. A normal TSH also excludes Graves' disease as a cause of diffuse goiter.

Clinical Course Clinical features generally worsen without treatment; mortality was 10–30% before the introduction of satisfactory therapy. Some patients with mild Graves' disease experience spontaneous relapses and remissions. Rarely, there may be fluctuation between hypo- and hyperthyroidism due to changes in the functional activity of TSH-R antibodies. About 15% of patients who enter remission after treatment develop hypothyroidism 10–15 years later as a result of the destructive autoimmune process.

The clinical course of ophthalmopathy does not follow that of the thyroid disease, although thyroid dysfunction can worsen eye signs. Ophthalmopathy typically worsens over the initial 3–6 months, followed by a plateau phase over the next 12–18 months,

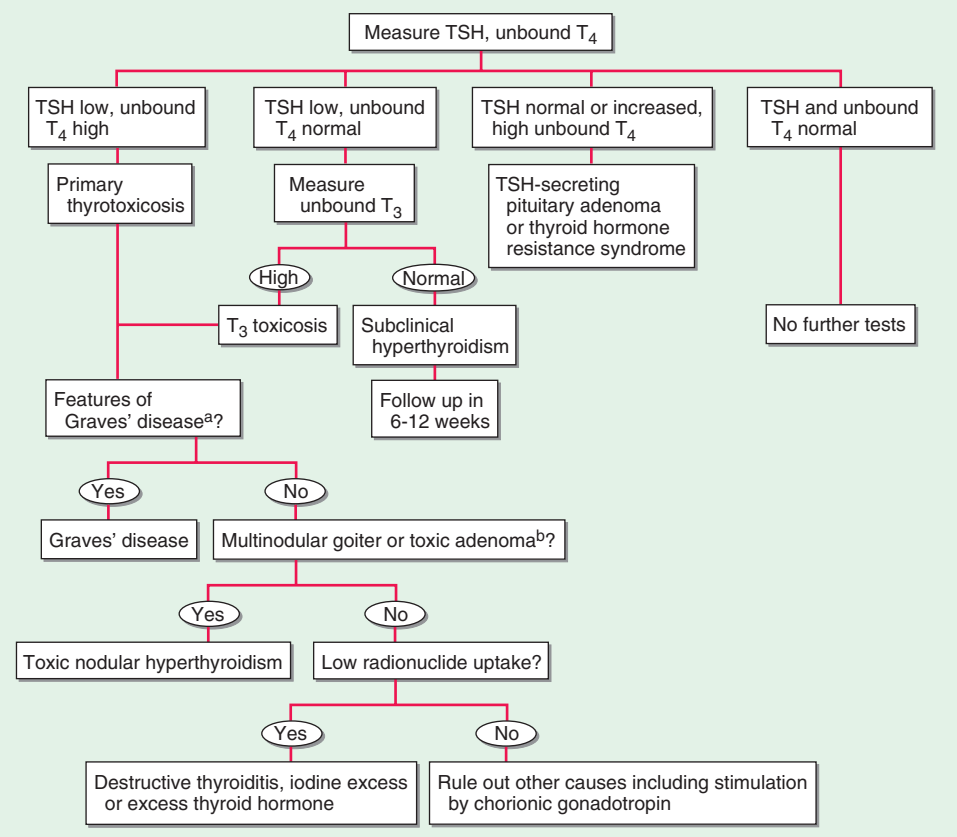

FIGURE 384-2 Evaluation of thyrotoxicosis. [a]Diffuse goiter, positive thyroid peroxidase (TPO) antibodies or thyroid-stimulating hormone (TSH) receptor antibody (TRAb), ophthalmopathy, dermopathy. [b]Can be confirmed by radionuclide scan.

and then some spontaneous improvement, particularly in the soft tissue changes. However, the course is more fulminant in up to 5% of patients, requiring intervention in the acute phase if there is optic nerve compression or corneal ulceration. Diplopia may appear late in the disease due to fibrosis of the extraocular muscles. Radioiodine treatment for hyperthyroidism worsens the eye disease in a small proportion of patients (especially smokers). Antithyroid drugs and surgery have no adverse effects on the clinical course of ophthalmopathy. Thyroid dermopathy, when it occurs, usually appears 1–2 years after the development of Graves' hyperthyroidism; it may improve spontaneously.

TREATMENT

Graves' Disease

The *hyperthyroidism* of Graves' disease is treated by reducing thyroid hormone synthesis, using an antithyroid drug, or reducing the amount of thyroid tissue with radioiodine (^{131}I) treatment or by thyroidectomy. Antithyroid drugs are the predominant therapy in many centers in Europe, Latin America, and Japan, whereas radioiodine is more often the first line of treatment in North America. These differences reflect the fact that no single approach is optimal and that patients may require multiple treatments to achieve remission.

The main *antithyroid drugs* are thionamides: propylthiouracil, carbimazole (not available in the United States), and the active metabolite of the latter, methimazole. All inhibit the function of TPO, reducing oxidation and organification of iodide. These drugs also reduce thyroid antibody levels by mechanisms that remain unclear, and they appear to enhance spontaneous rates of remission. Propylthiouracil inhibits deiodination of $T_4 \rightarrow T_3$. However, this effect is of minor benefit, except in the most severe thyrotoxicosis, and is offset by the much shorter half-life of this drug (90 min) compared to methimazole (6 h). Due to the hepatotoxicity of propylthiouracil, the U.S. Food and Drug Administration (FDA) has limited indications for its use to the first trimester of pregnancy, the treatment of thyroid storm, and patients with minor adverse reactions to methimazole. If propylthiouracil is used, monitoring of liver function tests is recommended.

There are many variations of antithyroid drug regimens. The initial dose of carbimazole or methimazole is usually 10–20 mg every 8 or 12 h, but once-daily dosing is possible after euthyroidism is restored. Propylthiouracil is given at a dose of 100–200 mg every 6–8 h, and divided doses are usually given throughout the course. Lower doses of each drug may suffice in areas of low iodine intake. The starting dose of an antithyroid drug can be gradually reduced (titration regimen) as thyrotoxicosis improves. Less commonly, high doses may be given combined with levothyroxine (LT4) supplementation (block-replace regimen) to avoid drug-induced hypothyroidism. The titration regimen is preferred to minimize the dose of antithyroid drug and provide an index of treatment response.

Thyroid function tests and clinical manifestations are reviewed 4–6 weeks after starting treatment, and the dose is titrated based on unbound T_4 levels. Most patients do not achieve euthyroidism until 6–8 weeks after treatment is initiated. TSH levels often remain suppressed for several months and therefore do not provide a sensitive index of treatment response. The usual daily maintenance doses of antithyroid drugs in the titration regimen are 2.5–10 mg of carbimazole or methimazole and 50–100 mg of propylthiouracil. In the block-replace regimen, the initial dose of antithyroid drug is held constant, and the dose of LT4 is adjusted to maintain normal unbound T_4 levels. When TSH suppression is alleviated, TSH levels can also be used to monitor therapy.

Maximum remission rates (up to 30–60% in some populations) are achieved by 12–18 months for the titration regimen compared to 6 months for the block-replace regimen and are higher in patients in whom TRAb levels are no longer detected than in those with TRAb persistence. For unclear reasons, remission rates appear to vary in different geographic regions. Younger patients, males, smokers, and patients with a history of allergy, severe hyperthyroidism, or large goiters are most likely to relapse when treatment stops, but outcomes are difficult to predict. All patients should be followed closely for relapse during the first year after treatment and at least annually thereafter.

The common minor side effects of antithyroid drugs are rash, urticaria, fever, and arthralgia (1–5% of patients). These may resolve spontaneously or after substituting an alternative antithyroid drug; rashes may respond to an antihistamine. Rare but major side effects include hepatitis (especially with propylthiouracil; avoid use in children) and cholestasis (methimazole and carbimazole); vasculitis; and, most important, agranulocytosis (<1%). It is essential that antithyroid drugs are stopped and not restarted if a patient develops major side effects. Written instructions should be provided regarding the symptoms of possible agranulocytosis (e.g., sore throat, fever, mouth ulcers) and the need to stop treatment pending an urgent complete blood count to confirm that agranulocytosis is not present. Management of agranulocytosis is described in **Chap. 102**. It is not useful to monitor blood counts prospectively, because the onset of agranulocytosis is idiosyncratic and abrupt.

Propranolol (20–40 mg every 6 h) or longer-acting selective β_1 receptor blockers such as atenolol may be helpful to control adrenergic symptoms, especially in the early stages before antithyroid drugs take effect. Beta blockers are also useful in patients with thyrotoxic periodic paralysis, pending correction of thyrotoxicosis. In consultation with a cardiologist, anticoagulation should be considered in all patients with atrial fibrillation; there is often spontaneous reversion to sinus rhythm with control of hyperthyroidism, and long-term anticoagulation is not usually needed. Decreased warfarin doses are required when patients are thyrotoxic. If digoxin is used, increased doses are often needed in the thyrotoxic state.

Radioiodine causes progressive destruction of thyroid cells and can be used as initial treatment or for relapses after a trial of antithyroid drugs. There is a small risk of thyrotoxic crisis (see below) after radioiodine, which can be minimized by pretreatment with antithyroid drugs for at least a month before treatment. Antecedent treatment with an antithyroid drug and a beta blocker should be considered for all elderly patients or for those with cardiac problems. Carbimazole or methimazole must be stopped 2–3 days before radioiodine administration to achieve optimum iodine uptake and can be restarted 3–7 days after radioiodine in those at risk of complications from worsening thyrotoxicosis. Propylthiouracil appears to have a prolonged radioprotective effect and should be stopped for a longer period before radioiodine is given, or a larger dose of radioiodine will be necessary.

Efforts to calculate an optimal dose of radioiodine that achieves euthyroidism without a high incidence of relapse or progression to hypothyroidism have not been successful. Some patients inevitably relapse after a single dose because the biologic effects of radiation vary between individuals, and hypothyroidism cannot be uniformly avoided even using accurate dosimetry. A practical strategy is to give a fixed dose based on clinical features, such as the severity of thyrotoxicosis, the size of the goiter (increases the dose needed), and the level of radioiodine uptake (decreases the dose needed). ^{131}I dosage generally ranges between 370 MBq (10 mCi) and 555 MBq (15 mCi). Most authorities favor an approach aimed at thyroid ablation (as opposed to euthyroidism), given that LT4 replacement is straightforward and most patients ultimately progress to hypothyroidism over 5–10 years, frequently with some delay in the diagnosis of hypothyroidism.

Certain radiation safety precautions are necessary in the first few days after radioiodine treatment, but the exact guidelines vary depending on local protocols. In general, patients need to avoid close, prolonged contact with children and pregnant women for 5–7 days because of possible transmission of residual isotope and exposure to radiation emanating from the gland. Rarely, there may be mild pain due to radiation thyroiditis 1–2 weeks after treatment. Hyperthyroidism can persist for 2–3 months before radioiodine

takes full effect. For this reason, β-adrenergic blockers or antithyroid drugs can be used to control symptoms during this interval. Persistent hyperthyroidism can be treated with a second dose of radioiodine, usually 6 months after the first dose. The risk of hypothyroidism after radioiodine depends on the dosage but is at least 10–20% in the first year and 5% per year thereafter. Patients should be informed of this possibility before treatment and require close follow-up during the first year followed by annual thyroid function testing.

Pregnancy and breast-feeding are absolute contraindications to radioiodine treatment, but patients can conceive safely 6 months after treatment. The presence of ophthalmopathy, especially in smokers, requires caution. Prednisone, 0.2–0.5 mg/kg per d (depending on ophthalmopathy severity), at the time of radioiodine treatment, tapered over 6–12 weeks, may prevent exacerbation of ophthalmopathy, but radioiodine should generally be avoided in patients with active moderate to severe eye disease. Although many physicians avoid radioiodine in children and adolescents because of the potential risks of malignancy, others have advocated radioiodine use in older children. A recent long-term follow-up study of adults found a modest increased lifetime risk of solid cancers after radioiodine treatment, contrary to previous findings. It is unclear how this will alter management in the future.

Total or near-total thyroidectomy is an option for patients who relapse after antithyroid drugs and prefer this treatment to radioiodine. Some experts recommend surgery in young individuals, particularly when the goiter is very large. Careful control of thyrotoxicosis with antithyroid drugs, followed by potassium iodide (SSKI; 1–2 drops orally tid for 10 days), is needed prior to surgery to avoid thyrotoxic crisis and to reduce the vascularity of the gland. The major complications of surgery—bleeding, laryngeal edema, hypoparathyroidism, and damage to the recurrent laryngeal nerves—are unusual when the procedure is performed by highly experienced surgeons. Recurrence rates in the best series are <2%, but the rate of hypothyroidism is similar to that following radioiodine treatment, especially with the current trend away from subtotal thyroidectomy.

Antithyroid drugs should be used to manage Graves' disease in *pregnancy.* Because transplacental passage of these drugs may produce fetal hypothyroidism and goiter if the maternal dose is excessive, maternal antithyroid dose titration should target serum free or total T_4 levels at or just above the pregnancy reference range. If available, propylthiouracil should be used until 14–16 weeks' gestation because of the association of rare cases of methimazole/carbimazole embryopathy, including *aplasia cutis* and other defects, such as choanal atresia and tracheoesophageal fistulae. Because of the potential for teratogenic effects, recent recommendations suggest discontinuation of antithyroid medication in a newly pregnant woman with Graves' disease who is euthyroid on a low dose of methimazole (<5–10 mg/d) or propylthiouracil (<100–200 mg/d), after evaluating recent thyroid function tests, disease history, goiter size, duration of therapy, and TRAb measurement. Following cessation, careful monitoring of maternal thyroid function tests is essential. On the other hand, for women at high risk of developing thyrotoxicosis if antithyroid drugs are discontinued (large goiter, requirement for higher antithyroid drug dosage), continued therapy is necessary, with propylthiouracil (if available) administration in the first trimester. However, because of its rare association with hepatotoxicity, propylthiouracil should be limited to the first trimester and then maternal therapy should be converted to methimazole (or carbimazole) at a ratio of 15–20 mg of propylthiouracil to 1 mg of methimazole. It is often possible to stop treatment in the last trimester because TSIs tend to decline in pregnancy. Nonetheless, the transplacental transfer of these antibodies if present at levels three times higher than the normative range rarely causes *fetal* or *neonatal thyrotoxicosis*. Poor intrauterine growth, a fetal heart rate of >160 beats/min, advanced bone age, fetal goiter, and high levels of maternal TSI after 26 weeks' gestation may herald this complication. Antithyroid drugs given to the mother can be used to treat the fetus and may be needed for 1–3 months after delivery, until the maternal antibodies disappear from the baby's circulation. The postpartum period is a time of major risk for relapse of Graves' disease. Breast-feeding is safe with low doses of antithyroid drugs. Graves' disease in *children* is usually managed initially with methimazole or carbimazole (avoid propylthiouracil), often given as a prolonged course of the titration regimen. Surgery or radioiodine may be indicated for severe or relapsing disease.

Thyrotoxic crisis, or *thyroid storm*, is rare and presents as a life-threatening exacerbation of hyperthyroidism, accompanied by fever, delirium, seizures, coma, vomiting, diarrhea, and jaundice. The mortality rate due to cardiac failure, arrhythmia, or hyperthermia is as high as 30%, even with treatment. Thyrotoxic crisis is usually precipitated by acute illness (e.g., stroke, infection, trauma, diabetic ketoacidosis), surgery (especially on the thyroid), or radioiodine treatment of a patient with partially treated or untreated hyperthyroidism. Management requires intensive monitoring and supportive care, identification and treatment of the precipitating cause, and measures that reduce thyroid hormone synthesis. Large doses of propylthiouracil (500–1000 mg loading dose and 250 mg every 4 h) should be given orally or by nasogastric tube or per rectum; the drug's inhibitory action on $T_4 \rightarrow T_3$ conversion makes it the antithyroid drug of choice. If not available, methimazole can be used in doses of 20 mg every 6 h. One hour after the first dose of propylthiouracil, stable iodide (5 drops SSKI every 6 h) is given to block thyroid hormone synthesis via the Wolff-Chaikoff effect (the delay allows the antithyroid drug to prevent the excess iodine from being incorporated into new hormone). Propranolol should also be given to reduce tachycardia and other adrenergic manifestations (60–80 mg PO every 4 h, or 2 mg IV every 4 h). Although other β-adrenergic blockers can be used, high doses of propranolol decrease $T_4 \rightarrow T_3$ conversion, and the doses can be easily adjusted. Caution is needed to avoid acute negative inotropic effects, but controlling the heart rate is important, as some patients develop a form of high-output heart failure. Short-acting IV esmolol can be used to decrease heart rate while monitoring for signs of heart failure. Additional therapeutic measures include glucocorticoids (e.g., hydrocortisone 300 mg IV bolus, then 100 mg every 8 h), antibiotics if infection is present, cholestyramine to sequester thyroid hormones, cooling, oxygen, and IV fluids.

Ophthalmopathy requires no active treatment when it is mild or moderate, because there is usually spontaneous improvement. General measures include meticulous control of thyroid hormone levels, cessation of smoking, and an explanation of the natural history of ophthalmopathy. Discomfort can be relieved with artificial tears (e.g., hypromellose 0.3% or carbomer 0.2% ophthalmic gel), paraffin-based eye ointment, and the use of dark glasses with side frames. Periorbital edema may respond to a more upright sleeping position or a diuretic. Corneal exposure during sleep can be avoided by using patches or taping the eyelids shut. Minor degrees of diplopia improve with prisms fitted to spectacles. Some authorities also advocate selenium 100 μg bid. Severe ophthalmopathy, with optic nerve involvement or chemosis resulting in corneal damage, is an emergency requiring joint management with an ophthalmologist. Pulse therapy with IV methylprednisolone (e.g., 500 mg of methylprednisolone once weekly for 6 weeks, then 250 mg once weekly for 6 weeks) is preferable to oral glucocorticoids, which are used for moderately active disease. When glucocorticoids are ineffective, orbital decompression can be achieved by removing bone from any wall of the orbit, thereby allowing displacement of fat and swollen extraocular muscles. The transantral route is used most often because it requires no external incision. Proptosis recedes an average of 5 mm, but there may be residual or even worsened diplopia. Once the eye disease has stabilized, surgery may be indicated for relief of diplopia and correction of the appearance. External beam radiotherapy of the orbits has been used for many years, but the efficacy of this therapy remains unclear, and it is best reserved for those with moderately active disease who have failed or are not candidates for glucocorticoid therapy.

Teprotumumab, a human monoclonal antibody, received breakthrough designation and was approved by the FDA in 2020. Randomized clinical trials of patients with active thyroid eye disease demonstrated rapid effects on proptosis, diplopia, clinical activity score, and quality of life. Responses appear comparable to surgery. Teprotumumab is administered at an initial dose of 10 mg/kg IV and thereafter at 20 mg/kg IV every 3 weeks for 21 weeks.

Thyroid dermopathy does not usually require treatment, but it can cause cosmetic problems or interfere with the fit of shoes. Surgical removal is not indicated. If necessary, treatment consists of topical, high-potency glucocorticoid ointment under an occlusive dressing. Octreotide may be beneficial in some cases.

OTHER CAUSES OF THYROTOXICOSIS

Destructive thyroiditis (subacute or silent thyroiditis) typically presents with a short thyrotoxic phase due to the release of preformed thyroid hormones and catabolism of Tg (see "Subacute Thyroiditis," below). True hyperthyroidism is absent, as demonstrated by a low radionuclide uptake. Circulating Tg levels are typically increased. Other causes of thyrotoxicosis with low or absent thyroid radionuclide uptake include *thyrotoxicosis factitia*, iodine excess, and, rarely, ectopic thyroid tissue, particularly teratomas of the ovary (*struma ovarii*) and functional metastatic follicular carcinoma. Whole-body radionuclide studies can demonstrate ectopic thyroid tissue, and thyrotoxicosis factitia can be distinguished from destructive thyroiditis by the clinical features and low levels of Tg. Amiodarone treatment is associated with thyrotoxicosis in up to 10% of patients, particularly in areas of low iodine intake (see below).

TSH-secreting pituitary adenoma is a rare cause of thyrotoxicosis. It is characterized by the presence of an inappropriately normal or increased TSH level in a patient with hyperthyroidism, diffuse goiter, and elevated T_4 and T_3 levels **(Chap. 380)**. Elevated levels of the α subunit of TSH, released by the TSH-secreting adenoma, support this diagnosis, which can be confirmed by demonstrating the pituitary tumor on MRI or CT scan. A combination of transsphenoidal surgery, sella irradiation, and octreotide may be required to normalize TSH, because many of these tumors are large and locally invasive at the time of diagnosis. Radioiodine or antithyroid drugs can be used to control thyrotoxicosis.

Thyrotoxicosis caused by *toxic MNG* and *hyperfunctioning solitary nodules* is discussed below.

THYROIDITIS

There are several classification systems to describe the clinical syndromes of thyroiditis. One is based on the onset and duration of disease **(Table 384-3)**; others are based on the absence or presence of pain.

TABLE 384-3 Causes of Thyroiditis

Acute
Bacterial infection: especially *Staphylococcus, Streptococcus,* and *Enterobacter*
Fungal infection: *Aspergillus, Candida, Coccidioides, Histoplasma,* and *Pneumocystis*
Radiation thyroiditis after ^{131}I treatment
Amiodarone (may also be subacute or chronic)
Subacute
Viral (or granulomatous) thyroiditis
Silent thyroiditis (including postpartum thyroiditis)
Mycobacterial infection
Drug induced (interferon, amiodarone)
Chronic
Autoimmunity: focal thyroiditis, Hashimoto's thyroiditis, atrophic thyroiditis
Riedel's thyroiditis
Parasitic thyroiditis: echinococcosis, strongyloidiasis, cysticercosis
Traumatic: after palpation

ACUTE THYROIDITIS

Acute thyroiditis is rare and due to suppurative infection of the thyroid. In children and young adults, the most common cause is the presence of a piriform sinus, a remnant of the fourth branchial pouch that connects the oropharynx with the thyroid. Such sinuses are predominantly left-sided. A long-standing goiter and degeneration in a thyroid malignancy are risk factors in the elderly. The patient presents with thyroid pain, often referred to the throat or ears, and a small, tender goiter that may be asymmetric. Fever, dysphagia, and erythema over the thyroid are common, as are systemic symptoms of a febrile illness and lymphadenopathy.

The differential diagnosis of *thyroid pain* includes subacute or, rarely, chronic thyroiditis; hemorrhage into a cyst; malignancy including lymphoma; and, rarely, amiodarone-induced thyroiditis or amyloidosis. However, the abrupt presentation and clinical features of acute thyroiditis rarely cause confusion. The erythrocyte sedimentation rate (ESR) and white cell count are usually increased, but thyroid function is normal. Fine-needle aspiration (FNA) biopsy shows infiltration by polymorphonuclear leukocytes; culture of the sample can identify the organism. Caution is needed in immunocompromised patients as fungal, mycobacterial, or *Pneumocystis* thyroiditis can occur in this setting. Antibiotic treatment is guided initially by Gram stain and, subsequently, by cultures of the FNA biopsy. Surgery may be needed to drain an abscess, which can be localized by CT scan or ultrasound. Tracheal obstruction, septicemia, retropharyngeal abscess, mediastinitis, and jugular venous thrombosis may complicate acute thyroiditis but are uncommon with prompt use of antibiotics.

SUBACUTE THYROIDITIS

This is also termed *de Quervain's thyroiditis*, *granulomatous thyroiditis*, or *viral thyroiditis*. Many viruses have been implicated, including mumps, coxsackie, influenza, adenoviruses, and echoviruses, but attempts to identify the virus in an individual patient are often unsuccessful and do not influence management. Recently, subacute thyroiditis associated with the SARS-CoV-2 was described. The diagnosis of subacute thyroiditis is often overlooked because the symptoms can mimic pharyngitis. The peak incidence occurs at 30–50 years, and women are affected three times more frequently than men.

Pathophysiology The thyroid shows a characteristic patchy inflammatory infiltrate with disruption of the thyroid follicles and multinucleated giant cells within some follicles. The follicular changes progress to granulomas accompanied by fibrosis. Finally, the thyroid returns to normal, usually several months after onset. During the initial phase of follicular destruction, there is release of Tg and thyroid hormones, leading to increased circulating T_4 and T_3 and suppression of TSH **(Fig. 384-3)**. During this destructive phase, radioactive iodine uptake is low or undetectable. After several weeks, the thyroid is depleted of stored thyroid hormone and a phase of hypothyroidism typically occurs, with low unbound T_4 (and sometimes T_3) and moderately increased TSH levels. Radioactive iodine uptake returns to normal or is even increased as a result of the rise in TSH. Finally, thyroid hormone and TSH levels return to normal as the disease subsides.

Clinical Manifestations The patient usually presents with a painful and enlarged thyroid, sometimes accompanied by fever. There may be features of thyrotoxicosis or hypothyroidism, depending on the phase of the illness. Malaise and symptoms of an upper respiratory tract infection may precede the thyroid-related features by several weeks. In other patients, the onset is acute, severe, and without obvious antecedent. The patient typically complains of a sore throat, and examination reveals a small goiter that is exquisitely tender. Pain is often referred to the jaw or ear. Complete resolution is the usual outcome, but late-onset permanent hypothyroidism occurs in 15% of cases, particularly in those with coincidental thyroid autoimmunity. A prolonged course over many months, with one or more relapses, occurs in a small percentage of patients.

Laboratory Evaluation As depicted in Fig. 384-3, thyroid function tests characteristically evolve through three distinct phases over

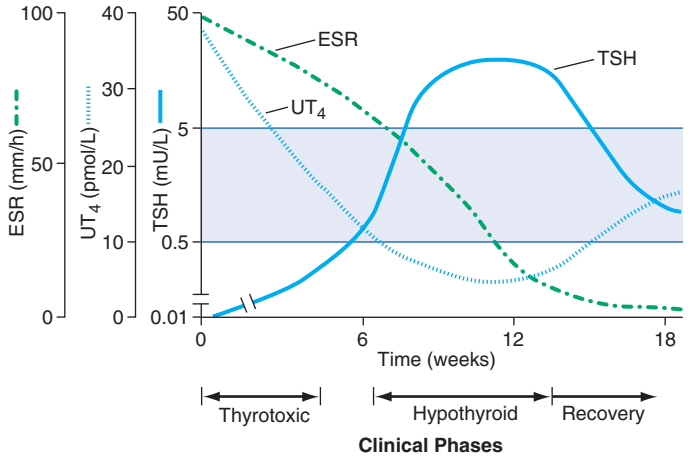

FIGURE 384-3 Clinical course of subacute thyroiditis. The release of thyroid hormones is initially associated with a thyrotoxic phase and suppressed thyroid-stimulating hormone (TSH). A hypothyroid phase then ensues, with low T_4 and TSH levels that are initially low but gradually increase. During the recovery phase, increased TSH levels combined with resolution of thyroid follicular injury lead to normalization of thyroid function, often several months after the beginning of the illness. ESR, erythrocyte sedimentation rate; UT_4, free or unbound T_4.

about 6 months: (1) thyrotoxic phase, (2) hypothyroid phase, and (3) recovery phase. In the thyrotoxic phase, T_4 and T_3 levels are increased, reflecting their discharge from the damaged thyroid cells, and TSH is suppressed. The T_4/T_3 ratio is greater than in Graves' disease or thyroid autonomy, in which T_3 is often disproportionately increased. The diagnosis is confirmed by a high ESR and low uptake of radioiodine (<5%) or ^{99m}Tc pertechnetate (as compared to salivary gland pertechnetate concentration). The white blood cell count may be increased, and thyroid antibodies are negative. If the diagnosis is in doubt, FNA biopsy may be useful, particularly to distinguish unilateral involvement from bleeding into a cyst or neoplasm.

TREATMENT

Subacute Thyroiditis

Relatively large doses of aspirin (e.g., 600 mg every 4–6 h) or nonsteroidal anti-inflammatory drugs (NSAIDs) are sufficient to control symptoms in many cases. If this treatment is inadequate, or if the patient has marked local or systemic symptoms, glucocorticoids should be given. The usual starting dose is 15–40 mg of prednisone, depending on severity. The dose is gradually tapered over 6–8 weeks, in response to improvement in symptoms and the ESR. If a relapse occurs during glucocorticoid withdrawal, the dosage should be increased and then withdrawn more gradually. Thyroid function should be monitored every 2–4 weeks using TSH and free T_4 levels. Symptoms of thyrotoxicosis improve spontaneously but may be ameliorated by β-adrenergic blockers; antithyroid drugs play no role in treatment of the thyrotoxic phase. LT4 replacement may be needed if the hypothyroid phase is prolonged, but doses should be low enough (50–100 μg daily) to allow TSH-mediated recovery.

SILENT THYROIDITIS

Painless thyroiditis, or "*silent*" *thyroiditis*, occurs in patients with underlying autoimmune thyroid disease and has a clinical course similar to that of subacute thyroiditis. The condition occurs in up to 5% of women 3–6 months after pregnancy and is then termed *postpartum thyroiditis*. Typically, patients have a brief phase of thyrotoxicosis lasting 2–4 weeks, followed by hypothyroidism for 4–12 weeks, and then resolution; often, however, only one phase is apparent. The condition is associated with the presence of TPO antibodies antepartum, and it is three times more common in women with type 1 diabetes mellitus. As in subacute thyroiditis, the uptake of ^{99m}Tc pertechnetate or radioactive iodine is initially suppressed. In addition to the painless goiter, silent thyroiditis can be distinguished from subacute thyroiditis by a normal ESR and the presence of TPO antibodies. Glucocorticoid treatment is not indicated for silent thyroiditis. Severe thyrotoxic symptoms can be managed with a brief course of propranolol, 20–40 mg three or four times daily. Thyroxine replacement may be needed for the hypothyroid phase but should be withdrawn after 6–9 months, as recovery is the rule. Annual follow-up thereafter is recommended, because a proportion of these individuals develop permanent hypothyroidism. The condition may recur in subsequent pregnancies.

DRUG-INDUCED THYROIDITIS

Patients receiving cytokines, such as IFN-α, tyrosine kinase inhibitors, and immune checkpoint inhibitors may develop painless thyroiditis. IFN-α, which is used to treat chronic hepatitis B or C and hematologic and skin malignancies, causes thyroid dysfunction in up to 5% of treated patients. It has been associated with painless thyroiditis, hypothyroidism, and Graves' disease and is most common in women with TPO antibodies prior to treatment. For discussion of amiodarone, see "Amiodarone Effects on Thyroid Function," below.

CHRONIC THYROIDITIS

Focal thyroiditis is present in 20–40% of euthyroid autopsy cases and is associated with serologic evidence of autoimmunity, particularly the presence of TPO antibodies. The most common clinically apparent cause of chronic thyroiditis is *Hashimoto's thyroiditis*, an autoimmune disorder that often presents as a firm or hard goiter of variable size (Chap. 383). *Riedel's thyroiditis* is a rare disorder that typically occurs in middle-aged women. It presents with an insidious, painless goiter with local symptoms due to compression of the esophagus, trachea, neck veins, or recurrent laryngeal nerves. Dense fibrosis disrupts normal gland architecture and can extend outside the thyroid capsule. Despite these extensive histologic changes, thyroid dysfunction is uncommon. The goiter is hard, nontender, often asymmetric, and fixed, leading to suspicion of a malignancy. Diagnosis requires open biopsy as FNA biopsy is usually inadequate. Treatment is directed to surgical relief of compressive symptoms. Tamoxifen may also be beneficial. There is an association between Riedel's thyroiditis and IgG4-related disease causing idiopathic fibrosis at other sites (retroperitoneum, mediastinum, biliary tree, lung, and orbit).

SICK EUTHYROID SYNDROME (NONTHYROIDAL ILLNESS)

Any acute, severe illness can cause abnormalities of circulating TSH or thyroid hormone levels in the absence of underlying thyroid disease, making these measurements potentially misleading. The major cause of these hormonal changes is the release of cytokines such as IL-6. Unless a thyroid disorder is strongly suspected, the routine testing of thyroid function should be avoided in acutely ill patients.

The most common hormone pattern in sick euthyroid syndrome (SES), also called nonthyroidal illness (NTI), is a decrease in total and unbound T_3 levels (low T_3 syndrome) with normal levels of T_4 and TSH. The magnitude of the fall in T_3 correlates with the severity of the illness. T_4 conversion to T_3 via peripheral 5′ (outer ring) deiodination is impaired, leading to increased reverse T_3 (rT_3). Since rT_3 is metabolized by 5′ deiodination, its clearance is also reduced. Thus, decreased clearance rather than increased production is the major basis for increased rT_3. Also, T_4 is alternately metabolized to the hormonally inactive T_3 sulfate. It is generally assumed that this low T_3 state is adaptive, because it can be induced in normal individuals by fasting. Teleologically, the fall in T_3 may limit catabolism in starved or ill patients.

Very sick patients may exhibit a dramatic fall in total T_4 and T_3 levels (low T_4 syndrome). With decreased tissue perfusion, muscle and liver expression of the type 3 deiodinase leads to accelerated T_4 and T_3 metabolism. This state has a poor prognosis. Another key factor in the fall in T_4 levels is altered binding to thyroxine-binding globulin (TBG). The commonly used free T_4 assays are subject to artifact when

serum binding proteins are low and underestimate the true free T_4 level. Fluctuation in TSH levels also creates challenges in the interpretation of thyroid function in sick patients. TSH levels may range from <0.1 mIU/L in very ill patients, especially with dopamine or glucocorticoid therapy, to >20 mIU/L during the recovery phase of SES. The exact mechanisms underlying the subnormal TSH seen in 10% of sick patients and the increased TSH seen in 5% remain unclear but may be mediated by cytokines including IL-12 and IL-18.

Any severe illness can induce changes in thyroid hormone levels, but certain disorders exhibit a distinctive pattern of abnormalities. Acute liver disease is associated with an initial rise in total (but not unbound) T_3 and T_4 levels due to TBG release; these levels become subnormal with progression to liver failure. A transient increase in total and unbound T_4 levels, usually with a normal T_3 level, is seen in 5–30% of acutely ill psychiatric patients. TSH values may be transiently low, normal, or high in these patients. In the early stage of HIV infection, T_3 and T_4 levels rise, even if there is weight loss. T_3 levels fall with progression to AIDS, but TSH usually remains normal. Renal disease is often accompanied by low T_3 concentrations, but with normal rather than increased rT_3 levels, due to an unknown factor that increases uptake of rT_3 into the liver.

The diagnosis of NTI is challenging. Historic information may be limited, and patients often have multiple metabolic derangements. Useful features to consider include previous history of thyroid disease and thyroid function tests, evaluation of the severity and time course of the patient's acute illness, documentation of medications that may affect thyroid function or thyroid hormone levels, and measurements of rT_3 together with unbound thyroid hormones and TSH. The diagnosis of NTI is frequently presumptive, given the clinical context and pattern of laboratory values; only resolution of the test results with clinical recovery can clearly establish this disorder. Treatment of NTI with thyroid hormone (T_4 and/or T_3) is controversial, but most authorities recommend monitoring the patient's thyroid function tests during recovery, without administering thyroid hormone, unless there is historic or clinical evidence suggestive of hypothyroidism. Sufficiently large randomized controlled trials using thyroid hormone are unlikely to resolve this therapeutic controversy in the near future, because clinical presentations and outcomes are highly variable.

AMIODARONE EFFECTS ON THYROID FUNCTION

Amiodarone is a commonly used type III antiarrhythmic agent **(Chap. 252)**. It is structurally related to thyroid hormone and contains 39% iodine by weight. Thus, typical doses of amiodarone (200 mg/d) are associated with very high iodine intake, leading to greater than fortyfold increases in plasma and urinary iodine levels. Moreover, because amiodarone is stored in adipose tissue, high iodine levels persist for >6 months after discontinuation of the drug. Amiodarone inhibits deiodinase activity, and its metabolites function as weak antagonists of thyroid hormone action. Amiodarone has the following effects on thyroid function: (1) acute, transient suppression of thyroid function; (2) inhibition of T_4 to T_3 conversion causing either euthyroid hyperthyroxinemia or increased dosage requirement in LT4-treated hypothyroid patients; (3) hypothyroidism in patients susceptible to the inhibitory effects of a high iodine load; and (4) thyrotoxicosis that may be caused by either a Jod-Basedow effect from the iodine load, in the setting of MNG or incipient Graves' disease, or a thyroiditis-like condition due to a toxic effect on thyroid follicular cells.

The initiation of amiodarone treatment is associated with a transient decrease of T_4 levels, reflecting the inhibitory effect of iodine on T_4 release. Soon thereafter, most individuals escape from iodide-dependent suppression of the thyroid (Wolff-Chaikoff effect), and the inhibitory effects on deiodinase activity and thyroid hormone receptor action become predominant. These events lead to the following pattern of thyroid function tests: increased T_4, decreased T_3, increased rT_3, and a transient TSH increase (up to 20 mIU/L). TSH levels normalize or are slightly suppressed within 1–3 months.

The incidence of hypothyroidism from amiodarone varies geographically, apparently correlating with iodine intake. Hypothyroidism occurs in up to 13% of amiodarone-treated patients in iodine-replete countries, such as the United States, but is less common (<6% incidence) in areas of lower iodine intake, such as Italy or Spain. The pathogenesis appears to involve an inability of the thyroid gland to escape from the Wolff-Chaikoff effect in autoimmune thyroiditis. Consequently, amiodarone-associated hypothyroidism is more common in women and individuals with positive TPO antibodies. It is usually unnecessary to discontinue amiodarone for this side effect, because LT4 can be used to normalize thyroid function. TSH levels should be monitored, because T_4 levels are often increased for the reasons described above. In addition, TSH levels need to be monitored in LT4-replaced hypothyroid patients because a dosage increase is often required.

The management of amiodarone-induced thyrotoxicosis (AIT) is complicated by the fact that there are different causes of thyrotoxicosis and because the increased thyroid hormone levels exacerbate underlying arrhythmias and coronary artery disease. Amiodarone treatment causes thyrotoxicosis in 10% of patients living in areas of low iodine intake and in 2% of patients in regions of high iodine intake. There are two major forms of AIT, although some patients have features of both. Type 1 AIT is associated with an underlying thyroid abnormality (preclinical Graves' disease or nodular goiter). Thyroid hormone synthesis becomes excessive as a result of increased iodine exposure (Jod-Basedow phenomenon). Type 2 AIT occurs in individuals with no intrinsic thyroid abnormalities and is the result of drug-induced lysosomal activation leading to destructive thyroiditis with histiocyte accumulation in the thyroid; the incidence rises as cumulative amiodarone dosage increases. Mild forms of type 2 AIT can resolve spontaneously or can occasionally lead to hypothyroidism. Color-flow Doppler ultrasonography shows increased vascularity in type 1 AIT but decreased vascularity in type 2 AIT. Thyroid scintiscans are difficult to interpret in this setting because the high endogenous iodine levels diminish tracer uptake. However, the presence of normal or rarely increased uptake favors type 1 AIT.

In AIT, the drug should be stopped, if possible, although this is often impractical because of the underlying cardiac disorder. Discontinuation of amiodarone will not have an acute effect because of its storage and prolonged half-life. High doses of antithyroid drugs can be used in type 1 AIT but are often ineffective. Potassium perchlorate, 200 mg every 6 h, has been used to reduce thyroidal iodide content. Perchlorate treatment has been associated with agranulocytosis, although the risk appears relatively low with short-term use. Glucocorticoids, as administered for subacute thyroiditis, have modest benefit in type 2 AIT and are generally initiated as prednisone 40 mg PO daily. Lithium blocks thyroid hormone release and can also provide some benefit. Near-total thyroidectomy rapidly decreases thyroid hormone levels and may be the most effective long-term solution if the patient can undergo the procedure safely.

385 Thyroid Nodular Disease and Thyroid Cancer

J. Larry Jameson, Susan J. Mandel, Anthony P. Weetman

GOITER AND THYROID NODULAR DISEASE

Goiter refers to an enlarged thyroid gland. Biosynthetic defects, iodine deficiency, autoimmune disease, and nodular diseases can each lead to goiter, although by different mechanisms. Biosynthetic defects and iodine deficiency are associated with reduced efficiency of thyroid hormone synthesis, leading to increased thyroid-stimulating hormone (TSH), which stimulates thyroid growth as a compensatory mechanism to overcome the block in hormone synthesis. Graves' disease and Hashimoto's thyroiditis are also associated with goiter. In Graves' disease, the goiter results mainly from the TSH-R–mediated effects of thyroid-stimulating immunoglobulins. The goitrous form of Hashimoto's thyroiditis occurs because of acquired defects in hormone synthesis, leading to elevated levels of TSH and its consequent growth effects. Lymphocytic infiltration and immune system–induced growth factors also contribute to thyroid enlargement in Hashimoto's thyroiditis.

Thyroid nodular disease is characterized by the disordered growth of thyroid cells, which can be either hyperplastic or neoplastic. A patient may have a multinodular goiter (MNG) in which thyroid nodules (generally hyperplastic) replace the majority of the normal thyroid parenchyma; this presentation is more common in areas of borderline iodine deficiency. Or, the thyroid gland may be normal in size and contain discrete thyroid nodules. Because the management of goiter depends on the etiology, the detection of thyroid enlargement on physical examination should prompt further evaluation to identify its cause.

Nodular thyroid disease is common, occurring in about 3–7% of adults when assessed by physical examination. Using ultrasound, nodules are present in up to 50% of adults, with the majority being <1 cm in diameter. Thyroid nodules may be solitary or multiple, and they may be functional or nonfunctional.

DIFFUSE NONTOXIC (SIMPLE) GOITER

Etiology and Pathogenesis When diffuse enlargement of the thyroid occurs in the absence of nodules and hyperthyroidism, it is referred to as a *diffuse nontoxic goiter*. This is sometimes called *simple goiter*, because of the absence of nodules, or *colloid goiter*, because of the presence of uniform follicles that are filled with colloid. Worldwide, diffuse goiter is most commonly caused by iodine deficiency and is termed *endemic goiter* when it affects >5% of the population. In nonendemic regions, *sporadic goiter* occurs, and the cause is usually unknown. Thyroid enlargement in teenagers is sometimes referred to as *juvenile goiter*. In general, goiter is more common in women than men, probably because of the greater prevalence of underlying autoimmune disease and the increased iodine demands associated with pregnancy.

In *iodine-deficient areas*, thyroid enlargement reflects a compensatory effort to trap iodide and produce sufficient hormone under conditions in which hormone synthesis is relatively inefficient. Somewhat surprisingly, TSH levels are usually normal or only slightly increased, suggesting increased sensitivity to TSH or activation of other pathways that lead to thyroid growth. Iodide appears to have direct actions on thyroid vasculature and may indirectly affect growth through vasoactive substances such as endothelins and nitric oxide. Endemic goiter may also be caused by exposure to environmental *goitrogens* such as cassava root, which contains a thiocyanate; vegetables of the Cruciferae family (known as cruciferous vegetables) (e.g., Brussels sprouts, cabbage, and cauliflower); and milk from regions where goitrogens are present in grass. Although relatively rare, inherited defects in thyroid hormone synthesis lead to a diffuse nontoxic goiter. Abnormalities at each step of hormone synthesis, including iodide transport (sodium/iodide symporter [NIS]), thyroglobulin (Tg) synthesis, organification and coupling (thyroid peroxidase [TPO]), and the regeneration of iodide (dehalogenase), have been described.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

If thyroid function is preserved, most goiters are asymptomatic. Examination of a diffuse goiter reveals a symmetrically enlarged, nontender, generally soft gland without palpable nodules. Goiter is defined, somewhat arbitrarily, as a lateral lobe with a volume greater than the thumb of the individual being examined. On ultrasound, total thyroid volume exceeding 30 mL is considered abnormal. If the thyroid is markedly enlarged, it can cause tracheal or esophageal compression. These features are unusual, however, in the absence of nodular disease and fibrosis. *Substernal goiter* may obstruct the thoracic inlet. *Pemberton's sign* refers to facial and neck congestion due to jugular venous obstruction when the arms are raised above the head, a maneuver that draws the thyroid into the thoracic inlet. Respiratory flow measurements and CT or MRI should be used to evaluate substernal goiter in patients with obstructive signs or symptoms.

Thyroid function tests should be performed in all patients with goiter to exclude thyrotoxicosis or hypothyroidism. It is not unusual, particularly in iodine deficiency, to find a low total T_4, with normal T_3 and TSH, reflecting enhanced $T_4 \rightarrow T_3$ conversion. A low TSH with a normal free T_3 and free T_4, particularly in older patients, suggests the possibility of thyroid autonomy or undiagnosed Graves' disease, and is termed *subclinical thyrotoxicosis*. The benefit of treatment (typically with radioiodine) in subclinical thyrotoxicosis, versus follow-up and implementing treatment if free T_3 or free T_4 levels become abnormal, is unclear, but treatment is increasingly recommended in the elderly to reduce the risk of atrial fibrillation and bone loss. Low urinary iodine levels (<50 μg/L) support a diagnosis of iodine deficiency. Thyroid scanning is not generally necessary but will reveal increased uptake in iodine deficiency and most cases of dyshormonogenesis.

TREATMENT

Diffuse Nontoxic (Simple) Goiter

Iodine replacement induces variable regression of goiter in iodine deficiency, depending on duration and the degree of hyperplasia, with accompanying fibrosis, and autonomous function that may have developed. Surgery is rarely indicated for diffuse goiter. Exceptions include documented evidence of tracheal compression or obstruction of the thoracic inlet, which are more likely to be associated with substernal MNGs (see below). Subtotal or near-total thyroidectomy for these or cosmetic reasons should be performed by an experienced surgeon to minimize complication rates. Surgery should be followed by replacement with levothyroxine (LT4).

NONTOXIC MULTINODULAR GOITER

Etiology and Pathogenesis Depending on the population studied, MNG or the presence of nodules in a thyroid of normal size occurs in up to 12% of adults. MNG should be distinguished from the presence of nodules in a normal-size thyroid gland (see "Approach to the Patient with Thyroid Nodules"). MNG is more common in women than men and increases in prevalence with age. It is more common in iodine-deficient regions but also occurs in regions of iodine sufficiency, reflecting multiple genetic, autoimmune, and environmental influences on the pathogenesis.

There is typically wide variation in nodule size. Histology reveals a spectrum of morphologies ranging from hypercellular, hyperplastic regions to cystic areas filled with colloid. Fibrosis is often extensive, and areas of hemorrhage or lymphocytic infiltration may be seen. Using molecular techniques, most nodules within an MNG are polyclonal in origin, suggesting a hyperplastic response to locally produced growth factors and cytokines. TSH, which is usually not elevated, may play a permissive or contributory role. Monoclonal neoplastic lesions may also occur, reflecting mutations in genes that confer a selective growth advantage to the progenitor cell.

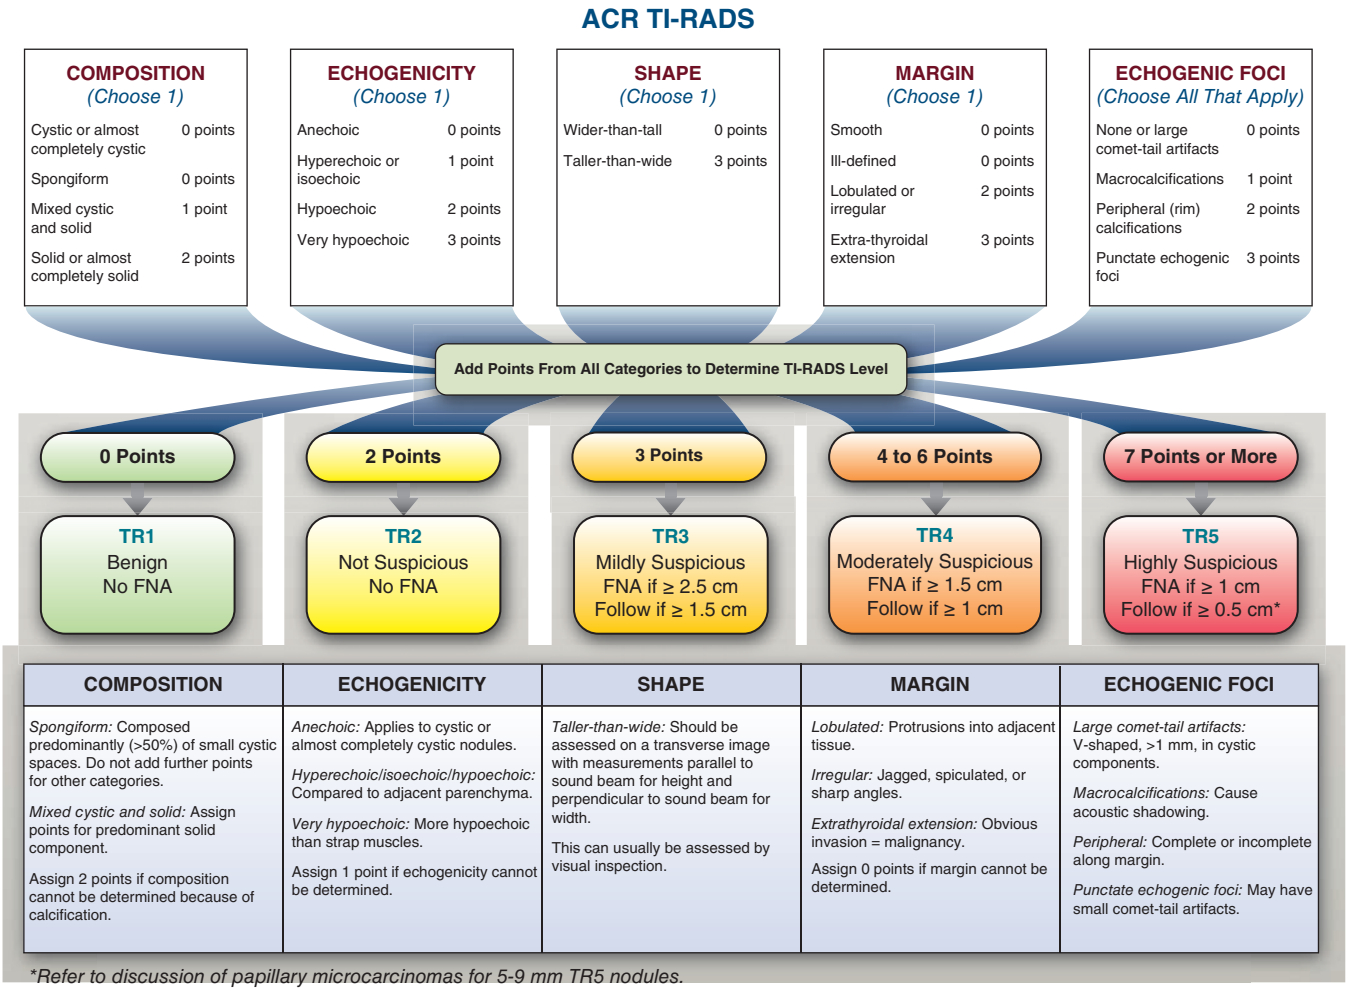

FIGURE 385-1 American College of Radiology (ACR) Thyroid Imaging Reporting and Data System (TI-RADS). TI-RADS is a five-tiered system categorizing the sonographic appearance of thyroid nodules based on increased risk for malignancy. For each level (TR1–5), there are recommendations for both fine-needle aspiration (FNA) minimum size cutoffs and follow-up. *(Reproduced with permission from FN Tessler et al: ACR Thyroid Imaging, Reporting and Data System (TI-RADS): White Paper of the ACR TI-RADS Committee. J Am Coll Radiol 14:587, 2017.)*

Clinical Manifestations Most patients with nontoxic MNG are asymptomatic and euthyroid. MNG typically develops over many years and is detected on routine physical examination, when an individual notices an enlargement in the neck, or as an incidental finding on imaging. If the goiter is large enough, it can ultimately lead to compressive symptoms including difficulty swallowing, respiratory distress (tracheal compression), or plethora (venous congestion), but these symptoms are uncommon. Symptomatic MNGs are usually extraordinarily large and/or develop fibrotic areas that cause compression. Sudden pain in an MNG is usually caused by hemorrhage into a nodule. Hoarseness, reflecting laryngeal nerve involvement may suggest malignancy but more commonly is due to others causes such as gastroesophageal reflux.

Diagnosis On examination, thyroid architecture is distorted, and multiple nodules of varying size can be appreciated. Because many nodules are deeply embedded in thyroid tissue or reside in posterior or substernal locations, it is not possible to palpate all nodules. Pemberton's sign, characterized by facial suffusion when the patient's arms are elevated above the head, suggests that the goiter has increased pressure in the thoracic inlet. A TSH level should be measured to exclude subclinical hyper- or hypothyroidism, but thyroid function is usually normal. Tracheal deviation is common, but compression must usually exceed 70% of the tracheal diameter before there is significant airway compromise. Pulmonary function testing can be used to assess the functional effects of compression, which characteristically causes inspiratory stridor. CT or MRI can be used to evaluate the anatomy of the goiter and the extent of substernal extension or tracheal narrowing. A barium swallow may reveal the extent of esophageal compression. The risk of malignancy in MNG is similar to that in solitary nodules. Ultrasonography should be used to identify which nodules should be biopsied based on a combination of size and sonographic pattern (Fig. 385-1) (Chap. 382). For nodules with more suspicious sonographic patterns (e.g., hypoechoic solid nodules with infiltrative borders), biopsy is recommended at a lower size cutoff than those with less suspicious imaging features (Figs. 385-1 and 385-2).

TREATMENT

Nontoxic Multinodular Goiter

Most nontoxic MNGs can be managed conservatively. T_4 suppression is rarely effective for reducing goiter size and introduces the risk of subclinical or overt thyrotoxicosis, particularly if there is underlying autonomy or if it develops during treatment. Contrast agents and other iodine-containing substances should be avoided because of the risk of inducing the *Jod-Basedow effect*, characterized by enhanced thyroid hormone production by autonomous nodules. Radioiodine has been used when surgery is contraindicated in areas where large nodular goiters are more prevalent (e.g., some areas of Europe and Brazil) because it can decrease MNG volume and may selectively ablate regions of autonomy. Dosage of ^{131}I depends on the size of the goiter and radioiodine uptake but is usually about 3.7 MBq (0.1 mCi) per gram of tissue, corrected for uptake

(typical dose 370–1070 MBq [10–29 mCi]). Repeat treatment may be needed, and effectiveness may be increased by concurrent administration of low-dose recombinant TSH (0.1 mg IM). It is possible to achieve a 40–50% reduction in goiter size in most patients. Earlier concerns about radiation-induced thyroid swelling and tracheal compression have diminished, as studies have shown this complication to be rare. When acute compression occurs, glucocorticoid treatment or surgery may be needed. Radiation-induced hypothyroidism is less common than after treatment for Graves' disease. However, posttreatment autoimmune thyrotoxicosis may occur in up to 5% of patients treated for nontoxic MNG. Surgery remains highly effective but is not without risk, particularly in older patients with underlying cardiopulmonary disease.

TOXIC MULTINODULAR GOITER

The pathogenesis of toxic MNG appears to be similar to that of nontoxic MNG; the major difference is the presence of functional autonomy in toxic MNG. The molecular basis for autonomy in toxic MNG remains unknown. As in nontoxic goiters, many nodules are polyclonal, whereas others are monoclonal and vary in their clonal origins. Genetic abnormalities known to confer functional autonomy, such as activating TSH-R or $G_s\alpha$ mutations (see below), are not usually found in the autonomous regions of toxic MNG goiter.

In addition to features of goiter, the clinical presentation of toxic MNG includes subclinical or mild overt hyperthyroidism. The patient is usually elderly and may present with atrial fibrillation or palpitations, tachycardia, nervousness, tremor, or weight loss. Recent exposure to iodine, from contrast dyes or other sources, may precipitate or exacerbate thyrotoxicosis. The TSH level is low. The uncombined T_4 level may be normal or minimally increased; T_3 is often elevated to a greater degree than T_4. Thyroid scan shows heterogeneous uptake with multiple regions of increased and decreased uptake; 24-h uptake of radioiodine may not be increased but is usually in the upper normal range.

Prior to definitive treatment of the hyperthyroidism, ultrasound imaging should be performed to assess the presence of discrete nodules corresponding to areas of decreased uptake ("cold" nodules). If present, fine-needle aspiration (FNA) may be indicated based on sonographic patterns and size cutoffs (see "Approach to the Patient with Thyroid Nodules"). The cytology results, if indeterminate or suspicious, may direct the therapy to surgery.

TREATMENT

Toxic Multinodular Goiter

Antithyroid drugs normalize thyroid function and are particularly useful in the elderly or ill patients with limited life span. In contrast to Graves' disease, spontaneous remission does not occur and so treatment is long term. Radioiodine is generally the treatment of choice; it treats areas of autonomy as well as decreasing the mass of the goiter by ablating the functioning nodules. Sometimes, however, a degree of autonomy may persist, presumably because multiple autonomous regions may emerge after others are treated, and further radioiodine treatment may be necessary. Surgery provides definitive treatment of underlying thyrotoxicosis as well as goiter. Patients should be rendered euthyroid using an antithyroid drug before operation.

HYPERFUNCTIONING SOLITARY NODULE

A solitary, autonomously functioning thyroid nodule is referred to as *toxic adenoma*. The pathogenesis of this disorder has been unraveled by demonstrating the functional effects of mutations that stimulate the TSH-R signaling pathway. Most patients with solitary hyperfunctioning nodules have acquired somatic, activating mutations in the TSH-R **(Fig. 385-3)**. These mutations, located primarily in the receptor transmembrane domain, induce constitutive receptor coupling to $G_s\alpha$, increasing cyclic adenosine monophosphate (AMP) levels and leading to enhanced thyroid follicular cell proliferation and function. Less commonly, somatic mutations are identified in $G_s\alpha$. These mutations, which are similar to those seen in McCune-Albright syndrome **(Chap. 412)** or in a subset of somatotrope adenomas **(Chap. 380)**, impair guanosine triphosphate (GTP) hydrolysis, causing constitutive activation of the cyclic AMP signaling pathway. In most series, activating mutations in either the TSH-R or the $G_s\alpha$ subunit genes are identified in >90% of patients with solitary hyperfunctioning nodules.

Thyrotoxicosis is usually mild and is generally only detected when a nodule is >3 cm. The disorder is suggested by a subnormal TSH level; the presence of the thyroid nodule, often large enough to be palpable; and the absence of clinical features suggestive of Graves' disease or other causes of thyrotoxicosis. A thyroid scan provides a definitive diagnostic test, demonstrating focal uptake in the hyperfunctioning nodule and diminished uptake in the remainder of the gland, as activity of the normal thyroid is suppressed.

TREATMENT

Hyperfunctioning Solitary Nodule

Radioiodine ablation is usually the treatment of choice. Because normal thyroid function is suppressed, ^{131}I is concentrated in the hyperfunctioning nodule with minimal uptake and damage to

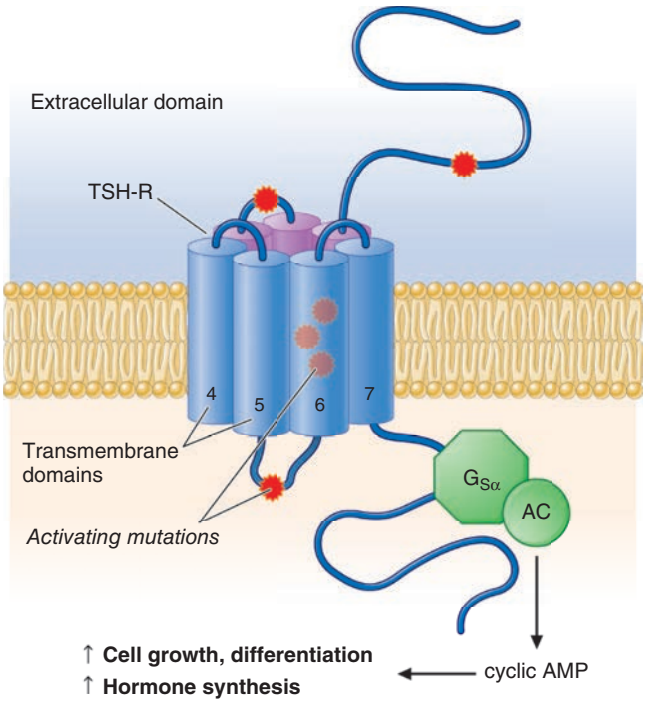

FIGURE 385-3 Activating mutations of the thyroid-stimulating hormone receptor (TSH-R). Mutations (*) that activate TSH-R reside mainly in transmembrane 5 and intracellular loop 3, although mutations have occurred in a variety of different locations. The effect of these mutations is to induce conformational changes that mimic TSH binding, thereby leading to coupling to stimulatory G protein ($G_{S\alpha}$) and activation of adenylate cyclase (AC), an enzyme that generates cyclic AMP.

normal thyroid tissue. Relatively large radioiodine doses (e.g., 370–1110 MBq [10–29.9 mCi] ^{131}I) have been shown to correct thyrotoxicosis in ~75% of patients within 3 months. Hypothyroidism occurs in <10% of those patients over the next 5 years. Surgical resection is also effective and is usually limited to lobectomy, thereby preserving thyroid function and minimizing risk of hypoparathyroidism or damage to the recurrent laryngeal nerves. Medical therapy using antithyroid drugs and beta blockers can normalize thyroid function but is not an optimal long-term treatment. Using ultrasound guidance, percutaneous radiofrequency ablation has been used successfully in some centers to ablate hyperfunctioning nodules, and this technique has also been used to reduce the size of nonfunctioning thyroid nodules.

BENIGN LESIONS

The various types of benign thyroid nodules are listed in Table 385-1. Benign nodules may be hyperplastic and reflect a combination of both macro- and microfollicular architecture or they may be neoplastic, encapsulated adenomas that generally have a more monotonous microfollicular pattern. If the adenoma is composed of oncocytic follicular cells arranged in a follicular pattern, this is termed Hürthle cell adenoma. Hyperplastic nodules generally appear as mixed cystic/solid or spongiform lesions on ultrasound. The definition of spongiform requires the presence of microcystic areas comprising >50% of the nodule volume, with the concept that this microcystic sonographic pattern recapitulates the histology of macrofollicles containing colloid (Fig. 385-2*B*). However, the majority of solid nodules (whether hypo-, iso-, or hyperechoic) are also benign. FNA, usually performed with ultrasound guidance, is the diagnostic procedure of choice to evaluate thyroid nodules (see the "Approach to the Patient with Thyroid Nodules" section). Pure thyroid cysts, <1% of all thyroid growths, consist of colloid and are benign as well. Cysts frequently recur, even after repeated aspiration, and may require surgical excision if they are large. Ethanol ablation to sclerose the cyst has been used successfully for patients who are symptomatic.

TSH suppression with LT4 therapy does not decrease thyroid nodule size in iodine-sufficient populations. However, if there is relative iodine deficiency, both iodine and LT4 therapy have been demonstrated to decrease nodule volume. If LT4 is administered in this situation, the TSH should be maintained at or just below the lower limit of normal, but not frankly suppressed. If the nodule has not decreased in size after 6–12 months of therapy, treatment should be discontinued because little benefit is likely to accrue from long-term treatment; the risk of iatrogenic subclinical thyrotoxicosis should also be considered.

THYROID CANCER

Thyroid carcinoma is the most common malignancy of the endocrine system. Malignant tumors derived from the follicular epithelium are classified according to histologic features. Differentiated tumors, such as papillary thyroid cancer (PTC) or follicular thyroid cancer (FTC), are often curable, and the prognosis is good for patients identified with early-stage disease. In contrast, anaplastic thyroid cancer (ATC) is aggressive, responds poorly to treatment, and is associated with a bleak prognosis.

Over the past 30 years, the incidence of thyroid cancer has increased from 4.9 to >15 cases per 100,000 individuals in the United States. However, disease-specific mortality has only minimally increased. The increased incidence is predominantly attributable to small T1 papillary cancer tumors (<2 cm) and has led experts to consider that thyroid cancer is being overdiagnosed, suggesting that cancers are being detected that would otherwise be unlikely to harm a patient. The concept of cancer overdiagnosis is predicated upon the presence of a disease reservoir (the autopsy prevalence of PTC is ~25%), activities leading to disease detection (increased diagnostic imaging with incidental detection of nodules), and a mismatch in the directional rate between diagnosis and mortality (thyroid cancer disease-specific mortality not changed in 40 years). Similar trends have been observed worldwide, especially in countries with a higher proportion of privately financed health care, leading to increased resource utilization including imaging. The 20-year disease-specific mortality for low-risk

TABLE 385-2 Risk Factors for Thyroid Carcinoma in Patients with Thyroid Nodule from History and Physical Examination

History of head and neck irradiation before the age of 18, including mantle radiation for Hodgkin's disease and brain radiation for childhood leukemia or other cranial malignancies	Family history of papillary thyroid cancer in two or more first-degree relatives, MEN 2, or other genetic syndromes associated with thyroid malignancy (e.g., Cowden's syndrome, familial adenomatous polyposis, Carney complex, PTEN [phosphatase and tensin homolog] hamartoma tumor)
Exposure to ionizing radiation from fallout in childhood or adolescence	Vocal cord paralysis, hoarse voice
Age <20 or >65 years	Nodule fixed to adjacent structures
Rapidly enlarging neck mass	Lateral cervical lymphadenopathy (ipsilateral to the nodule)
Male gender	

Abbreviation: MEN, multiple endocrine neoplasia.

thyroid cancer is 1%. Fortunately, epidemiologic data in the United States document a decrease in new thyroid cancer diagnoses (62,450 cases in 2015 and 52,070 cases in 2019), and this trend correlates with the implementation of evidence-based guidelines that recommend higher size thresholds for nodule FNA.

Current trends in thyroid cancer care focus on (1) avoiding overdiagnosis by limiting FNA by sonographic risk stratification with size cutoffs; (2) limiting surgery, radioiodine, and subsequent surveillance for low-risk tumors; and (3) identifying patients at higher recurrence risk for more aggressive treatment and monitoring. Prognosis is worse in older persons (>65 years). Thyroid cancer is twice as common in women as men, but male gender is associated with a worse prognosis. Additional important risk factors include a history of childhood (before age 18) head or neck irradiation, evidence for local tumor fixation or gross metastatic involvement of lymph nodes, and the presence of distant metastases **(Table 385-2)**.

Several unique features of thyroid cancer facilitate its management: (1) thyroid nodules are amenable to biopsy by FNA; (2) iodine radioisotopes can be used to diagnose (^{123}I and ^{131}I) and potentially treat (^{131}I) differentiated thyroid cancer, reflecting the unique uptake of this anion by the thyroid gland; and (3) serum markers allow the detection of residual or recurrent disease, including the use of Tg levels for PTC and FTC and calcitonin for medullary thyroid cancer (MTC).

CLASSIFICATION

Thyroid neoplasms can arise in each of the cell types that populate the gland, including thyroid follicular cells, calcitonin-producing C cells, lymphocytes, and stromal and vascular elements, as well as metastases from other sites (Table 385-1). The American Joint Committee on Cancer (AJCC) staging system using the tumor, node, metastasis (TNM) classification is most commonly used **(Table 385-3)**.

TABLE 385-3 Definitions of AJCC TNM

Definition of Primary Tumor (T)

Papillary, Follicular, Poorly Differentiated, Hürthle Cell and Anaplastic Thyroid Carcinoma

T Category	T Criteria
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor ≤2 cm in greatest dimension limited to the thyroid
T1a	Tumor ≤1 cm in greatest dimension limited to the thyroid
T1b	Tumor >1 cm but ≤2 cm in greatest dimension limited to the thyroid
T2	Tumor >2 cm but ≤4 cm in greatest dimension limited to the thyroid
T3	Tumor >4 cm limited to the thyroid, or gross extrathyroidal extension invading only strap muscles
T3a	Tumor >4 cm limited to the thyroid
T3b	Gross extrathyroidal extension invading only strap muscles (sternohyoid, sternothyroid, thyrohyoid, or omohyoid muscles) from a tumor of any size
T4	Includes gross extrathyroidal extension beyond the strap muscles
T4a	Gross extrathyroidal extension invading subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve from a tumor of any size
T4b	Gross extrathyroidal extension invading prevertebral fascia or encasing the carotid artery or mediastinal vessels from a tumor of any size

Note: All categories may be subdivided: (s) solitary tumor and (m) multifocal tumor (the largest tumor determines the classification).

Definition of Regional Lymph Node (N)

N Category	N Criteria
NX	Regional lymph nodes cannot be assessed
N0	No evidence of locoregional lymph node metastasis
N0a	One or more cytologically or histologically confirmed benign lymph nodes
N0b	No radiologic or clinical evidence of locoregional lymph node metastasis
N1	Metastasis to regional nodes
N1a	Metastasis to level VI or VII (pretracheal, paratracheal, or prelaryngeal/Delphian, or upper mediastinal) lymph nodes. This can be unilateral or bilateral disease.
N1b	Metastasis to unilateral, bilateral, or contralateral lateral neck lymph nodes (levels I, II, III, IV, or V) or retropharyngeal lymph nodes

Definition of Distant Metastasis (M)

M Category	M Criteria
M0	No distant metastasis
M1	Distant metastasis
MX	Distant metastasis cannot be assessed

PATHOGENESIS AND GENETIC BASIS

Radiation Early studies of the pathogenesis of thyroid cancer focused on the role of external radiation, which predisposes to chromosomal breaks, leading to genetic rearrangements and loss of tumor-suppressor genes. External radiation of the mediastinum, face, head, and neck region was administered in the past to treat an array of conditions, including acne and enlargement of the thymus, tonsils, and adenoids. Radiation exposure increases the risk of benign and malignant thyroid nodules, is associated with multicentric cancers, and shifts the incidence of thyroid cancer to an earlier age group. Radiation from nuclear fallout also increases the risk of thyroid cancer. Children seem more predisposed to the effects of radiation than adults.

TSH and Growth Factors Many differentiated thyroid cancers express TSH receptors and, therefore, remain responsive to TSH. Higher serum TSH levels, even within normal range, are associated with increased thyroid cancer risk in patients with thyroid nodules. These observations provide the rationale for T_4 suppression of TSH in patients with thyroid cancer. Residual expression of TSH receptors also allows TSH-stimulated uptake of ^{131}I therapy (see below).

Oncogenes and Tumor-Suppressor Genes Thyroid cancers are monoclonal in origin, consistent with the idea that they originate as a consequence of mutations that confer a growth advantage to a single cell. In addition to increased rates of proliferation, some thyroid cancers exhibit impaired apoptosis and features that enhance invasion, angiogenesis, and metastasis. Thyroid neoplasms have been analyzed for a variety of genetic alterations, but without clear evidence of an ordered acquisition of somatic mutations as they progress from the benign to the malignant state. On the other hand, certain mutations, such as *RET/PTC* and *PAX-8-PPARγ1* rearrangements, are relatively specific for thyroid neoplasia.

As described above, activating mutations of the TSH-R and the $G_s\alpha$ subunit are associated with autonomously functioning nodules. Although these mutations induce thyroid cell growth, this type of nodule is almost always benign, likely because they drive differentiation pathways.

Activation of the RET-RAS-BRAF signaling pathway is seen in up to 70% of PTCs, although the types of mutations are heterogeneous. A variety of rearrangements involving the *RET* gene on chromosome 10 bring this receptor tyrosine kinase under the control of other promoters, leading to receptor overexpression. *RET* rearrangements occur in 20–40% of PTCs in different series and were observed with increased

frequency in tumors developing after the Chernobyl radiation accident. Rearrangements in PTC have also occurred for another tyrosine kinase gene, *TRK1*, which is located on chromosome 1. To date, the identification of PTC with *RET* or *TRK1* rearrangements has not proven useful for predicting prognosis or treatment responses. *BRAF* V600E mutations appear to be the most common genetic alteration in PTC. These mutations activate the kinase, which stimulates the mitogen-activated protein kinase (MAPK) cascade. *RAS* mutations, which also stimulate the MAPK cascade, are found in ~20–30% of thyroid neoplasms (*NRAS* > *HRAS* > *KRAS*), including both PTC follicular variant and FTC. Of note, simultaneous *RET*, *BRAF*, and *RAS* mutations rarely occur in the same tumor, suggesting that activation of the MAPK cascade is critical for tumor development, independent of the step that initiates the cascade.

RAS mutations also occur in FTCs. In addition, a rearrangement of the thyroid developmental transcription factor PAX8 with the nuclear receptor PPARγ is identified in a significant fraction of FTCs. Overall, ~70% of follicular cancers have mutations or genetic rearrangements. Loss of heterozygosity of 3p or 11q, consistent with deletions of tumor-suppressor genes, is also common in FTCs.

Most of the mutations seen in differentiated thyroid cancers have also been detected in ATCs. *TERT* promoter mutations occur in <10% of differentiated PTCs but are more common in ATC. *BRAF* mutations are seen in up to 50% of ATCs. Mutations in *CTNNB1*, which encodes β-catenin, occur in about two-thirds of ATCs, but not in PTC or FTC. Mutations of the tumor-suppressor *P53* also play an important role in the development of ATC. Because *P53* plays a role in cell-cycle surveillance, DNA repair, and apoptosis, its loss may contribute to the rapid acquisition of genetic instability as well as poor treatment responses **(Chap. 72)**.

The role of molecular diagnostics in the clinical management of thyroid cancer is under investigation. In principle, analyses of specific mutations might aid in classification, prognosis, or choice of treatment. Although *BRAF* V600E mutations are associated with loss of iodine uptake by tumor cells. As discussed below, trials of multikinase pathway inhibitors are ongoing as a means to restore iodine uptake and enhance sensitivity to radioiodine treatment. Higher recurrence rates have been variably reported in patients with *BRAF*-positive PTC, but the impact on survival rates is unclear.

MTC, when associated with multiple endocrine neoplasia (MEN) type 2, harbors an inherited mutation of the *RET* gene. Unlike the rearrangements of *RET* seen in PTC, the mutations in MEN 2 are point mutations that induce constitutive activity of the tyrosine kinase **(Chap. 388)**. MTC is preceded by hyperplasia of the C cells, raising the likelihood that as-yet-unidentified "second hits" lead to cellular transformation. A subset of sporadic MTC contains somatic mutations that activate *RET*.

WELL-DIFFERENTIATED THYROID CANCER

Papillary PTC is the most common type of thyroid cancer, accounting for 80–85% of well-differentiated thyroid malignancies. Microscopic PTC is present in up to 25% of thyroid glands at autopsy, but most of these lesions are very small (several millimeters) and are not clinically significant. Characteristic cytologic features of PTC help make the diagnosis by FNA or after surgical resection; these include, large, clear nuclei with powdery chromatin (described as an "orphan Annie eye" appearance) with nuclear grooves and prominent nucleoli. The histologic finding of these cells arranged in either papillary structures or follicles distinguishes the classic and follicular variants of PTC, respectively. There are several subtypes of papillary thyroid cancer. The more differentiated classic and follicular variants are likely to have an indolent course in the absence of angioinvasion or metastatic adenopathy. The aggressive variants (tall cell, columnar cell, hobnail, poorly differentiated) require more intensive therapy and closer follow-up. Recently, a subtype previously known as the encapsulated PTC follicular variant, without capsular or angioinvasion, is no longer considered malignant and has been renamed noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP).

PTC may be multifocal and invade locally within the thyroid gland as well as through the thyroid capsule and into adjacent structures in the neck. It has a propensity to spread via the lymphatic system but can metastasize hematogenously as well, particularly to bone and lung. Because of the relatively slow growth of the tumor, a significant burden of pulmonary metastases may accumulate, sometimes with remarkably few symptoms. The prognostic implication of lymph node spread depends on the volume of metastatic disease. Micrometastases, defined as <2 mm of cancer in a lymph node, do not affect prognosis. However, gross metastatic involvement of multiple 2- to 3-cm lymph nodes indicates a 25–30% chance of recurrence and may increase mortality in older patients. The staging of PTC by the TNM system is outlined in Table 385-3. Most papillary cancers are identified in the early stages (>95% stages I or II) and have an excellent prognosis, with survival curves similar to expected survival **(Fig. 385-4)**. Mortality is markedly increased in stage IV disease, especially in the presence of distant metastases (stage IVB), but this group comprises only about 1% of patients. The treatment of PTC is described below.

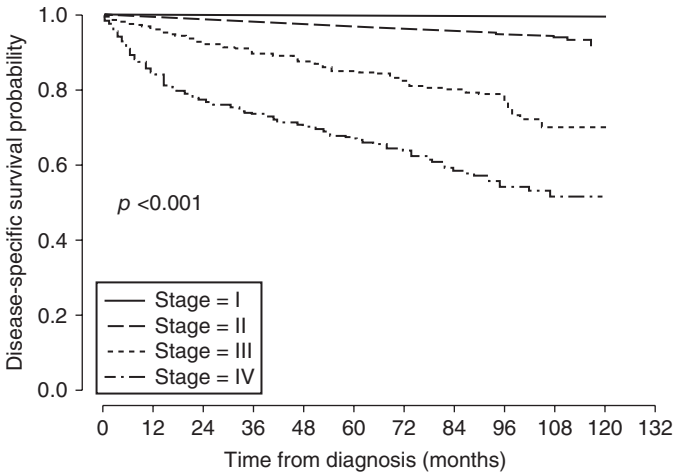

FIGURE 385-4 Unadjusted disease-specific survival curves for patients with papillary thyroid cancer in the AJCC/UICC 8th edition TNM staging system. *(Reproduced with permission from LN Pontius et al: Projecting survival in papillary thyroid cancer: A comparison of the seventh and eighth editions of the American Joint Commission on Cancer/Union for International Cancer Control staging systems in two contemporary national patient cohorts. Thyroid 27:1408, 2017.)*

Follicular The incidence of FTC varies widely in different parts of the world; it is more common in iodine-deficient regions. Currently, FTC accounts for only about 5% of all thyroid cancers diagnosed in the United States. FTC is difficult to diagnose by FNA because the distinction between benign and malignant follicular neoplasms requires histology because the nuclear features of follicular adenomas and carcinomas do not differ. Rather, follicular carcinoma is diagnosed by the presence of capsular and/or vascular invasion. Follicular carcinomas with only capsular invasion have a very low risk of metastasis, and lobectomy alone suffices. Angioinvasive FTC is more aggressive and may metastasize to bone, lung, and the central nervous system. Mortality rates associated with angioinvasive FTC are less favorable than for PTC, in part because a larger proportion of patients present with stage IV disease. Poor prognostic features include distant metastases, age >55 years, primary tumor size >4 cm, and the presence of marked vascular invasion.

TREATMENT

Surgery for Well-Differentiated Thyroid Cancer

All well-differentiated thyroid cancers >1 cm (T1b or larger) should be surgically excised, although active surveillance is an option for small intrathyroidal micropapillary thyroid cancers (T1a) without metastases. In addition to removing the primary lesion, surgery allows accurate histologic diagnosis and staging. Because there is no compelling evidence that bilateral thyroid surgery improves survival, the initial surgical procedure may be either a unilateral (lobectomy) or bilateral (near-total thyroidectomy) procedure for patients with intrathyroidal cancers >1 cm and <4 cm (T1b and T2 tumors) in the absence of metastatic disease and after a careful sonographic evaluation for metastatic cervical adenopathy. For patients at high risk for recurrence, bilateral surgery allows administration of radioiodine for remnant ablation and potential treatment

of iodine-avid metastases, if indicated, as well as for monitoring of serum Tg levels. Therefore, near-total thyroidectomy is appropriate for tumors >4 cm or in the presence of metastases or clinical evidence of extrathyroidal invasion. In addition, for patients found to have a high-risk tumor after lobectomy based upon aggressive pathology features (e.g., vascular invasion or a less differentiated subtype), completion surgery should be performed. Surgical complication rates are acceptably low if the surgeon is highly experienced in the procedure. Preoperative sonography should be performed in all patients to assess the central and lateral cervical lymph node compartments for suspicious adenopathy, which if present, should undergo FNA and be removed, as indicated, at surgery.

TSH SUPPRESSION THERAPY

Because most tumors are still TSH-responsive, LT4 suppression of TSH is a mainstay of thyroid cancer treatment. Although TSH suppression clearly provides therapeutic benefit, there are no prospective studies that define the optimal level of TSH suppression. The degree of TSH suppression should be individualized based on a patient's risk of recurrence. It should be adjusted over time as surveillance blood tests and imaging confirm absence of disease or, alternatively, indicate possible residual/recurrent cancer. For patients at low risk of recurrence, TSH should be maintained in the lower normal limit (0.5–2.0 mIU/L). For patients either at intermediate or high risk of recurrence, TSH levels should be kept to 0.1–0.5 mIU/L and <0.1 mIU/L, respectively, if there are no strong contraindications to mild thyrotoxicosis. TSH should be <0.1 mIU/L for those with known metastatic disease.

RADIOIODINE TREATMENT

After near-total thyroidectomy, <1 g of thyroid tissue remains in the thyroid bed. Postsurgical radioablation of the remnant thyroid eliminates residual normal thyroid, facilitating the use of Tg determinations. In addition, well-differentiated thyroid cancer often incorporates radioiodine, although less efficiently than normal thyroid follicular cells. Radioiodine uptake is determined primarily by expression of the NIS and is stimulated by TSH, requiring expression of the TSH-R. The retention time for radioactivity is influenced by the extent to which the tumor retains differentiated functions such as iodide trapping and organification. Consequently, for patients at higher risk of recurrence and for those with known distant metastatic disease, ^{131}I therapy may provide an adjuvant role and potentially treat residual tumor cells.

Indications Not all patients benefit from radioiodine therapy. Neither recurrence nor survival rates are improved in stage I patients with T1 tumors (≤2 cm) confined to the thyroid. No benefit has been demonstrated for larger (>2 cm but <4 cm) low-risk tumors. However, in higher risk patients (larger tumors, more aggressive variants of papillary cancer, tumor vascular invasion, extrathyroidal invasion, presence of large-volume lymph node metastases), radioiodine reduces recurrence and may increase survival for older patients.

^{131}I Thyroid Ablation and Treatment As noted above, the decision to use ^{131}I for thyroid ablation should be coordinated with the surgical approach, because radioablation is much more effective when there is minimal remaining normal thyroid tissue. Radioiodine is administered after iodine depletion (patient follows a low-iodine diet for 1–2 weeks) and in the presence of elevated serum TSH levels to stimulate uptake of the isotope into both the remnant and potentially any residual tumor. To achieve high serum TSH levels, there are two approaches. A patient may be withdrawn from thyroid hormone so that endogenous TSH is secreted and, ideally, the serum TSH level is >25 mIU/L at the time of ^{131}I therapy. A typical strategy is to treat the patient for several weeks postoperatively with liothyronine (25 μg qd or bid), followed by thyroid hormone withdrawal for 2 weeks. Alternatively, recombinant human TSH (rhTSH) is administered as two daily consecutive injections (0.9 mg) with administration of ^{131}I 24 h after the second injection. The patient can continue to take LT4 and remains euthyroid. Both approaches have equal success in achieving remnant ablation.

A pretreatment scanning dose of ^{131}I (usually 111 MBq [3 mCi]) or ^{123}I (74 MBq [2 mCi]) can reveal the amount of residual tissue and provides guidance about the dose needed to accomplish ablation. However, because of concerns about radioactive "stunning" that impairs subsequent treatment, there is a trend to avoid pretreatment scanning with ^{131}I and use either ^{123}I or proceed directly to ablation, unless there is suspicion that the amount of residual tissue will alter therapy or that there is distant metastatic disease. In the United States, outpatient doses of up to 6475 MBq (175 mCi) can be given at most centers. The administered dose depends on the indication for therapy, with lower doses of 1100 MBq (30 mCi) given for remnant ablation but higher doses of up to 5500 MBq (150 mCi) reserved for use as adjuvant therapy when residual disease is suspected or present. Whole-body scanning (WBS) following radioiodine treatment is used to confirm the ^{131}I uptake in the remnant and to identify possible metastatic disease.

Surveillance Testing Serum thyroglobulin is a sensitive marker of residual/recurrent thyroid cancer after ablation of the residual postsurgical thyroid tissue. Current Tg assays have functional sensitivities as low as 0.1 ng/mL, as opposed to older assays with functional sensitivities of 1–2 ng/mL, reducing the number of patients with truly undetectable serum Tg levels. Because the vast majority of PTC recurrences are in cervical lymph nodes, a neck ultrasound should be performed about 6 months after thyroid ablation; ultrasound has been shown to be more sensitive than WBS in this scenario.

In low-risk patients who have no clinical evidence of residual disease after ablation, negative cervical sonography, and a basal Tg <0.2 ng/mL on LT4, the risk of structural recurrence is <3% at 5 years, and the frequency of follow-up testing can be decreased to annual TSH and Tg testing, with only periodic ultrasound examination.

The use of WBS is reserved for patients with known iodine-avid metastases or those with elevated serum thyroglobulin levels and negative imaging with ultrasound, chest CT, neck cross-sectional imaging, and positron emission tomography (PET) CT who may require additional ^{131}I therapy.

In addition to radioiodine, external beam radiotherapy is also used to treat gross residual neck disease or specific metastatic lesions, particularly when they cause bone pain or threaten neurologic injury (e.g., vertebral metastases).

New Potential Therapies Kinase inhibitors target pathways known to be active in thyroid cancer, including the RAS, BRAF, RET, EGFR, VEGFR, and angiogenesis pathways. Treatment has been shown to stabilize progressive metastatic disease that is refractory to radioiodine therapy, although only one study has demonstrated improved survival. Given the significant associated toxicities and the need for ongoing therapy, patient selection is critical to limit systemic therapy to those with significant morbidity risk. The American Thyroid Association guidelines recommend active surveillance for asymptomatic patients with metastatic tumors between 1 and 2 cm and then intervention as the rate of tumor growth increases. In addition, based on genetic analyses of metastases, mutation-selective kinase inhibitors are now being used. Ongoing trials are also exploring whether differentiation protocols, targeting the MAPK pathway, might enhance radioiodine uptake and efficacy.

ANAPLASTIC AND OTHER FORMS OF THYROID CANCER

Anaplastic Thyroid Cancer As noted above, ATC is a poorly differentiated and aggressive cancer. The prognosis is poor, and most patients die within 6 months of diagnosis. Because of the undifferentiated state of these tumors, the uptake of radioiodine is usually negligible, but it can be used therapeutically if there is residual uptake. Chemotherapy has been attempted with multiple agents, including anthracyclines and paclitaxel, but it is usually ineffective. External beam radiation therapy can be attempted and continued if tumors are responsive. Both multitargeted and mutation-directed kinase inhibitors are in clinical trials and may prolong survival by a few months.

Thyroid Lymphoma Lymphoma in the thyroid gland often arises in the background of Hashimoto's thyroiditis. A rapidly expanding thyroid mass suggests the possibility of this diagnosis. Diffuse large-cell

lymphoma is the most common type in the thyroid. Biopsies reveal sheets of lymphoid cells that can be difficult to distinguish from small-cell lung cancer or ATC. These tumors are often highly sensitive to external radiation. Surgical resection should be avoided as initial therapy because it may spread disease that is otherwise localized to the thyroid. If staging indicates disease outside of the thyroid, treatment should follow guidelines used for other forms of lymphoma (Chap. 108).

MEDULLARY THYROID CARCINOMA

MTC can be sporadic or familial and accounts for ~5% of thyroid cancers. There are three familial forms of MTC: MEN 2A, MEN 2B, and familial MTC without other features of MEN (Chap. 388). In general, MTC is more aggressive in MEN 2B than in MEN 2A, and familial MTC is more aggressive than sporadic MTC. Elevated serum calcitonin provides a marker of residual or recurrent disease. All patients with MTC should be tested for *RET* mutations, because genetic counseling and testing of family members can be offered to those individuals who test positive for mutations.

The management of MTC is primarily surgical. Prior to surgery, pheochromocytoma should be excluded in all patients with a *RET* mutation. Unlike tumors derived from thyroid follicular cells, these tumors do not take up radioiodine. External radiation treatment and targeted kinase inhibitors may provide palliation in patients with advanced disease (Chap. 388).

APPROACH TO THE PATIENT

Thyroid Nodules

Palpable thyroid nodules are found in ~5% of adults, but the prevalence varies considerably worldwide. Given this high prevalence rate, practitioners may identify thyroid nodules on physical examination. However, the increased usage of diagnostic medical imaging (e.g., carotid ultrasound, cervical spine MRI) has led to an increased frequency of incidental nodule detection, accounting for the majority of patients currently presenting for nodule evaluation. The main goal of this evaluation is to identify, in a cost-effective manner, the small subgroup of individuals with malignant lesions that have the potential to be clinically significant.

Nodules are more common in iodine-deficient areas, in women, and with aging. Most palpable nodules are >1 cm in diameter, but the ability to feel a nodule is influenced by its location within the gland (superficial vs deeply embedded), the anatomy of the patient's neck, and the experience of the examiner. More sensitive methods of detection, such as CT, thyroid ultrasound, and pathologic studies, reveal thyroid nodules in up to 50% of glands in individuals aged >50 years. The presence of these thyroid incidentalomas has led to much debate about how to detect nodules and which nodules to investigate further.

An approach to the evaluation of thyroid nodules detected by either palpation or imaging is outlined in Fig. 385-5. Most patients with thyroid nodules have normal thyroid function tests. Nonetheless, thyroid function should be assessed by measuring a TSH level, which may be suppressed by one or more autonomously functioning nodules. If the TSH is suppressed, a radionuclide scan is indicated to determine if the identified nodule is "hot," as lesions with increased uptake are almost never malignant and FNA is unnecessary. Otherwise, the next step in evaluation is performance of a thyroid ultrasound for three reasons: (1) For nodules detected on physical examination, ultrasound will confirm if the palpable nodule is indeed a nodule. About 15% of "palpable" nodules are

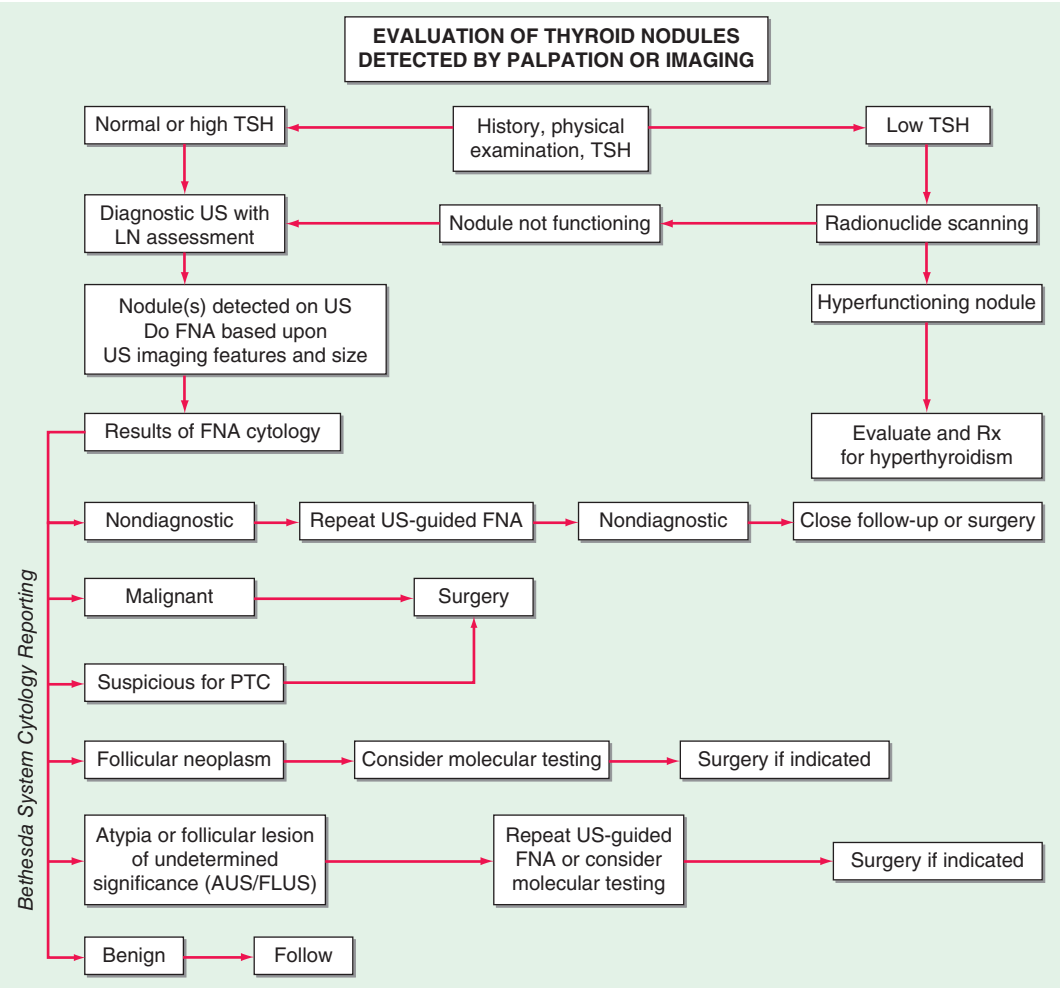

FIGURE 385-5 Approach to the patient with a thyroid nodule. See text and references for details. FNA, fine-needle aspiration; LN, lymph node; PTC, papillary thyroid cancer; Rx, therapy; TSH, thyroid-stimulating hormone; US, ultrasound.

not confirmed on imaging, and therefore no further evaluation is required. (2) Ultrasound will assess if there are additional nonpalpable nodules for which FNA may be recommended based on imaging features and size. (3) Ultrasound will characterize the imaging pattern of the nodule, which, combined with the nodule's size, facilitates decision-making about FNA. There are several validated risk stratification systems (RSS) for sonographic imaging of thyroid nodules (American College of Radiology [ACR] Thyroid Imaging Reporting and Data System [TI-RADS], American Thyroid Association, European Thyroid Association [EU-TIRADS], among others). These demonstrate consistent risk estimates for thyroid cancer based on certain sonographic patterns. All provide size cutoff recommendations for nodule FNA based on sonographic patterns, with lower size cutoffs for nodules with more suspicious ultrasound patterns, but the specific size cutoff criteria differ among the RSS. Not surprisingly, the RSSs with lower size cutoffs have higher sensitivity and lower specificity for thyroid cancer diagnosis than those with higher cutoffs. Nevertheless, all have been shown to reduce unnecessary FNAs by at least 45%, in part due to the recommendation not to perform FNA for spongiform nodules. ACR TI-RADS is currently the most widely used RSS in the United States, and nodules are classified from TR1 to TR5 (Fig. 385-1).

For example, a spongiform nodule (TR1) has a <3% chance of cancer, and observation rather than FNA is generally recommended by all RSSs, whereas 10–20% of solid hypoechoic nodules with smooth borders (TR4) are malignant and FNA is recommended at size cutoffs ranging from 1–1.5 cm. All the RSSs recommend FNA at 1 cm for the highest suspicion pattern nodule, TR5 (Figs. 385-1 and 385-2). Given what is known about the prevalence and generally indolent behavior of small thyroid cancers <1 cm, none of the RSSs recommend FNA for any nodule <1 cm unless metastatic cervical lymph nodes are present.

FNA biopsy, ideally performed with ultrasound guidance, is the best diagnostic test when performed by physicians familiar with the procedure and when the results are interpreted by experienced cytopathologists. The technique is particularly useful for detecting PTC. However, the distinction between benign and malignant follicular patterned lesions is often not possible using cytology alone because of the absence of characteristic nuclear features in follicular carcinoma. Using the current ultrasound RSS for FNA decision-making, FNA biopsies yield the following spectrum of cytology diagnoses: 55–60% benign, 5% malignant or suspicious for malignancy, 5–7% nondiagnostic or yielding insufficient material for diagnosis, and 25–30% indeterminate. The Bethesda System is now widely used to provide more uniform terminology for reporting thyroid nodule FNA cytology results. This six-tiered classification system with the respective estimated malignancy rates is shown in **Table 385-4**. Importantly, because NIFTP can only be diagnosed by surgical pathology, NIFTP is included in the malignancy estimates. Specifically, the Bethesda System subcategorized cytology specimens previously labeled as indeterminate into three categories: atypia or follicular lesion of undetermined significance (AUS/FLUS), follicular neoplasm, and suspicious for malignancy.

TABLE 385-4 Bethesda Classification for Thyroid Cytology Version 2

DIAGNOSTIC CATEGORY	RISK OF MALIGNANCY (INCLUDING NIFTP)
I. Nondiagnostic or unsatisfactory	5–10%
II. Benign	0–3%
III. Atypia or follicular lesion of unknown significance (AUS/FLUS)	~10–30%
IV. Follicular neoplasm	25–40%
V. Suspicious for malignancy	50–75%
VI. Malignant	97–99%

Abbreviation: NIFTP, noninvasive follicular thyroid neoplasm with papillary-like nuclear features.

Cytology results indicative of malignancy generally mandate surgery, after performing preoperative sonography to evaluate the cervical lymph nodes. Nondiagnostic cytology specimens most often result from cystic lesions but may also occur in fibrous long-standing nodules or very vascular nodules where a longer needle dwell time may result in a hemorrhagic specimen. Ultrasound-guided FNA is indicated when a repeat FNA is necessary. Repeat FNA will yield a diagnostic cytology in ~50% of cases. Given the low false-negative rate of a benign cytology (<3%), benign nodules with a low suspicion sonographic pattern (TR2, TR3) can be followed. Those with more worrisome ultrasound features, especially TR5 nodules, should undergo repeat FNA because of a higher likelihood of a missed malignancy. The use of LT4 to suppress serum TSH is not effective in shrinking nodules in iodine-replete populations, and therefore, LT4 suppression should not be used. The three indeterminate cytology classifications introduced by the Bethesda System are associated with different risks of malignancy (Table 385-4). For nodules with suspicious for malignancy cytology, surgery is recommended after ultrasound assessment of cervical lymph nodes. Options to be discussed with the patient include lobectomy versus total thyroidectomy.

On the other hand, the majority of nodules with AUS/FLUS and follicular neoplasm cytology results are benign; the range of malignancy (ROM) varies from 10 to 40%. The traditional approach for these patients is diagnostic lobectomy for histopathologic diagnosis. Therefore, many patients undergo surgery for benign nodules. Over the past decade, the uncertainty about the ROM for indeterminate cytology nodules has been the driver for the development of molecular testing, which can better differentiate benign from malignant nodules. Based on results from next-generation sequencing, which includes point mutations, small insertions/deletions, and gene fusions, as well as results from microRNA analyses and gene expression, the current validated and commercially available molecular tests combine these techniques with the following two goals: (1) risk stratification of thyroid nodules based on a positive result; and (2) reduction in cancer risk to an acceptable level for nonsurgical surveillance based on a negative result. Assuming a 25–30% ROM for nodules with indeterminate cytology, the negative predictive values for the currently validated molecular tests are >95%.

The evaluation of a thyroid nodule is stressful for most patients. They are concerned about the possibility of thyroid cancer, whether verbalized or not. It is constructive, therefore, to review the diagnostic approach and to reassure patients when no malignancy is found. When a suspicious lesion or thyroid cancer is identified, the generally favorable prognosis and available treatment options can be reassuring.

386 Disorders of the Adrenal Cortex

Wiebke Arlt

The adrenal cortex produces three classes of corticosteroid hormones: glucocorticoids (e.g., cortisol), mineralocorticoids (e.g., aldosterone), and adrenal androgen precursors (e.g., dehydroepiandrosterone [DHEA]) **(Fig. 386-1)**. Glucocorticoids and mineralocorticoids act through specific nuclear receptors, regulating aspects of the physiologic stress response as well as blood pressure and electrolyte homeostasis. Adrenal androgen precursors are converted in the gonads and peripheral target cells to sex steroids that act via nuclear androgen and estrogen receptors.

Disorders of the adrenal cortex are characterized by deficiency or excess of one or several of the three major corticosteroid classes. Hormone deficiency can be caused by inherited glandular or enzymatic disorders or by destruction of the pituitary or adrenal gland by autoimmune disorders, infection, infarction, or iatrogenic events such as surgery or hormonal suppression. Hormone excess is usually the result of neoplasia, leading to increased production of adrenocorticotropic hormone (ACTH) by the pituitary or neuroendocrine ectopic ACTH-producing cells or increased production of glucocorticoids, mineralocorticoids, or adrenal androgen precursors by adrenal nodules. Adrenal nodules are increasingly identified incidentally during cross-sectional imaging of chest or abdomen performed for other reasons.

ADRENAL ANATOMY AND DEVELOPMENT

The normal adrenal glands weigh 6–11 g each. They are located above the kidneys and have their own blood supply. Arterial blood flows

initially to the subcapsular region and then meanders from the outer cortical zona glomerulosa through the intermediate zona fasciculata to the inner zona reticularis and eventually to the adrenal medulla. The right suprarenal vein drains directly into the vena cava, while the left suprarenal vein drains into the left renal vein.

During early embryonic development, the adrenals originate from the urogenital ridge and then separate from gonads and kidneys at about the sixth week of gestation. Concordant with the time of sexual differentiation (seventh to ninth week of gestation, **Chap. 390**), the adrenal cortex starts to produce cortisol and the adrenal sex steroid precursor DHEA. The orphan nuclear receptors SF1 (steroidogenic factor 1; encoded by the gene *NR5A1*) and DAX1 (dosage-sensitive sex reversal gene 1; encoded by the gene *NR0B1*), among others, play a crucial role during this period of development, as they regulate a multitude of adrenal genes involved in steroidogenesis.

REGULATORY CONTROL OF STEROIDOGENESIS

Production of glucocorticoids and adrenal androgens is under the control of the hypothalamic-pituitary-adrenal (HPA) axis, whereas mineralocorticoids are regulated by the renin-angiotensin-aldosterone (RAA) system.

Glucocorticoid synthesis is under inhibitory feedback control by the hypothalamus and the pituitary **(Fig. 386-2)**. Hypothalamic release of corticotropin-releasing hormone (CRH) occurs in response to endogenous or exogenous stress. CRH stimulates the cleavage of the 241–amino acid polypeptide proopiomelanocortin (POMC) by pituitary-specific prohormone convertase 1 (PC1), yielding the 39–amino acid peptide ACTH. ACTH is released by the corticotrope cells of the anterior pituitary and acts as the pivotal regulator of adrenal cortisol synthesis, with additional short-term effects on mineralocorticoid and adrenal androgen synthesis. The release of CRH, and subsequently ACTH, occurs in a pulsatile fashion that follows a circadian rhythm under the control of the hypothalamus, specifically its suprachiasmatic nucleus (SCN), with additional regulation by a complex network of cell-specific clock genes. Reflecting the pattern of ACTH secretion, adrenal cortisol secretion exhibits a distinct circadian rhythm, starting to rise in the early morning hours prior to awakening, with peak levels in the morning and low levels in the evening **(Fig. 386-3)**.

Diagnostic tests assessing the HPA axis make use of the fact that it is regulated by negative feedback. Glucocorticoid excess is diagnosed by employing a dexamethasone suppression test. Dexamethasone, a potent synthetic glucocorticoid, suppresses CRH/ACTH by binding hypothalamic-pituitary glucocorticoid receptors (GRs) and, therefore, results in downregulation of endogenous cortisol synthesis. Various versions of the dexamethasone suppression test are described in detail in **Chap. 380**. If cortisol production is autonomous (e.g., adrenal nodule), ACTH is already suppressed, and dexamethasone has little additional effect. If cortisol production is driven by an ACTH-producing pituitary adenoma, dexamethasone suppression is ineffective at low doses but usually induces suppression at high doses. If cortisol production is driven by an ectopic source of ACTH, the tumors are usually resistant to dexamethasone suppression. Thus, the dexamethasone suppression test is useful to establish the diagnosis of Cushing's syndrome and assist with the differential diagnosis of cortisol excess.

Conversely, to assess glucocorticoid deficiency, ACTH stimulation of cortisol production is used. The ACTH peptide contains 39 amino acids, but the first 24 are sufficient to elicit a physiologic response. The standard ACTH stimulation test involves administration of cosyntropin (ACTH 1-24), 0.25 mg IM or IV, and collection of blood samples at 0, 30, and 60 min for cortisol. A normal response is defined as a cortisol level >15–20 μg/dL (>400–550 nmol/L) 30–60 min after cosyntropin stimulation, with the precise cutoff dependent on the assay used. A low-dose (1 μg cosyntropin IV) version of this test has been advocated; however, it has no superior diagnostic value and is more cumbersome to carry out. Alternatively, an insulin tolerance test (ITT) can be used to assess adrenal function. It involves injection of insulin to induce hypoglycemia, which represents a strong stress signal that triggers

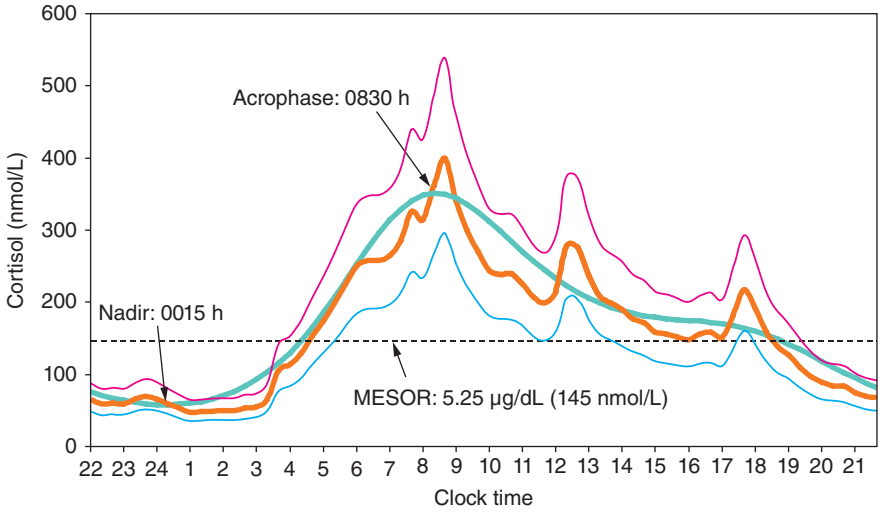

FIGURE 386-3 Physiologic cortisol circadian rhythm. Circulating cortisol concentrations (geometrical mean ± standard deviation values and fitted cosinor) drop under the rhythm-adjusted mean (MESOR) in the early evening hours, with nadir levels around midnight and a rise in the early morning hours; peak levels are observed ~8:30 A.M. (acrophase). *(Reproduced with permission from M Debono et al: Modified-release hydrocortisone to provide circadian cortisol profiles. J Clin Endocrinol Metab 94:1548, 2009.)*

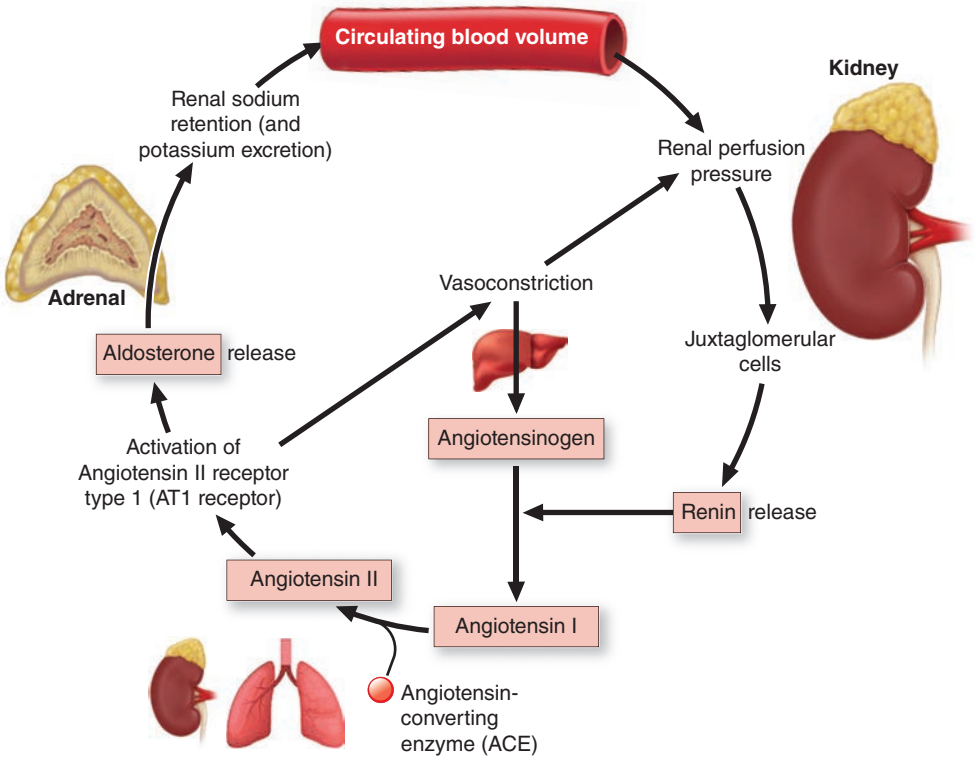

FIGURE 386-4 Regulation of the renin-angiotensin-aldosterone (RAA) system.

hypothalamic CRH release and activation of the entire HPA axis. The ITT involves administration of regular insulin 0.1 U/kg IV (dose should be lower if hypopituitarism is likely) and collection of blood samples at 0, 30, 60, and 120 min for glucose, cortisol, and growth hormone (GH), if also assessing the GH axis. Oral or IV glucose is administered after the patient has achieved symptomatic hypoglycemia (usually plasma glucose <40 mg/dL). A normal response is defined as a cortisol >20 μg/dL and GH >5.1 μg/L, again with assay-specific cutoff variability. The ITT requires careful clinical monitoring and sequential measurements of glucose. It is contraindicated in patients with coronary disease, cerebrovascular disease, or seizure disorders, which has made the short cosyntropin test the commonly accepted first-line test.

Mineralocorticoid production is controlled by the RAA regulatory cycle, which is initiated by the release of renin from the juxtaglomerular cells in the kidney, resulting in cleavage of angiotensinogen to angiotensin I in the liver (Fig. 386-4). Angiotensin-converting enzyme (ACE) cleaves angiotensin I to angiotensin II, which binds and activates the angiotensin II receptor type 1 (AT1 receptor [AT1R]), resulting in increased adrenal aldosterone production and vasoconstriction. Aldosterone enhances sodium retention and potassium excretion and increases the arterial perfusion pressure, which in turn regulates renin release. Because mineralocorticoid synthesis is primarily under the control of the RAA system, hypothalamic-pituitary damage does not significantly impact the capacity of the adrenal to synthesize aldosterone.

Similar to the HPA axis, the assessment of the RAA system can be used for diagnostic purposes. If mineralocorticoid excess is present, there is a counter-regulatory downregulation of plasma renin (see below for testing). Conversely, in mineralocorticoid deficiency, plasma renin is markedly increased. Physiologically, oral or IV sodium loading results in suppression of aldosterone, a response that is attenuated or absent in patients with autonomous mineralocorticoid excess.

STEROID HORMONE SYNTHESIS, METABOLISM, AND ACTION

ACTH stimulation is required for the initiation of steroidogenesis. The ACTH receptor MC2R (melanocortin 2 receptor) interacts with the MC2R-accessory protein MRAP, and the complex is transported to the adrenocortical cell membrane, where it binds to ACTH (Fig. 386-5). ACTH stimulation generates cyclic AMP (cAMP), which upregulates the protein kinase A (PKA) signaling pathway. Inactive PKA is a tetramer of two regulatory and two catalytic subunits that is dissociated by cAMP into a dimer of two regulatory subunits bound to cAMP and two free and active catalytic subunits. PKA activation impacts steroidogenesis in three distinct ways: (1) increases the import of cholesterol esters; (2) increases the activity of hormone-sensitive lipase, which cleaves cholesterol esters to cholesterol for import into the mitochondrion; and (3) increases the availability and phosphorylation of CREB (cAMP response element binding), a transcription factor that enhances transcription of CYP11A1 and other enzymes required for glucocorticoid synthesis.

Adrenal steroidogenesis occurs in a zone-specific fashion, with mineralocorticoid synthesis occurring in the outer zona glomerulosa, glucocorticoid synthesis in the zona fasciculata, and adrenal androgen biosynthesis in the inner zona reticularis serving as precursors for both classic and 11-oxygenated androgens (Fig. 386-1). All steroidogenic pathways require cholesterol import into the mitochondrion, a process initiated by the action of the steroidogenic acute regulatory (StAR) protein, which shuttles cholesterol from the outer to the inner mitochondrial membrane. The majority of steroidogenic enzymes are cytochrome P450 (CYP) enzymes, which are either located in the mitochondrion (side chain cleavage enzyme, CYP11A1; 11β-hydroxylase, CYP11B1; aldosterone synthase, CYP11B2) or in the endoplasmic reticulum membrane (17α-hydroxylase, CYP17A1; 21-hydroxylase, CYP21A2; aromatase, CYP19A1). These enzymes require electron donation via specific redox cofactor enzymes, P450 oxidoreductase (POR), and adrenodoxin/adrenodoxin reductase (ADX/ADR) for the microsomal and mitochondrial CYP enzymes, respectively. In addition, the short-chain dehydrogenase 3β-hydroxysteroid dehydrogenase type 2 (3β-HSD2), also termed Δ4, Δ5 isomerase, plays a major role in adrenal steroidogenesis.

The cholesterol side chain cleavage enzyme CYP11A1 generates pregnenolone. Glucocorticoid synthesis requires conversion of pregnenolone to progesterone by 3β-HSD2, followed by conversion

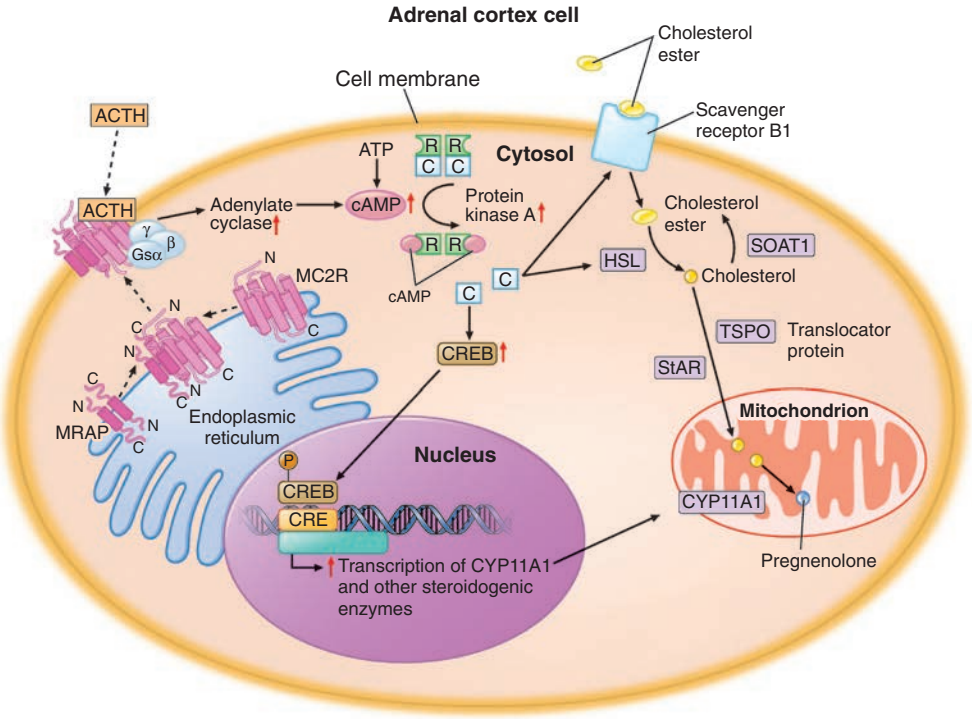

FIGURE 386-5 ACTH effects on adrenal steroidogenesis. to 17-hydroxyprogesterone (17OHP) by CYP17A1, further hydroxylation at carbon 21 by CYP21A2, and eventually, 11β-hydroxylation by CYP11B1 to generate active cortisol (Fig. 386-1). Mineralocorticoid synthesis also requires progesterone, which is first converted to deoxycorticosterone (DOC) by CYP21A2 and then converted via corticosterone and 18-hydroxycorticosterone to aldosterone in three steps catalyzed by CYP11B2. For adrenal androgen synthesis, pregnenolone undergoes conversion by CYP17A1, which uniquely catalyzes two enzymatic reactions. Via its 17α-hydroxylase activity, CYP17A1 converts pregnenolone to 17-hydroxypregnenolone, followed by generation of the universal sex steroid precursor DHEA via CYP17A1 17,20 lyase activity. The majority of DHEA is secreted by the adrenal in the form of its sulfate ester, DHEAS, generated by DHEA sulfotransferase (SULT2A1). DHEA is converted to androstenedione, which can be activated to testosterone or channeled into the 11-oxygenated androgen pathway by 11β-hydroxylation (CYP11B1).

Following its release from the adrenal, cortisol circulates in the bloodstream mainly bound to cortisol-binding globulin (CBG) and, to a lesser extent, to albumin, with only a minor fraction circulating as free, unbound hormone. Free cortisol is thought to enter cells directly, not requiring active transport. In addition, in a multitude of peripheral target tissues of glucocorticoid action, including adipose, liver, muscle, and brain, cortisol is generated from inactive cortisone within the cell by the enzyme 11β-hydroxysteroid dehydrogenase type 1 (11β-HSD1) **(Fig. 386-6)**. Thereby, 11β-HSD1 functions as a tissue-specific prereceptor regulator of glucocorticoid action. For the conversion of inactive cortisone to active cortisol, 11β-HSD1 requires nicotinamide adenine dinucleotide phosphate (NADPH [reduced form]), which is provided by the enzyme hexose-6-phosphate dehydrogenase (H6PDH). Like the catalytic domain of 11β-HSD1, H6PDH is located in the lumen of the endoplasmic reticulum and converts glucose-6-phosphate (G6P) to 6-phosphogluconate (6PGL), thereby regenerating $NADP^+$ to NADPH, which drives the activation of cortisol from cortisone by 11β-HSD1.

In the cytosol of target cells, cortisol binds and activates the GR, which results in dissociation of heat shock proteins (HSPs) from the receptor and subsequent dimerization (Fig. 386-6). Cortisol-bound GR dimers translocate to the nucleus and activate glucocorticoid response elements (GREs) in the DNA sequence, thereby enhancing transcription of glucocorticoid-regulated genes (GR transactivation). However, cortisol-bound GR can also form heterodimers with transcription factors such as AP-1 or NF-κB, resulting in transrepression of proinflammatory genes, a mechanism of major importance for the anti-inflammatory action of glucocorticoids. It is important to note that corticosterone also exerts glucocorticoid activity, albeit much weaker than cortisol itself. However, in rodents, corticosterone is the major glucocorticoid, and in patients with 17-hydroxylase deficiency, lack of cortisol can be compensated for by higher concentrations of corticosterone that accumulates as a consequence of the enzymatic block.

Cortisol is inactivated to cortisone by the microsomal enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2) **(Fig. 386-7)**, mainly in the kidney, but also in the colon, salivary glands, and other target tissues. Cortisol and aldosterone bind the mineralocorticoid receptor (MR) with equal affinity; however, cortisol circulates in the bloodstream at about a 1000-fold higher concentration. Thus, only rapid inactivation of cortisol to cortisone by 11β-HSD2 prevents MR activation by excess cortisol, thereby acting as a tissue-specific modulator of the MR pathway. In addition to cortisol and aldosterone, DOC (Fig. 386-1) also exerts mineralocorticoid activity. DOC accumulation due to 11β-hydroxylase deficiency or due to tumor-related excess production can result in mineralocorticoid excess.

Aldosterone synthesis in the adrenal zona glomerulosa cells is driven by the enzyme aldosterone synthase (CYP11B2). The binding of angiotensin II to the AT1 receptor causes glomerulosa cell membrane depolarization by increasing intracellular sodium through inhibition of sodium potassium (Na^+/K^+) ATPase enzymes as well as potassium channels. This drives an increase in intracellular calcium by opening of voltage-dependent calcium channels or inhibition of calcium (Ca^{2+}) ATPase enzymes. Consequently, the calcium signaling pathway is triggered, resulting in upregulation of CYP11B2 transcription **(Fig. 386-8)**.

Analogous to cortisol action via the GR, aldosterone (or cortisol) binding to the MR in the kidney tubule cell dissociates the HSP-receptor complex, allowing homodimerization of the MR and translocation of the hormone-bound MR dimer to the nucleus (Fig. 386-7). The activated MR enhances transcription of the epithelial sodium channel (ENaC) and serum glucocorticoid-inducible kinase 1 (SGK-1). In the cytosol, interaction of ENaC with Nedd4 prevents cell surface

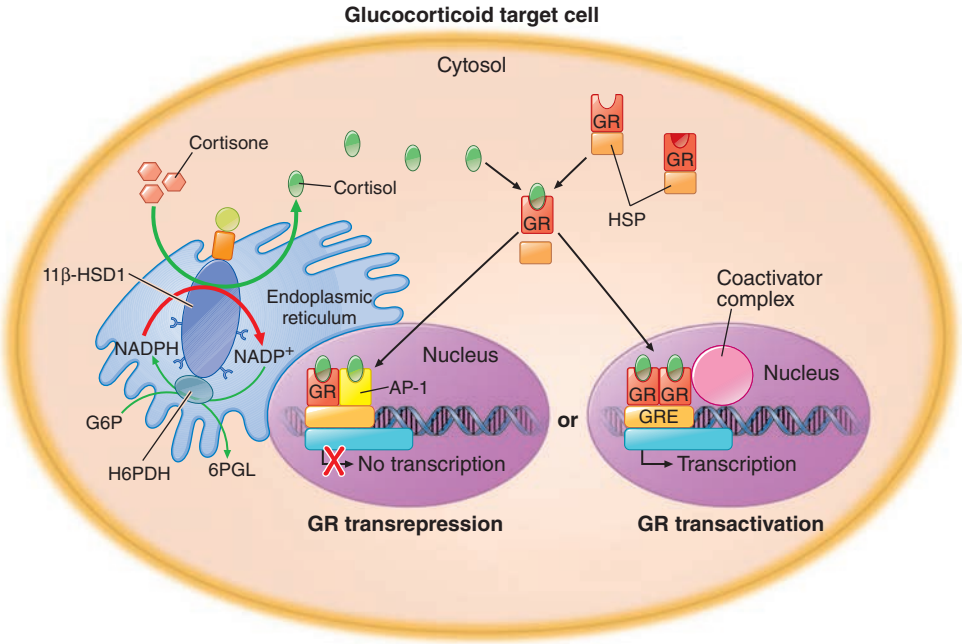

FIGURE 386-6 Prereceptor activation of cortisol and glucocorticoid receptor (GR) action. AP-1, activator protein-1; G6P, glucose-6-phosphate; GREs, glucocorticoid response elements; HSPs, heat shock proteins; NADPH, nicotinamide adenine dinucleotide phosphate (reduced form); 6PGL, 6-phosphogluconate.

expression of ENaC. However, SGK-1 phosphorylates serine residues within the Nedd4 protein, reduces the interaction between Nedd4 and ENaC, and consequently, enhances the trafficking of ENaC to the cell surface, where it mediates sodium retention.

CUSHING'S SYNDROME

(See also Chap. 380) Cushing's syndrome reflects a constellation of clinical features that result from chronic exposure to excess glucocorticoids of any etiology. The disorder can be ACTH-dependent (e.g., pituitary corticotrope adenoma, ectopic secretion of ACTH by nonpituitary tumor) or ACTH-independent (e.g., adrenocortical adenoma, adrenocortical carcinoma [ACC], nodular adrenal hyperplasia), as well as iatrogenic (e.g., administration of exogenous glucocorticoids to treat various inflammatory conditions). The term *Cushing's disease* refers specifically to Cushing's syndrome caused by a pituitary corticotrope adenoma.

Epidemiology Cushing's syndrome is generally considered a rare disease. It occurs with an incidence of 1–2 per 100,000 population per year. However, it is debated whether mild cortisol excess may be more prevalent among patients with features of Cushing's such as centripetal obesity, type 2 diabetes, and osteoporotic vertebral fractures, recognizing that these are relatively nonspecific and common in the population.

In the overwhelming majority of patients with endogenous Cushing's syndrome, the underlying cause is an ACTH-producing corticotrope adenoma of the pituitary (Table 386-1), as initially described by Harvey Cushing in 1912. Cushing's disease more frequently affects women, with the exception of prepubertal cases, where it is more common in boys. By contrast, ectopic ACTH syndrome is more frequently identified in men. Only 10% of patients with Cushing's syndrome have a primary, adrenal cause of their disease (e.g., autonomous cortisol excess independent of ACTH), and most of these patients are women. However, overall, the medical use of glucocorticoids for immunosuppression or for the treatment of inflammatory disorders is the most common cause of Cushing's syndrome, also termed iatrogenic Cushing's.

TABLE 386-1 Causes of Cushing's Syndrome

CAUSES OF CUSHING'S SYNDROME	FEMALE:MALE RATIO	%
ACTH-Dependent Cushing's		**90**
Cushing's disease (= ACTH-producing pituitary adenoma)	4:1	75
Ectopic ACTH syndrome (due to ACTH secretion by bronchial or pancreatic carcinoid tumors, small-cell lung cancer, medullary thyroid carcinoma, pheochromocytoma, and others)	1:1	15
ACTH-Independent Cushing's	**4:1**	**10**
Adrenocortical adenoma		5–10
Adrenocortical carcinoma		1
Rare causes: macronodular adrenal hyperplasia; primary pigmented nodular adrenal disease (micro- and/or macronodular); McCune-Albright syndrome		<1

Abbreviation: ACTH, adrenocorticotropic hormone.

Etiology In at least 90% of patients with Cushing's disease, ACTH excess is caused by a corticotrope pituitary microadenoma, often only a few millimeters in diameter. Pituitary macroadenomas (i.e., tumors >1 cm in size) are found in only 5–10% of patients. Pituitary corticotrope adenomas usually occur sporadically but very rarely can be found in the context of multiple endocrine neoplasia type 1 (MEN 1) (Chap. 388). Pituitary adenomas causative of Cushing's disease frequently harbor mutations in the deubiquitinase USP8, which leads to constitutive activation of epidermal growth factor (EGF) signaling and consequent upregulated expression of the ACTH precursor POMC. USP8 mutations are found more frequently in adults (41 vs 17% in children) and in women (43 vs 17% in men) with Cushing's disease.

Ectopic ACTH production is predominantly caused by occult carcinoid tumors, most frequently in the lung, but also in thymus or pancreas. Because of their small size, these tumors are often difficult to locate. Advanced small-cell lung cancer can cause ectopic ACTH production. In rare cases, ectopic CRH and/or ACTH production has been found to originate from medullary thyroid carcinoma or pheochromocytoma, the latter co-secreting catecholamines and ACTH.

The majority of patients with endogenous ACTH-independent cortisol excess harbor a cortisol-producing adrenal adenoma, and somatic mutations in the PKA catalytic subunit *PRKACA* have been identified as cause of disease in 40% of these tumors. ACCs may also cause ACTH-independent disease and are often large, with excess production of several corticosteroid classes.

A rare but notable cause of adrenal cortisol excess is primary bilateral macronodular adrenal hyperplasia (PBMAH) with low circulating ACTH but with evidence for autocrine stimulation of cortisol production via intraadrenal ACTH production. These hyperplastic nodules are often also characterized by ectopic expression of G protein–coupled receptors not usually found in the adrenal, including receptors for luteinizing hormone, vasopressin, serotonin, interleukin 1, catecholamines, or gastric inhibitory peptide (GIP), the cause of food-dependent Cushing's. Activation of these receptors results in upregulation of PKA signaling, as physiologically occurs with ACTH, with a subsequent increase in cortisol production. A combination of germline and somatic mutations in the tumor-suppressor gene *ARMC5* have been identified as a prevalent cause of Cushing's due to bilateral macronodular adrenal hyperplasia; these patients often present with biochemical evidence of Cushing's but lack specific clinical signs, which develop slowly over decades and accelerate cardiovascular risk. Constitutively activating mutations in the PKA catalytic subunit *PRKACA* are found as somatic mutations in one-third of cortisol-producing adrenocortical adenomas and, as germline mutations, can also represent a rare cause of macronodular adrenal hyperplasia associated with cortisol excess.

Germline mutations in one of the regulatory subunits of PKA, *PRKAR1A*, are found in patients with primary pigmented nodular adrenal disease (PPNAD) as part of *Carney's complex*, an autosomal dominant multiple neoplasia condition associated with cardiac myxomas, hyperlentiginosis, Sertoli cell tumors, and PPNAD. PPNAD can present as micronodular or macronodular hyperplasia, or both. Phosphodiesterases can influence intracellular cAMP and can thereby impact PKA activation. Mutations in *PDE11A* and *PDE8B* have been identified in patients with bilateral adrenal hyperplasia and Cushing's, with and without evidence of PPNAD.

Another rare cause of ACTH-independent Cushing's is *McCune-Albright syndrome*, also associated with polyostotic fibrous dysplasia, unilateral café-au-lait spots, and precocious puberty. McCune-Albright

TABLE 386-2 Signs and Symptoms of Cushing's Syndrome

BODY COMPARTMENT/ SYSTEM	SIGNS AND SYMPTOMS
Body fat	Weight gain, central obesity, rounded face, fat pad on back of neck ("buffalo hump")
Skin	Facial plethora, thin and brittle skin, easy bruising, broad and purple stretch marks, acne, hirsutism
Bone	Osteopenia, osteoporosis (vertebral fractures), decreased linear growth in children
Muscle	Weakness, proximal myopathy (prominent atrophy of gluteal and upper leg muscles with difficulty climbing stairs or getting up from a chair)
Cardiovascular system	Hypertension, hypokalemia, edema, atherosclerosis
Metabolism	Glucose intolerance/diabetes, dyslipidemia
Reproductive system	Decreased libido, in women amenorrhea (due to cortisol-mediated inhibition of gonadotropin release)
Central nervous system	Irritability, emotional lability, depression, sometimes cognitive defects; in severe cases, paranoid psychosis
Blood and immune system	Increased susceptibility to infections, increased white blood cell count, eosinopenia, hypercoagulation with increased risk of deep vein thrombosis and pulmonary embolism

syndrome is caused by activating mutations in the stimulatory G protein alpha subunit 1, GNAS-1 (guanine nucleotide-binding protein alpha stimulating activity polypeptide 1), and such mutations have also been found in bilateral macronodular hyperplasia without other McCune-Albright features and, in rare instances, also in isolated cortisol-producing adrenal adenomas (Table 386-1; **Chap. 412**).

Clinical Manifestations Glucocorticoids affect almost all cells of the body; thus, signs of cortisol excess impact multiple physiologic systems **(Table 386-2)**, with upregulation of gluconeogenesis, lipolysis, and protein catabolism causing the most prominent features. In addition, excess glucocorticoid secretion overcomes the ability of 11β-HSD2 to rapidly inactivate cortisol to cortisone in the kidney, thereby exerting mineralocorticoid actions, manifest as diastolic hypertension, hypokalemia, and edema. Excess glucocorticoids also interfere with central regulatory systems, leading to suppression of gonadotropins with subsequent hypogonadism and amenorrhea and suppression of the hypothalamic-pituitary-thyroid axis, resulting in decreased thyroid-stimulating hormone (TSH) secretion.

The majority of clinical signs and symptoms observed in Cushing's syndrome are relatively nonspecific and include features such as obesity, diabetes, diastolic hypertension, hirsutism, and depression that are commonly found in patients who do not have Cushing's. Therefore, careful clinical assessment is an important aspect of evaluating suspected cases. A diagnosis of Cushing's should be considered when several clinical features are found in the same patient, in particular when more specific features are found or manifest at an unusual age, e.g., osteoporosis in a young patient. Distinct features include fragility of the skin, with easy bruising and broad (>1 cm), purplish striae **(Fig. 386-9)**, and signs of proximal myopathy, which becomes most obvious when trying to stand up from a chair without the use of hands or when climbing stairs. Clinical manifestations of Cushing's do not differ substantially among the different causes of Cushing's. In ectopic ACTH syndrome, hyperpigmentation of the knuckles, scars, or skin areas exposed to increased friction can be observed (Fig. 386-9) and is caused by stimulatory effects of excess ACTH and other POMC cleavage products on melanocyte pigment production. Furthermore, patients with ectopic ACTH syndrome, and some with ACC as the cause of Cushing's, may have a more brisk onset and rapid progression of clinical signs and symptoms, namely of edema, hypokalemia, and hypertension.

Patients with Cushing's syndrome can be acutely endangered by deep vein thrombosis, with subsequent pulmonary embolism, due to a hypercoagulable state associated with Cushing's. The majority of patients also experience psychiatric symptoms, mostly in the form of

FIGURE 386-9 Clinical features of Cushing's syndrome. ***A.*** Note central obesity and broad, purple stretch marks (***B.*** close-up). ***C.*** Note thin and brittle skin in an elderly patient with Cushing's syndrome. ***D.*** Hyperpigmentation of the knuckles in a patient with ectopic adrenocorticotropic hormone (ACTH) excess.

anxiety or depression, but acute paranoid or depressive psychosis may occur. Even after cure, long-term health may be affected by persistently impaired health-related quality of life and increased risk of cardiovascular disease and osteoporosis with vertebral fractures, depending on the duration and degree of exposure to significant cortisol excess.

Diagnosis The most important first step in the management of patients with suspected Cushing's syndrome is to establish the correct diagnosis. Most mistakes in clinical management, leading to unnecessary imaging or surgery, are made because the diagnostic protocol is not followed **(Fig. 386-10)**. This protocol requires establishing the diagnosis of Cushing's beyond doubt prior to employing any tests used for the differential diagnosis of the condition. In principle, after excluding exogenous glucocorticoid use as the cause of clinical signs and symptoms, suspected cases should be tested if there are multiple and progressive features of Cushing's, particularly features with a potentially higher discriminatory value. Exclusion of Cushing's is also indicated in patients with incidentally discovered adrenal masses.

A diagnosis of Cushing's can be considered as established if the results of several tests are consistently suggestive of Cushing's. These tests may include increased 24-h urinary free cortisol excretion in three separate collections, failure to appropriately suppress morning cortisol after overnight exposure to dexamethasone, and evidence of loss of diurnal cortisol secretion with high levels at midnight, the time of the physiologically lowest secretion (Fig. 386-10). Factors potentially affecting the outcome of these diagnostic tests have to be excluded such as incomplete 24-h urine collection or rapid inactivation of dexamethasone due to concurrent intake of CYP3A4-inducing drugs (e.g., antiepileptics, rifampicin). Concurrent intake of oral contraceptives that raise CBG and thus total cortisol can cause failure to suppress after dexamethasone. If in doubt, testing should be repeated after 4–6 weeks off estrogens. Patients with pseudo-Cushing states, i.e., alcohol-related, and those with cyclic Cushing's may require further

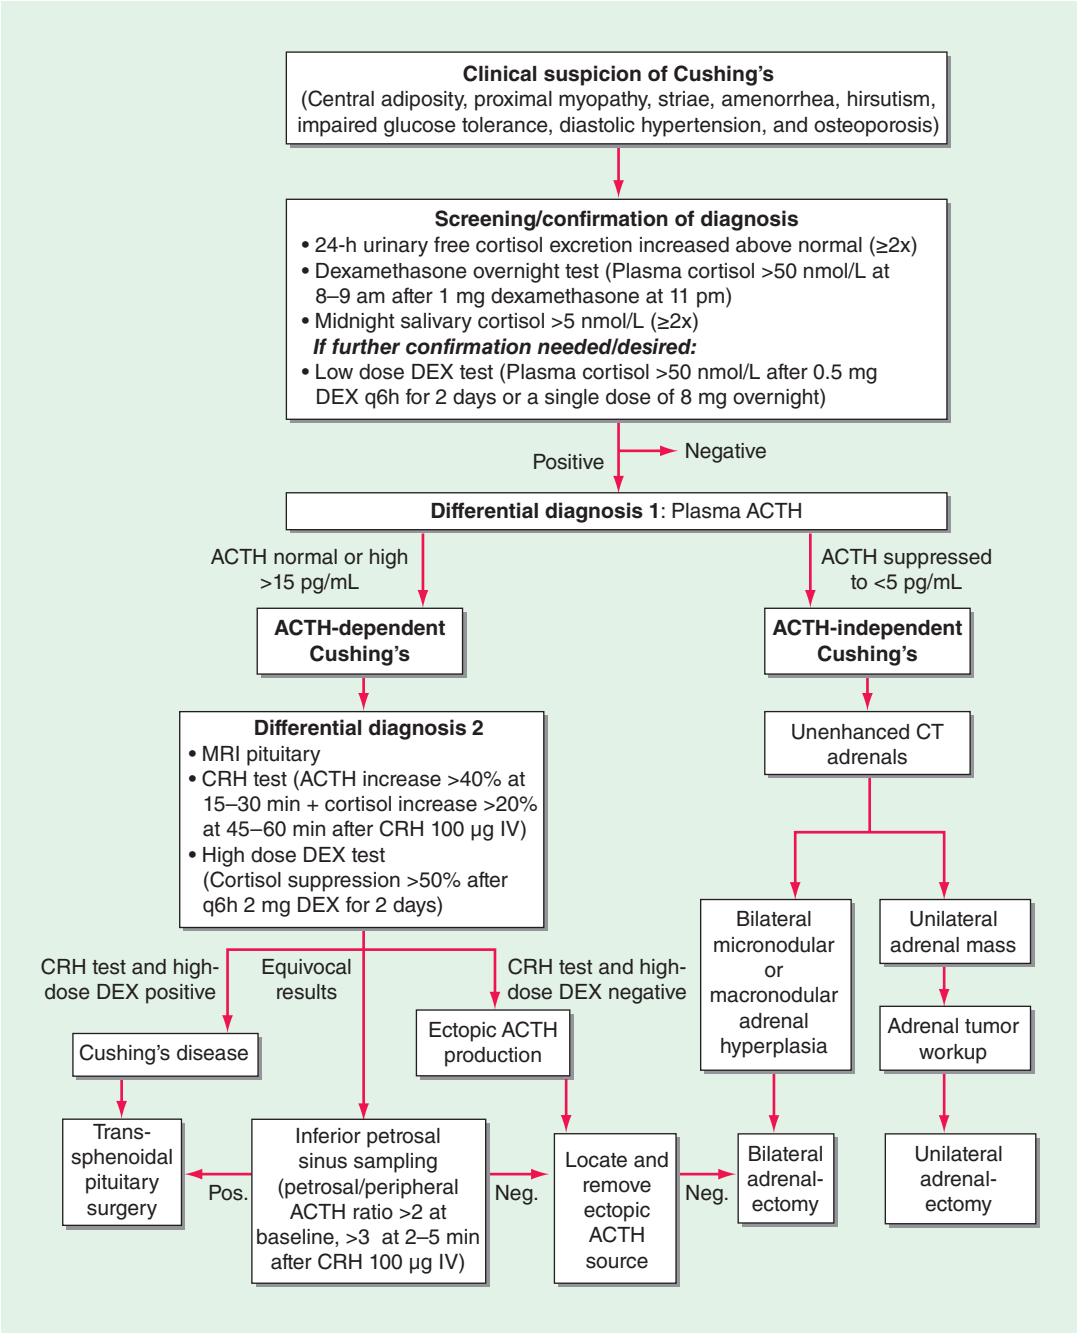

FIGURE 386-10 Management of the patient with suspected Cushing's syndrome. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; CT, computed tomography; DEX, dexamethasone; MRI, magnetic resonance imaging.

testing to safely confirm or exclude the diagnosis of Cushing's. In addition, the biochemical assays employed can affect the test results, with specificity representing a common problem with antibody-based assays for the measurement of urinary free cortisol. These assays have been greatly improved by the introduction of highly specific tandem mass spectrometry.

Differential Diagnosis The evaluation of patients with confirmed Cushing's should be carried out by an endocrinologist and begins with the differential diagnosis of ACTH-dependent and ACTH-independent cortisol excess (Fig. 386-10). Generally, plasma ACTH levels are suppressed in cases of autonomous adrenal cortisol excess, as a consequence of enhanced negative feedback to the hypothalamus and pituitary. By contrast, patients with ACTH-dependent Cushing's have normal or increased plasma ACTH, with very high levels being found in some patients with ectopic ACTH syndrome. Importantly, imaging should only be used after it is established whether the cortisol excess is ACTH-dependent or ACTH-independent because nodules in the pituitary or the adrenal are a common finding in the general population. In patients with confirmed ACTH-independent excess, adrenal imaging is indicated **(Fig. 386-11)**, preferably using an unenhanced computed tomography (CT) scan. This allows assessment of adrenal morphology and determination of precontrast tumor density in Hounsfield units (HUs), which helps to distinguish between benign and malignant adrenal lesions.

For ACTH-dependent cortisol excess **(Chap. 380)**, a magnetic resonance image (MRI) of the pituitary is the investigation of choice, but it may not show an abnormality in up to 40% of cases because of small tumors below the sensitivity of detection. Characteristically, pituitary corticotrope adenomas fail to enhance following gadolinium administration on T1-weighted MRI images. In all cases of confirmed ACTH-dependent Cushing's, further tests are required for the differential diagnosis of pituitary Cushing's disease and ectopic ACTH syndrome. These tests exploit the fact that most pituitary corticotrope adenomas still display regulatory features, including residual ACTH suppression by high-dose glucocorticoids and CRH responsiveness. In contrast, ectopic sources of ACTH are typically resistant to dexamethasone suppression and unresponsive to CRH (Fig. 386-10). However, it should be noted that a small minority of ectopic ACTH-producing tumors exhibit dynamic responses similar to pituitary corticotrope tumors. If the two tests show discordant results or if there is any other reason for doubt, the differential diagnosis can be further clarified by performing bilateral inferior petrosal sinus sampling (IPSS) with concurrent blood sampling for ACTH in the right and left inferior petrosal sinus and a peripheral vein. An increased central/peripheral plasma ACTH ratio >2 at baseline and >3 at 2–5 min after CRH injection is indicative of Cushing's disease (Fig. 386-10), with very high sensitivity and specificity. Of note, the results of the IPSS cannot be reliably used for lateralization (i.e., prediction of the location of the tumor within the pituitary) because there is broad interindividual variability in the venous drainage of the pituitary region. Importantly, no cortisol-lowering agents should be used prior to IPSS.

If the differential diagnostic testing indicates ectopic ACTH syndrome, then further imaging should include high-resolution, fine-cut CT scanning of the chest and abdomen for scrutiny of the lung, thymus, and pancreas. If no lesions are identified, an MRI of the chest can be considered because carcinoid tumors usually show high signal intensity on T2-weighted images. Furthermore, octreotide scintigraphy can be helpful in some cases because ectopic ACTH-producing tumors often express somatostatin receptors. Depending on the suspected cause, patients with ectopic ACTH syndrome should also undergo blood sampling for fasting gut hormones, chromogranin A, calcitonin, and biochemical exclusion of pheochromocytoma.

TREATMENT

Cushing's Syndrome

Overt Cushing's is associated with a poor prognosis if left untreated. In ACTH-independent disease, treatment consists of surgical removal of the adrenal tumor. For smaller tumors, a minimally invasive approach can be used, whereas for larger tumors and those suspected of malignancy, an open approach is preferred.

In Cushing's disease, the treatment of choice is selective removal of the pituitary corticotrope tumor, usually via an endoscopic transsphenoidal approach. This results in an initial cure rate of 70–80% when performed by a highly experienced surgeon. However, even after initial remission following surgery, long-term follow-up is important because late relapse occurs in a significant number of patients. If pituitary disease recurs, there are several options, including second surgery, radiotherapy, stereotactic radiosurgery, and bilateral adrenalectomy. These options need to be applied in a highly individualized fashion.

In some patients with very severe, overt Cushing's (e.g., difficult to control hypokalemic hypertension or acute psychosis), it may be necessary to introduce medical therapy to rapidly control the cortisol excess during the period leading up to surgery, which also can help to alleviate hypercoagulability and, thus, operative risk. Similarly, patients with metastasized, glucocorticoid-producing carcinomas may require long-term antiglucocorticoid drug treatment. In case of ectopic ACTH syndrome, in which the tumor cannot be located, one must carefully weigh whether drug treatment or bilateral adrenalectomy is the most appropriate choice, with the latter facilitating immediate cure but requiring life-long corticosteroid replacement. In this instance, it is paramount to ensure regular imaging follow-up for identification of the ectopic ACTH source.

Oral agents with established efficacy in Cushing's syndrome are metyrapone and ketoconazole. Metyrapone inhibits cortisol synthesis at the level of 11β-hydroxylase (Fig. 386-1), whereas the antimycotic drug ketoconazole inhibits the early steps of steroidogenesis. Typical starting doses are 500 mg tid for metyrapone (maximum dose, 6 g) and 200 mg tid for ketoconazole (maximum dose, 1200 mg). Recently, the potent 11β-hydroxylase inhibitor osilodrostat has been introduced for the treatment of Cushing's, which also exerts strong inhibition of aldosterone synthase (CYP11B2). Mitotane, a derivative of the insecticide o,p'DDD, is an adrenolytic agent that is also effective for reducing cortisol. Because of its side effect profile, it is most commonly used in the context of ACC, but low-dose treatment (500–1000 mg/d) has also been used in benign Cushing's. In severe cases of cortisol excess, etomidate, an agent that potently blocks 11β-hydroxylase and aldosterone synthase, can be used to lower cortisol. It is administered by continuous IV infusion in low, nonanesthetic doses. For Cushing's disease, the subcutaneous administration of pasireotide, a somatostatin receptor agonist, represents another therapeutic option, if surgical cure cannot be achieved.

After the successful removal of an ACTH- or cortisol-producing tumor, the HPA axis will remain suppressed. Thus, hydrocortisone replacement needs to be initiated at the time of surgery and slowly tapered following recovery, to allow physiologic adaptation to normal cortisol levels. Depending on degree and duration of cortisol excess, the HPA axis may require many months or even years to resume normal function and sometimes does not recover. Generally, ectopic ACTH syndrome shows the best recovery rate (80%) and adrenal Cushing's has the lowest (40%), with Cushing's disease intermediate (60%).

MINERALOCORTICOID EXCESS

Epidemiology Following the first description of a patient with an aldosterone-producing adrenal adenoma (*Conn's syndrome*), mineralocorticoid excess was thought to represent a rare cause of hypertension. However, in studies systematically screening all patients with hypertension, a much higher prevalence is now recognized, ranging from 5 to 12%. The prevalence is higher when patients are preselected for hypokalemic hypertension.

Etiology The most common cause of mineralocorticoid excess is primary aldosteronism, reflecting excess production of aldosterone by the adrenal zona glomerulosa. Bilateral micronodular hyperplasia is

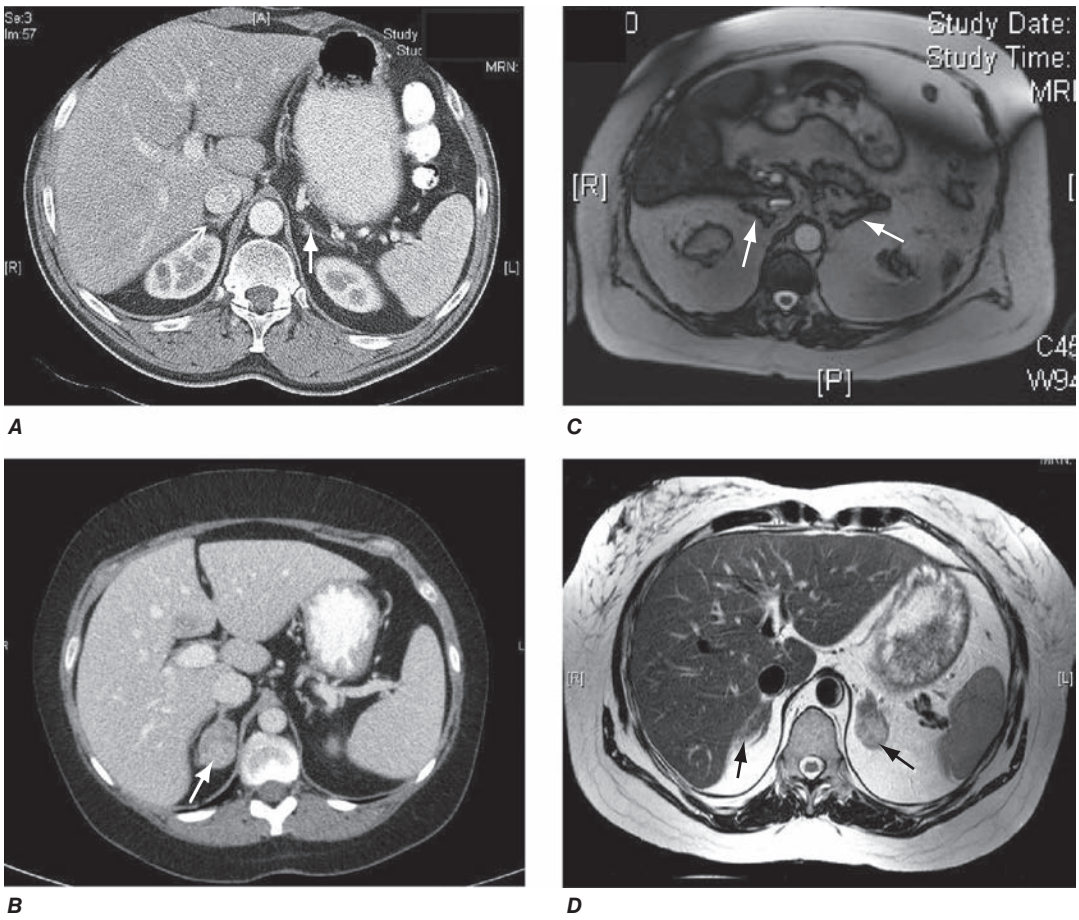

FIGURE 386-11 Adrenal imaging in Cushing's syndrome. ***A.*** Adrenal computed tomography (CT) showing normal bilateral adrenal morphology (*arrows*). ***B.*** CT scan depicting a right adrenocortical adenoma (*arrow*) causing Cushing's syndrome. ***C.*** Magnetic resonance imaging (MRI) showing bilateral adrenal hyperplasia due to excess adrenocorticotropic hormone stimulation in Cushing's disease. ***D.*** MRI showing bilateral macronodular hyperplasia causing Cushing's syndrome.

somewhat more common than unilateral adrenal adenomas (Table 386-3). Somatic mutations in channels and enzymes responsible for increasing sodium and calcium influx in adrenal zona glomerulosa cells have been identified as prevalent causes of aldosterone-producing adrenal adenomas (Table 386-3) and, in the case of germline mutations, also of primary aldosteronism due to bilateral macronodular adrenal hyperplasia. However, bilateral adrenal hyperplasia as a cause of mineralocorticoid excess is usually micronodular but can also contain larger nodules that might be mistaken for a unilateral adenoma. In rare instances, primary aldosteronism is caused by an ACC. Carcinomas should be considered in younger patients and in those with larger tumors because benign aldosterone-producing adenomas usually measure <2 cm in diameter.

A rare cause of aldosterone excess is glucocorticoid-remediable aldosteronism (GRA), which is caused by a chimeric gene resulting from crossover of promoter sequences between the *CYP11B1* and *CYP11B2* genes that are involved in glucocorticoid and mineralocorticoid synthesis, respectively (Fig. 386-1). This rearrangement brings *CYP11B2* transcription under the control of ACTH receptor signaling; consequently, aldosterone production is regulated by ACTH rather than by renin. The family history can be helpful because there may be evidence for dominant transmission of hypertension. Recognition of the disorder is important because it can be associated with early-onset hypertension and strokes. In addition, glucocorticoid suppression can reduce aldosterone production.

Other rare causes of mineralocorticoid excess are listed in Table 386-3. An important cause is excess binding and activation of the MR by a steroid other than aldosterone. Cortisol acts as a potent mineralocorticoid if it escapes efficient inactivation to cortisone by 11β-HSD2 in the kidney (Fig. 386-7). This can be caused by inactivating mutations in the *HSD11B2* gene resulting in the syndrome of apparent mineralocorticoid excess (SAME) that characteristically manifests with severe hypokalemic hypertension in childhood. However, milder mutations may cause normokalemic hypertension manifesting in adulthood (type II SAME). Inhibition of 11β-HSD2 by excess licorice ingestion also results in hypokalemic hypertension, as does overwhelming of 11β-HSD2 conversion capacity by cortisol excess in Cushing's syndrome. DOC also binds and activates the MR and can cause hypertension if its circulating concentrations are increased. This can arise through autonomous DOC secretion by an ACC, but also when DOC accumulates as a consequence of an adrenal enzymatic block, as seen in congenital adrenal hyperplasia (CAH) due to CYP11B1 (11β-hydroxylase) or CYP17A1 (17α-hydroxylase) deficiency (Fig. 386-1). Progesterone can cause hypokalemic hypertension in rare individuals who harbor a MR mutation that enhances binding and activation by progesterone; physiologically, progesterone normally exerts antimineralocorticoid activity. Finally, excess mineralocorticoid activity can be caused by mutations in the β or γ subunits of the ENaC, disrupting its interaction with Nedd4 (Fig. 386-7), and thereby decreasing receptor internalization and degradation. The constitutively active ENaC drives hypokalemic hypertension, resulting in an autosomal dominant disorder termed *Liddle's syndrome*.

Clinical Manifestations Excess activation of the MR leads to potassium depletion and increased sodium retention, with the latter causing an expansion of extracellular and plasma volume. Increased ENaC activity also results in hydrogen depletion that can cause metabolic alkalosis. Aldosterone also has direct effects on the vascular system, where it increases cardiac remodeling and decreases compliance. Aldosterone excess may cause direct damage to the myocardium and the kidney glomeruli, in addition to secondary damage due to systemic hypertension.

TABLE 386-3 Causes of Mineralocorticoid Excess

CAUSES OF MINERALOCORTICOID EXCESS	MECHANISM	%
Primary Aldosteronism		
Adrenal (Conn's) adenoma	Autonomous aldosterone excess can be caused by somatic (intratumor) mutations in the potassium channel GIRK4 (encoded by *KCNJ5*; identified as cause of disease in 40% of aldosterone-producing adenomas; rare germline mutations can cause bilateral macronodular adrenal hyperplasia). Further causes include somatic mutations affecting the α-subunit of the Na^+/K^+-ATPase (encoded by *ATP1A1*), the plasma membrane calcium-transporting ATPase 3 (encoded by *ATP2B3*), and somatic mutations in *CACNA1D* or *CACNA1H* encoding the voltage-gated calcium channel CaV1.3 and CaV3.2, respectively. All mutations result in upregulation of CYP11B2 and hence aldosterone synthesis.	40
Bilateral (micronodular) adrenal hyperplasia	Autonomous aldosterone excess, mostly micronodular and rarely macronodular, with germline *KCNJ5* mutations being a rare cause.	60
Glucocorticoid-remediable hyperaldosteronism (dexamethasone-suppressible hyperaldosteronism)	Crossover between the *CYP11B1* and *CYP11B2* genes results in ACTH-driven aldosterone production	<1
Other Causes (Rare)		**<1**
Syndrome of apparent mineralocorticoid excess (SAME)	Mutations in *HSD11B2* result in lack of renal inactivation of cortisol to cortisone, leading to excess activation of the MR by cortisol (inhibition of 11β-hydroxysteroid dehydrogenase type 2 by excess licorice ingestion can have similar effects)	
Cushing's syndrome	Cortisol excess overcomes the capacity of HSD11B2 to inactivate cortisol to cortisone, consequently flooding the MR	
Glucocorticoid resistance	Upregulation of cortisol production due to GR mutations results in flooding of the MR by cortisol	
Adrenocortical carcinoma	Autonomous aldosterone and/or DOC excess	
Congenital adrenal hyperplasia	Accumulation of DOC due to mutations in *CYP11B1* or *CYP17A1*	
Progesterone-induced hypertension	Progesterone acts as an abnormal ligand due to mutations in the MR gene	
Liddle's syndrome	Mutant ENaC β or γ subunits resulting in reduced degradation of ENaC keeping the membrane channel in open conformation for longer, enhancing mineralocorticoid action	

Abbreviations: ACTH, adrenocorticotropic hormone; DOC, deoxycorticosterone; ENaC, epithelial sodium channel; GR, glucocorticoid receptor; HSD11B2, 11β-hydroxysteroid dehydrogenase type 2; MR, mineralocorticoid receptor.

The clinical hallmark of mineralocorticoid excess is hypokalemic hypertension; however, only 50% of patients with primary aldosteronism exhibit hypokalemia. Serum sodium tends to be normal due to the concurrent fluid retention, which in some cases can lead to peripheral edema. Hypomagnesemia is also a common finding. Hypokalemia can be exacerbated by thiazide drug treatment, which leads to increased delivery of sodium to the distal renal tubule, thereby driving potassium excretion. Severe hypokalemia can be associated with muscle weakness, overt proximal myopathy, or even hypokalemic paralysis. Severe alkalosis contributes to muscle cramps and, in severe cases, can cause tetany.

Of note, patients with primary aldosteronism show increased rates of osteoporosis, type 2 diabetes, and cognitive dysfunction. A significant proportion of patients suffer from concurrent mild autonomous cortisol excess (MACE), termed *Connshing syndrome*.

Diagnosis Diagnostic screening for mineralocorticoid excess is not currently recommended for all patients with hypertension but should be restricted to those who exhibit hypertension associated with drug resistance, hypokalemia, an adrenal mass, or onset of disease before the age of 40 years **(Fig. 386-12)**. The accepted screening test is concurrent measurement of plasma renin and aldosterone with subsequent calculation of the aldosterone-renin ratio (ARR) (Fig. 386-12); serum potassium needs to be normalized prior to testing. Stopping antihypertensive medication can be cumbersome, particularly in patients with severe hypertension. Thus, for practical purposes, in the first instance, the patient can remain on the usual antihypertensive medications, with the exception that MR antagonists need to be ceased at least 4 weeks prior to ARR measurement. The remaining antihypertensive drugs usually do not affect the outcome of ARR testing, except that beta blocker treatment can cause false-positive results and ACE/AT1R inhibitors can cause false-negative results in milder cases **(Table 386-4)**.

ARR screening is positive if the ratio is >750 pmol/L per ng/mL per hour, with a concurrently high normal or increased aldosterone (Fig. 386-12). If one relies on the ARR only, the likelihood of a false-positive ARR becomes greater when renin levels are very low. The characteristics of the biochemical assays are also important. Some labs measure plasma renin activity, whereas others measure plasma renin concentrations. Antibody-based assays for the measurement of serum aldosterone lack the reliability of tandem mass spectrometry assays, but these are not yet ubiquitously available.

Diagnostic confirmation of mineralocorticoid excess in a patient with a positive ARR screening result should be undertaken by an endocrinologist as the tests lack optimized validation. The most straightforward is the saline infusion test, which involves the IV administration of 2 L of physiologic saline over a 4-h period. Failure of aldosterone to suppress <140 pmol/L (5 ng/dL) is indicative of autonomous mineralocorticoid excess. Alternative tests are the oral sodium loading test (300 mmol NaCl/d for 3 days) or the fludrocortisone suppression test (0.1 mg q6h with 30 mmol NaCl q8h for 4 days); the latter can be difficult because of the risk of profound hypokalemia and increased hypertension. In patients with overt hypokalemic hypertension, strongly positive ARR, and concurrently increased aldosterone levels, confirmatory testing is usually not necessary.

Differential Diagnosis and Treatment After the diagnosis of hyperaldosteronism is established, the next step is to use adrenal imaging to further assess the cause. Fine-cut CT scanning of the adrenal region is the method of choice because it provides excellent visualization of adrenal morphology and most aldosterone-producing adenomas are <1 cm. CT will readily identify larger tumors suspicious of malignancy but may miss lesions <5 mm. The differentiation between bilateral micronodular hyperplasia and a unilateral adenoma is only required if a surgical approach is feasible and desired. Consequently, selective adrenal vein sampling (AVS) should only be carried out in surgical candidates with either no obvious lesion on CT or evidence of a unilateral lesion but with age >40 years because the latter patients have a high likelihood of harboring a coincidental, endocrine-inactive adrenal adenoma (Fig. 386-12). AVS is used to compare aldosterone levels in the inferior vena cava and between the right and left adrenal veins. AVS requires concurrent measurement of cortisol to document correct placement of the catheter in the adrenal veins and should demonstrate a cortisol gradient >3 between the vena cava and each adrenal vein. Lateralization is confirmed by an aldosterone/cortisol ratio that is at least twofold higher on one side than the other. AVS is a

complex procedure that requires a highly skilled interventional radiologist. Even then, the right adrenal vein can be difficult to cannulate correctly, which, if not achieved, invalidates the procedure. There is also no agreement as to whether the two adrenal veins should be cannulated simultaneously or successively and whether ACTH stimulation enhances the diagnostic value of AVS.

Patients <40 years with confirmed mineralocorticoid excess and a unilateral lesion on CT can go straight to surgery, which is also indicated in patients with confirmed lateralization documented by a valid AVS procedure. Laparoscopic adrenalectomy is the preferred approach. Patients who are not surgical candidates, or with evidence of bilateral hyperplasia based on CT or AVS, should be treated medically (Fig. 386-12). Medical treatment, which can also be considered prior to surgery to avoid postsurgical hypoaldosteronism, consists primarily of the MR antagonist spironolactone. It can be started at 12.5–50 mg bid

and titrated up to a maximum of 400 mg/d to control blood pressure and normalize potassium. Side effects include menstrual irregularity, decreased libido, and gynecomastia. The more selective MR antagonist eplerenone can also be used. Doses start at 25 mg bid, and it can be titrated up to 200 mg/d. Another useful drug is the sodium channel blocker amiloride (5–10 mg bid).

In patients with normal adrenal morphology and family history of early-onset, severe hypertension, a diagnosis of GRA should be considered and can be evaluated using genetic testing. Treatment of GRA consists of administering dexamethasone, using the lowest dose possible to control blood pressure. Some patients also require additional MR antagonist treatment.

The diagnosis of non-aldosterone-related mineralocorticoid excess is based on documentation of suppressed renin and suppressed aldosterone in the presence of hypokalemic hypertension. This testing is best carried out by employing urinary steroid metabolite profiling by gas chromatography/mass spectrometry (GC/MS). An increased free cortisol over free cortisone ratio is suggestive of SAME and can be treated with dexamethasone. Steroid profiling by GC/MS also detects the steroids associated with CYP11B1 and CYP17A1 deficiency or the irregular steroid secretion pattern in a DOC-producing ACC (Fig. 386-12). If the GC/MS profile is normal, Liddle's syndrome should be considered. It is very sensitive to amiloride treatment but will not respond to MR antagonist treatment because the defect is due to a constitutively active ENaC.

APPROACH TO THE PATIENT: INCIDENTALLY DISCOVERED ADRENAL MASS

Epidemiology Incidentally discovered adrenal masses, commonly termed adrenal "incidentalomas," are common, with a prevalence of 2–5% in the general population as documented in CT and autopsy series. The prevalence increases with age, with 1% of 40-year-olds and 7% of 70-year-olds harboring an adrenal mass. The widespread use of cross-sectional imaging has also increased the recognized prevalence.

Etiology Most solitary adrenal tumors are monoclonal neoplasms. Several genetic syndromes, including MEN 1 (*MEN1*), MEN 2 (*RET*), Carney's complex (*PRKAR1A*), and McCune-Albright (*GNAS1*), can have adrenal tumors as one of their features. Somatic mutations in *MEN1*, *GNAS1*, and *PRKAR1A* have been identified in a small proportion of sporadic adrenocortical adenomas. Aberrant expression of membrane receptors (GIP, α- and β-adrenergic, luteinizing hormone, vasopressin V1, and interleukin 1 receptors) has been identified in some sporadic cases of macronodular adrenocortical hyperplasia.

The majority of adrenal nodules are endocrine-inactive adrenocortical adenomas. However, larger series suggest that up to 25% of adrenal nodules are hormonally active, due to a cortisol- or aldosterone-producing adrenocortical adenoma or a pheochromocytoma associated with catecholamine excess **(Table 386-5)**. ACC is rare but is the cause of an adrenal mass in 5% of patients. However, metastases originating from another solid tissue tumor are an additional cause of adrenal incidentaloma and have a higher incidence in patients undergoing imaging for tumor staging or follow-up monitoring (Table 386-5).

Differential Diagnosis and Treatment Patients with an adrenal mass >1 cm require a diagnostic evaluation. Two key questions need to be addressed: (1) Does the tumor autonomously secrete hormones that could have a detrimental effect on health? (2) Is the adrenal mass benign or malignant?

Hormone secretion by an adrenal mass occurs along a continuum, with a gradual increase in clinical manifestations in parallel with hormone levels. Exclusion of catecholamine excess from a pheochromocytoma arising from the adrenal medulla is a mandatory part of the diagnostic workup **(Fig. 386-13)**. Furthermore, autonomous cortisol resulting in Cushing's syndrome requires exclusion and, in patients with hypertension or low serum potassium, also primary aldosteronism. Adrenal incidentalomas can be associated with MACE, and patients usually lack overt clinical features of Cushing's syndrome. Nonetheless, they may exhibit one or more components of the metabolic syndrome (e.g., obesity, type 2 diabetes, or hypertension). There is ongoing debate about the optimal treatment for these patients. Overproduction of adrenal androgen precursors, DHEA and its sulfate, is rare and most frequently seen in the context of ACC, as are increased levels of steroid precursors such as 17OHP.

TABLE 386-5 Classification of Unilateral Adrenal Masses

MASS	APPROXIMATE PREVALENCE (%)
Benign	
Adrenocortical adenoma	
Endocrine-inactive	60–85
Cortisol-producing	5–10
Aldosterone-producing	2–5
Pheochromocytoma	5–10
Adrenal myelolipoma	<1
Adrenal ganglioneuroma	<0.1
Adrenal hemangioma	<0.1
Adrenal cyst	<1
Adrenal hematoma/hemorrhagic infarction	<1
Indeterminate	
Adrenocortical oncocytoma	<1
Malignant	
Adrenocortical carcinoma	2–5
Malignant pheochromocytoma	<1
Adrenal neuroblastoma	<0.1
Lymphomas (including primary adrenal lymphoma)	<1
Metastases (most frequent: breast, lung)	1–2

Note: Bilateral adrenal enlargement/masses may be caused by congenital adrenal hyperplasia, bilateral macronodular hyperplasia, bilateral hemorrhage (due to antiphospholipid syndrome or sepsis-associated Waterhouse-Friderichsen syndrome), granuloma, amyloidosis, or infiltrative disease including tuberculosis.

For the differentiation of benign from malignant adrenal masses, imaging is relatively sensitive, although specificity is suboptimal. Unenhanced CT is the procedure of choice for imaging the adrenal glands (Fig. 386-11). A diagnosis of ACC, pheochromocytoma, and benign adrenal myelolipoma becomes more likely with increasing diameter of the adrenal mass. However, size alone is of poor predictive value, with only 80% specificity for the differentiation of benign from malignant masses when using a 4-cm cutoff. Metastases are rare but are found with similar frequency in adrenal masses of all sizes. The tumor attenuation value on unenhanced CT is of high diagnostic value, as many adrenocortical adenomas are lipid rich and thus present with low attenuation values (i.e., densities of <20 Hounsfield units [HUs]). However, similar numbers of adrenocortical adenomas are lipid poor and present with higher HUs, making it difficult to differentiate them from ACCs, as well as also pheochromocytomas, both of which invariably have high attenuation values (i.e., densities >20 HU on precontrast scans). Generally, benign lesions are rounded and homogenous, whereas most malignant lesions appear lobulated and inhomogeneous. Pheochromocytoma and adrenomyelolipoma may also exhibit lobulated and inhomogeneous features. MRI also allows for the visualization of the adrenal glands with somewhat lower resolution than CT. However, because it does not involve exposure to ionizing radiation, it is preferred in children, young adults, and during pregnancy. MRI has a valuable role in the characterization of indeterminate adrenal lesions using chemical shift analysis, with malignant tumors rarely showing loss of signal on opposed-phase MRI; however, this may also be observed in a proportion of benign adrenocortical adenomas.

Fine-needle aspiration (FNA) or CT-guided biopsy of an adrenal mass is very rarely indicated. FNA of a pheochromocytoma can cause a life-threatening hypertensive crisis. FNA of an ACC violates the tumor capsule and can cause needle track metastasis. FNA should only be considered in a patient with a history of nonadrenal malignancy and a newly detected adrenal mass, after careful exclusion of

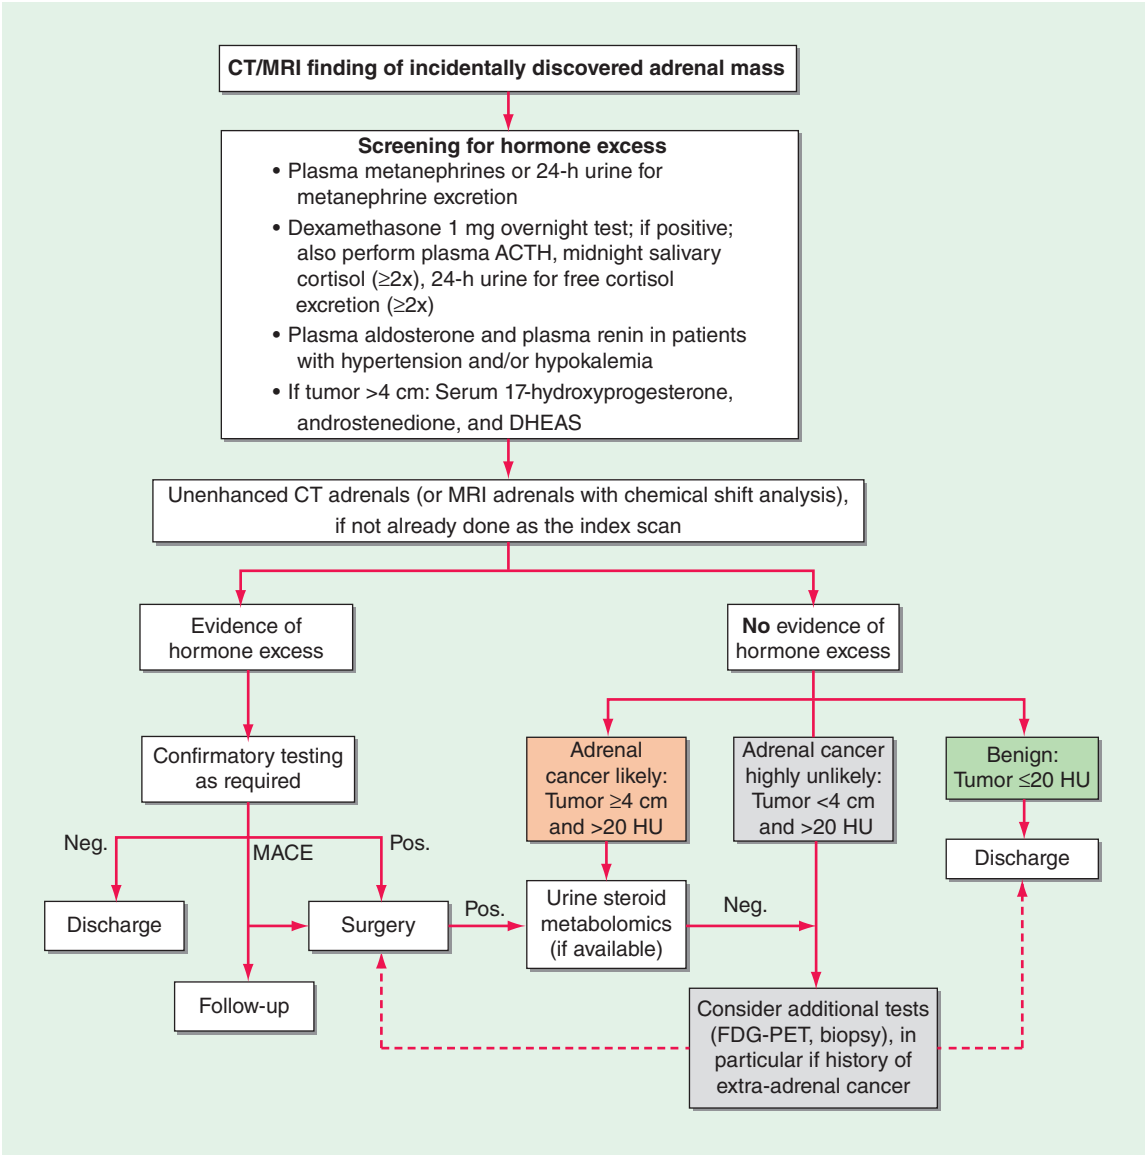

FIGURE 386-13 Management of the patient with an incidentally discovered adrenal mass. ACTH, adrenocorticotropic hormone; CT, computed tomography; FDG-PET, fluorodeoxyglucose positron emission tomography; MACE, mild autonomous cortisol excess; MRI, magnetic resonance imaging.

pheochromocytoma, and if the outcome will influence therapeutic management. It is important to recognize that in 25% of patients with a previous history of nonadrenal malignancy, a newly detected mass on CT is not a metastasis. While FNA can diagnose extra-adrenal malignancies, it has very limited ability to differentiate between benign and malignant adrenocortical lesions and hence should not be used for diagnosis of ACC.

Adrenal masses associated with confirmed hormone excess or suspected malignancy are usually treated surgically (Fig. 386-13) or, if adrenalectomy is not feasible or desired, with medication. Preoperative exclusion of glucocorticoid excess is particularly important for the prediction of postoperative suppression of the contralateral adrenal gland, which requires glucocorticoid replacement peri- and postoperatively. Adrenal masses with normal endocrine biochemistry at diagnosis and a tumor radiodensity of <20 HU on unenhanced CT can be considered benign and do not require further follow-up. In adrenal masses with suspicious imaging findings (>20 HU), further tests and surgery are feasible options (Fig. 386-13); however, the latter will still result in unnecessary surgery for benign tumors. A recently introduced diagnostic test, urine steroid metabolomics, has a twofold higher positive predictive value than imaging in detecting adrenocortical carcinoma, based on a distinct "steroid fingerprint" with accumulating precursor steroids in 24-h urine.

ADRENOCORTICAL CARCINOMA

ACC is a rare malignancy with an annual incidence of 1–2 per million population. ACC is generally considered a highly malignant tumor; however, it presents with broad interindividual variability with regard to biologic characteristics and clinical behavior. Somatic mutations in the tumor-suppressor gene *TP53* are found in 25% of apparently sporadic ACC. Germline *TP53* mutations are the cause of the Li-Fraumeni syndrome associated with multiple solid organ cancers including ACC and are found in 25% of pediatric ACC cases; the *TP53* mutation R337H is found in almost all pediatric ACC in Brazil. Other genetic changes identified in ACC include alterations in the Wnt/β-catenin pathway and in the insulin-like growth factor 2 (IGF2) cluster; IGF2 overexpression is found in 90% of ACCs.

Patients with large adrenal tumors suspicious of malignancy should be managed by a multidisciplinary specialist team, including an endocrinologist, an oncologist, a surgeon, a radiologist, and a histopathologist. FNA is not indicated in suspected ACC: first, cytology and also histopathology of a core biopsy cannot differentiate between benign and malignant primary adrenal masses; second, FNA violates the tumor capsule and may even cause needle canal metastasis. Even when the entire tumor specimen is available, the histopathologic differentiation between benign and malignant adrenocortical lesions is a diagnostic challenge. The most common histopathologic classification

TABLE 386-6 Classification System for Staging of Adrenocortical Carcinoma

ENSAT STAGE	TNM STAGE	TNM DEFINITIONS
I	T1,N0,M0	T1, tumor ≤5 cm N0, no positive lymph node M0, no distant metastases
II	T2,N0,M0	T2, tumor >5 cm N0, no positive lymph node M0, no distant metastases
III	T1–T2,N1,M0	N1, positive lymph node(s)
	T3–T4,N0–N1,M0	M0, no distant metastases T3, tumor infiltration into surrounding tissue T4, tumor invasion into adjacent organs *or* venous tumor thrombus in vena cava or renal vein
IV	T1–T4,N0–N1,M1	M1, presence of distant metastases

Abbreviations: ENSAT, European Network for the Study of Adrenal Tumors; TNM, tumor, node, metastasis.

is the Weiss score, taking into account high nuclear grade; mitotic rate (>5/HPF); atypical mitosis; <25% clear cells; diffuse architecture; and presence of necrosis, venous invasion, and invasion of sinusoidal structures and tumor capsule. The presence of three or more elements suggests ACC. However, FNA is a feasible option if looking for metastases of an extra-adrenal primary or other adrenal tumor entities, such as ganglioneuroma.

Although 60–70% of ACCs show biochemical evidence of steroid overproduction, in many patients, this is not clinically apparent due to the relatively inefficient steroid production by the adrenocortical cancer cells. Excess production of glucocorticoids and adrenal androgen precursors are most common and indicative of malignancy.

Tumor staging at ACC diagnosis **(Table 386-6)** has important prognostic implications and requires scanning of the chest and abdomen for local organ invasion, lymphadenopathy, and metastases. Intravenous contrast medium is necessary for maximum sensitivity for hepatic metastases. An adrenal origin may be difficult to determine on standard axial CT imaging if the tumors are large and invasive, but CT reconstructions and MRI are more informative **(Fig. 386-14)** using multiple planes and different sequences. Vascular and adjacent organ invasion is diagnostic of malignancy. 18-Fluoro-2-deoxy-D-glucose positron emission tomography (18-FDG-PET) is highly sensitive for the detection of malignancy and can be used to detect small metastases or local recurrence that may not be obvious on CT (Fig. 386-14). However, FDG-PET has limited specificity and therefore cannot be used for differentiating benign from malignant adrenal lesions. Metastasis in ACC most frequently occurs to liver and lung.

There is no established grading system for ACC, and the Weiss score carries no prognostic value; the most important prognostic histopathologic parameter is the Ki67 proliferation index, with Ki67 <10% indicative of slow to moderate growth velocity, whereas a Ki67 ≥10% is associated with poor prognosis including high risk of recurrence and rapid progression.

Cure of ACC can only be achieved by early detection and complete surgical removal. Capsule violation during primary surgery, metastasis at diagnosis, and primary treatment in a nonspecialist center and by a nonspecialist surgeon are major determinants of poor survival. If the primary tumor invades adjacent organs, en bloc removal of kidney and spleen should be considered to reduce the risk of recurrence, and regional lymph node dissection may further reduce this risk. Surgery can also be considered in a patient with metastases if there is severe tumor-related hormone excess. This indication needs to be carefully weighed against surgical risk, including thromboembolic complications, and the resulting delay in the introduction of other therapeutic options. Patients with confirmed ACC and successful removal of the primary tumor should receive adjuvant treatment with mitotane (o,p'DDD), particularly in patients with a high risk of recurrence as determined by tumor size >8 cm, histopathologic signs of vascular invasion, capsule invasion or violation, and a Ki67 proliferation index ≥10%. Adjuvant mitotane should be continued for at least 2 years, if side effects are tolerated. Regular monitoring of plasma mitotane levels is mandatory (therapeutic range 14–20 mg/L; neurotoxic complications more frequent at >20 mg/L). Mitotane is usually started at 500 mg tid, with stepwise increases to a maximum dose of 2000 mg tid in days (high-dose saturation) or weeks (low-dose saturation) as tolerated. Once therapeutic range plasma mitotane levels are achieved, the dose can be tapered to maintenance doses mostly ranging from 1000–1500 mg tid. Mitotane treatment results in disruption of cortisol synthesis and thus requires glucocorticoid replacement; glucocorticoid replacement dose should be at least double of that usually used in adrenal insufficiency (i.e., 20 mg tid) because mitotane induces hepatic CYP3A4 activity, resulting in rapid inactivation of glucocorticoids. Mitotane also increases circulating CBG, thereby decreasing the available free cortisol fraction. Single metastases can be addressed surgically or with radiofrequency ablation as appropriate. If the tumor recurs or progresses during mitotane treatment, cytotoxic chemotherapy should be considered; the established first-line chemotherapy regimen is the

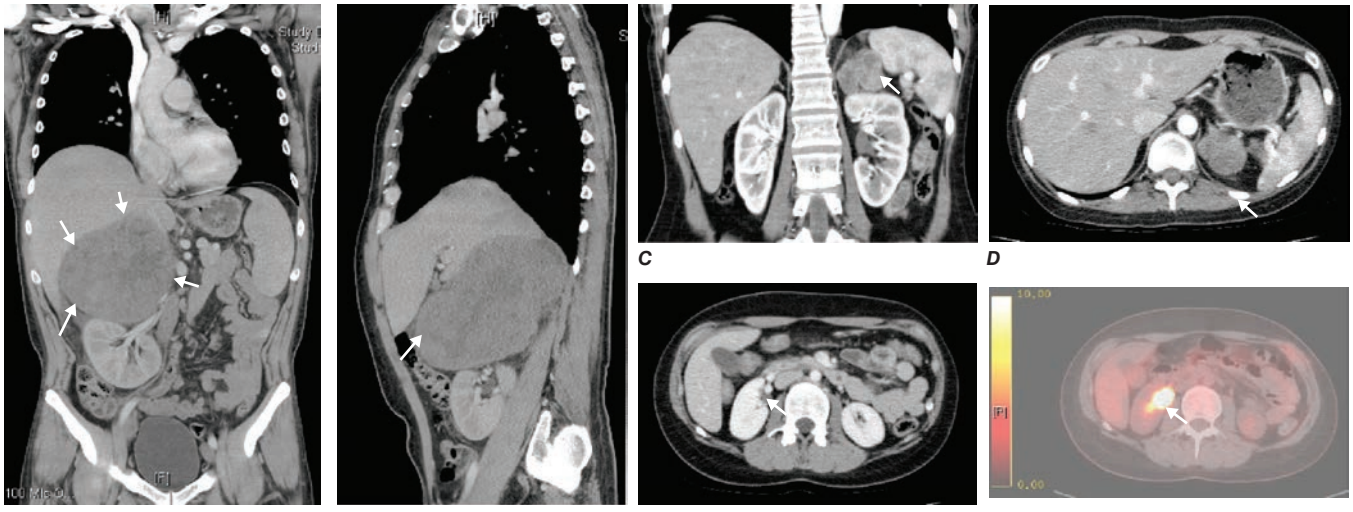

FIGURE 386-14 Imaging in adrenocortical carcinoma (ACC). Magnetic resonance imaging scan with (***A***) frontal and (***B***) lateral views of a right ACC that was detected incidentally. Computed tomography (CT) scan with (***C***) coronal and (***D***) transverse views depicting a right-sided ACC. Note the irregular border and inhomogeneous structure. CT scan (***E***) and positron emission tomography/CT (***F***) visualizing a peritoneal metastasis of an ACC in close proximity to the right kidney (*arrow*).

combination of cisplatin, etoposide, and doxorubicin plus continuing mitotane. Painful bone metastasis responds to irradiation. Overall survival in ACC is still poor, with 5-year survival rates of 30–40% and a median survival of 15 months in metastatic ACC.

ADRENAL INSUFFICIENCY

Epidemiology The prevalence of well-documented, permanent adrenal insufficiency is 5 in 10,000 in the general population. Hypothalamic-pituitary origin of disease is most frequent, with a prevalence of 3 in 10,000, whereas primary adrenal insufficiency has a prevalence of 2 in 10,000. Approximately one-half of the latter cases are acquired, mostly caused by autoimmune destruction of the adrenal glands; the other one-half are genetic, most commonly caused by distinct enzymatic blocks in adrenal steroidogenesis affecting glucocorticoid synthesis (i.e., CAH).

Adrenal insufficiency arising from suppression of the HPA axis as a consequence of exogenous glucocorticoid treatment is much more common, occurring in 0.5–2% of the population in developed countries.

Etiology *Primary adrenal insufficiency* is most commonly caused by autoimmune adrenalitis. Isolated autoimmune adrenalitis accounts for 30–40%, whereas 60–70% develop adrenal insufficiency as part of autoimmune polyglandular syndromes (APSs) **(Chap. 388)** **(Table 386-7)**. APS1, also termed APECED (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy), is the underlying cause in 10% of patients affected by APS. APS1 is transmitted in an autosomal recessive manner and is caused by mutations in the autoimmune regulator gene *AIRE*. Associated autoimmune conditions overlap with those seen in APS2 but may also include total alopecia, primary hypoparathyroidism, and, in rare cases, lymphoma. APS1 patients invariably develop chronic mucocutaneous candidiasis, usually manifested in childhood and preceding adrenal insufficiency by years or decades. The much more prevalent APS2 is of polygenic inheritance, with confirmed associations with the *HLA-DR3* gene region in the major histocompatibility complex and distinct gene regions involved in immune regulation (*CTLA-4, PTPN22, CLEC16A*). Coincident autoimmune disease most frequently includes thyroid autoimmune disease, vitiligo, and premature ovarian failure. Less commonly, additional features may include type 1 diabetes and pernicious anemia caused by vitamin B_{12} deficiency.

X-linked adrenoleukodystrophy has an incidence of 1:20,000 males and is caused by mutations in the *X-ALD* gene encoding the peroxisomal membrane transporter protein ABCD1; its disruption results in accumulation of very-long-chain (>24 carbon atoms) fatty acids. Approximately 50% of cases manifest in early childhood with rapidly progressive white matter disease (cerebral adrenoleukodystrophy); 35% present during adolescence or in early adulthood with neurologic features indicative of myelin and peripheral nervous system

TABLE 386-7 Causes of Primary Adrenal Insufficiency

DIAGNOSIS	GENE	ASSOCIATED FEATURES
Autoimmune polyglandular syndrome 1 (APS1)	*AIRE*	Hypoparathyroidism, chronic mucocutaneous candidiasis, other autoimmune disorders, rarely lymphomas
Autoimmune polyglandular syndrome 2 (APS2)	Associations with HLA-DR3, CTLA-4	Hypothyroidism, hyperthyroidism, premature ovarian failure, vitiligo, type 1 diabetes mellitus, pernicious anemia
Isolated autoimmune adrenalitis	Associations with HLA-DR3, CTLA-4	
Congenital adrenal hyperplasia (CAH)	*CYP21A2, CYP11B1, CYP17A1, HSD3B2, POR*	See Table 386-10 (see also **Chap. 390**)
Congenital lipoid adrenal hyperplasia (CLAH)	*STAR, CYP11A1*	46,XY DSD, gonadal failure (see also **Chap. 390**)
Adrenal hypoplasia congenita (AHC)	*NR0B1 (DAX-1), NR5A1 (SF-1)*	46,XY DSD, gonadal failure (see also **Chap. 390**)
Adrenoleukodystrophy (ALD), adrenomyeloneuropathy (AMN)	*ABCD1*	Demyelination of central nervous system (ALD) or spinal cord and peripheral nerves (AMN)
Familial glucocorticoid deficiency	*MC2R*	Tall stature
	MRAP	None
	STAR	None
	NNT	None
	TXNRD2	None
	MCM4	Growth retardation, natural killer cell deficiency
Triple A syndrome	*AAAS*	Alacrima, achalasia, neurologic impairment
Smith-Lemli-Opitz syndrome	*SLOS*	Cholesterol synthesis disorder associated with mental retardation, craniofacial malformations, growth failure
Kearns-Sayre syndrome	Mitochondrial DNA deletions	Progressive external ophthalmoplegia, pigmentary retinal degeneration, cardiac conduction defects, gonadal failure, hypoparathyroidism, type 1 diabetes,
IMAGe syndrome	*CDKN1C*	Intrauterine growth retardation, metaphyseal dysplasia, genital anomalies
MIRAGE syndrome	*SAMD9*	Myelodysplasia, infection, restriction of growth, genital phenotypes, and enteropathy
Sphingosine-1-phosphate lyase deficiency	*SGPL1*	Steroid-resistant nephrotic syndrome, immunodeficiency, neurological defects, ichthyosis, primary hypothyroidism, cryptorchidism
Adrenal infections		Tuberculosis, HIV, CMV, cryptococcosis, histoplasmosis, coccidioidomycosis
Adrenal infiltration		Metastases, lymphomas, sarcoidosis, amyloidosis, hemochromatosis
Adrenal hemorrhage		Meningococcal sepsis (Waterhouse-Friderichsen syndrome), primary antiphospholipid syndrome
Drug-induced		Mitotane, aminoglutethimide, abiraterone, trilostane, etomidate, ketoconazole, osilodrostat, suramin, RU486, interferon-alpha, ribavirin, megestrol acetate, immune checkpoint inhibitors (rare)
Bilateral adrenalectomy		E.g., in the management of Cushing's syndrome or after bilateral nephrectomy

Abbreviations: AIRE, autoimmune regulator; CMV, cytomegalovirus; DSD, disordered sex development; MC2R, ACTH receptor; MCM4, mini chromosome maintenance-deficient 4 homologue; MRAP, MC2R-accessory protein; NNT, nicotinamide nucleotide transhydrogenase.

involvement (adrenomyeloneuropathy [AMN]). In the remaining 15%, adrenal insufficiency is the sole manifestation of disease. Of note, distinct mutations manifest with variable penetrance and phenotypes within affected families.

Rarer causes of adrenal insufficiency involve destruction of the adrenal glands as a consequence of infection, hemorrhage, or infiltration (Table 386-7); tuberculous adrenalitis is still a frequent cause of disease in developing countries. Adrenal metastases rarely cause adrenal insufficiency, and this occurs only with bilateral, bulky metastases.

Inborn causes of primary adrenal insufficiency other than CAH are rare, causing <1% of cases. However, their elucidation provides important insights into adrenal gland development and physiology. Mutations causing primary adrenal insufficiency (Table 386-7) include factors regulating adrenal development and steroidogenesis (DAX-1, SF-1), cholesterol synthesis, import and cleavage (DHCR7, StAR, CYP11A1), elements of the adrenal ACTH response pathway (MC2R, MRAP) (Fig. 386-5), and factors involved in redox regulation (NNT, TXNRD2) and DNA repair (MCM4, CDKN1C).

Secondary (or central) adrenal insufficiency is the consequence of dysfunction of the hypothalamic-pituitary component of the HPA axis **(Table 386-8)**. Excluding iatrogenic suppression, the overwhelming majority of cases are caused by pituitary or hypothalamic tumors or their treatment by surgery or irradiation **(Chap. 380)**. Rarer causes include pituitary apoplexy, either as a consequence of an infarcted pituitary adenoma or transient reduction in the blood supply of the pituitary during surgery or after rapid blood loss associated with parturition, also termed Sheehan's syndrome. Isolated ACTH deficiency is rarely caused by autoimmune disease or pituitary infiltration (Table 386-8). Mutations in the ACTH precursor POMC or in factors regulating pituitary development are genetic causes of ACTH deficiency (Table 386-8).

Clinical Manifestations In principle, the clinical features of primary adrenal insufficiency (Addison's disease) are characterized by the loss of both glucocorticoid and mineralocorticoid secretion **(Table 386-9)**. In secondary adrenal insufficiency, only glucocorticoid deficiency is present, as the adrenal itself is intact and thus still amenable to regulation by the RAA system. Adrenal androgen secretion is disrupted in both primary and secondary adrenal insufficiency (Table 386-9). Hypothalamic-pituitary disease can lead to additional clinical manifestations due to involvement of other endocrine axes (thyroid, gonads, GH, prolactin) or visual impairment with bitemporal hemianopia caused by chiasmal compression. It is important to recognize that iatrogenic adrenal insufficiency caused by exogenous glucocorticoid suppression of the HPA axis may result in all symptoms associated with glucocorticoid deficiency (Table 386-9), if exogenous glucocorticoids are stopped abruptly. However, patients will appear clinically cushingoid as a result of the preceding overexposure to glucocorticoids.

Chronic adrenal insufficiency manifests with relatively nonspecific signs and symptoms, such as fatigue and loss of energy, often resulting in delayed or missed diagnoses (e.g., as depression or anorexia). A distinguishing feature of primary adrenal insufficiency is hyperpigmentation, which is caused by excess ACTH stimulation of melanocytes. Hyperpigmentation is most pronounced in skin areas exposed to increased friction or shear stress and is increased by sunlight **(Fig. 386-15)**. Conversely, in secondary adrenal insufficiency, the skin has an alabaster-like paleness due to lack of ACTH secretion.

Hyponatremia is a characteristic biochemical feature in primary adrenal insufficiency and is found in 80% of patients at presentation. Hyperkalemia is present in 40% of patients at initial diagnosis. Hyponatremia is primarily caused by mineralocorticoid deficiency but can also occur in secondary adrenal insufficiency due to diminished inhibition of antidiuretic hormone (ADH) release by cortisol, resulting in mild syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Glucocorticoid deficiency also results in slightly increased TSH concentrations that normalize within days to weeks after initiation of glucocorticoid replacement.

Acute adrenal insufficiency, also termed adrenal crisis, usually occurs after a prolonged period of nonspecific complaints and is more frequently observed in patients with primary adrenal insufficiency, due to the loss of both glucocorticoid and mineralocorticoid secretion. Postural hypotension may progress to hypovolemic shock. Adrenal insufficiency may mimic features of acute abdomen with abdominal tenderness, nausea, vomiting, and fever. In some cases, the primary presentation may resemble neurologic disease, with decreased responsiveness progressing to stupor and coma. An adrenal crisis can be triggered by an intercurrent illness, surgical or other stress, or increased glucocorticoid inactivation (e.g., hyperthyroidism). Prospective data indicate 8.3 adrenal crises and 0.5 adrenal crisis-related deaths per 100 patient-years.

TABLE 386-8 Causes of Secondary Adrenal Insufficiency

DIAGNOSIS	GENE	ASSOCIATED FEATURES
Pituitary tumors (endocrine active and inactive adenomas, very rare: carcinoma)		Depending on tumor size and location: visual field impairment (bilateral hemianopia), hyperprolactinemia, secondary hypothyroidism, hypogonadism, growth hormone deficiency
Other mass lesions affecting the hypothalamic-pituitary region		Craniopharyngioma, meningioma, ependymoma, metastases
Pituitary irradiation		Radiotherapy administered for pituitary tumors, brain tumors, or craniospinal irradiation in leukemia
Autoimmune hypophysitis		Often associated with pregnancy; may present with panhypopituitarism or isolated ACTH deficiency; can be associated with autoimmune thyroid disease, more rarely with vitiligo, premature ovarian failure, type 1 diabetes, pernicious anemia
Pituitary apoplexy/ hemorrhage		Hemorrhagic infarction of large pituitary adenomas or pituitary infarction consequent to traumatic major blood loss (e.g., surgery or pregnancy: Sheehan's syndrome)
Pituitary infiltration		Tuberculosis, actinomycosis, sarcoidosis, histiocytosis X, granulomatosis with polyangiitis (Wegener's), metastases
Drug-induced		Chronic glucocorticoid excess (endogenous or exogenous), immune check point inhibitors
Congenital isolated ACTH deficiency	*TBX19* (Tpit)	
Combined pituitary hormone deficiency (CPHD)	*PROP-1*	Progressive development of CPHD in the order GH, PRL, TSH, LH/FSH, ACTH
	HESX1	CPHD and septo-optic dysplasia
	LHX3	CPHD and limited neck rotation, sensorineural deafness
	LHX4	CPHD and cerebellar abnormalities
	SOX3	CPHD and variable mental retardation
Proopiomelanocortin (POMC) deficiency	*POMC*	Early-onset obesity, red hair pigmentation

Abbreviations: ACTH, adrenocorticotropic hormone; GH, growth hormone; LH/FSH, luteinizing hormone/follicle-stimulating hormone; PRL, prolactin; TSH, thyroid-stimulating hormone.

Diagnosis The diagnosis of adrenal insufficiency is established by the short cosyntropin test, a safe and reliable tool with excellent predictive diagnostic value **(Fig. 386-16)**. The cutoff for failure is usually defined at cortisol levels of <450–500 nmol/L (16–18 μg/dL) sampled 30–60 min after ACTH stimulation; the exact cutoff is dependent on the locally available assay, with generally lower cutoffs for mass spectrometry–based assays. During the early phase of HPA disruption (e.g., within 4 weeks of pituitary insufficiency), patients may still respond to exogenous ACTH stimulation. In this circumstance, the ITT is an

TABLE 386-9 Signs and Symptoms of Adrenal Insufficiency

Signs and Symptoms Caused by Glucocorticoid Deficiency
Fatigue, lack of energy
Weight loss, anorexia
Myalgia, joint pain
Fever
Normochromic anemia, lymphocytosis, eosinophilia
Slightly increased TSH (due to loss of feedback inhibition of TSH release)
Hypoglycemia (more frequent in children)
Low blood pressure, postural hypotension
Hyponatremia (due to loss of feedback inhibition of AVP release)
Signs and Symptoms Caused by Mineralocorticoid Deficiency (Primary Adrenal Insufficiency Only)
Abdominal pain, nausea, vomiting
Dizziness, postural hypotension
Salt craving
Low blood pressure, postural hypotension
Increased serum creatinine (due to volume depletion)
Hyponatremia
Hyperkalemia
Signs and Symptoms Caused by Adrenal Androgen Deficiency
Lack of energy
Dry and itchy skin (in women)
Loss of libido (in women)
Loss of axillary and pubic hair (in women)
Other Signs and Symptoms
Hyperpigmentation (primary adrenal insufficiency only) (due to excess of proopiomelanocortin [POMC]-derived peptides)
Alabaster-colored pale skin (secondary adrenal insufficiency only) (due to deficiency of POMC-derived peptides)

Abbreviations: AVP, arginine vasopressin; TSH, thyroid-stimulating hormone.

alternative choice but is more invasive and should be carried out only under a specialist's supervision (see above). Induction of hypoglycemia is contraindicated in individuals with diabetes mellitus, cardiovascular disease, or history of seizures. Random serum cortisol measurements are of limited diagnostic value because baseline cortisol levels may be coincidentally low due to the physiologic diurnal rhythm of cortisol secretion (Fig. 386-3). Similarly, many patients with secondary adrenal insufficiency have relatively normal baseline cortisol levels but fail to mount an appropriate cortisol response to ACTH, which can only be revealed by stimulation testing. Importantly, tests to establish the diagnosis of adrenal insufficiency should never delay treatment. Thus, in a patient with suspected adrenal crisis, it is reasonable to draw baseline cortisol levels, provide replacement therapy, and defer formal stimulation testing until a later time.

Once adrenal insufficiency is confirmed, measurement of plasma ACTH is the next step, with increased or inappropriately low levels defining primary and secondary origin of disease, respectively (Fig. 386-16). In primary adrenal insufficiency, increased plasma renin will confirm the presence of mineralocorticoid deficiency. At initial presentation, patients with primary adrenal insufficiency should undergo screening for steroid autoantibodies as a marker of autoimmune adrenalitis. If these tests are negative, adrenal imaging by CT is indicated to investigate possible hemorrhage, infiltration, or masses. In male patients with negative autoantibodies in the plasma, very-long-chain fatty acids should be measured to exclude X-ALD. Patients with inappropriately low ACTH, in the presence of confirmed cortisol deficiency, should undergo hypothalamic-pituitary imaging by MRI. Features suggestive of preceding pituitary apoplexy, such as sudden-onset severe headache or history of previous head trauma, should be carefully explored, particularly in patients with no obvious MRI lesion.

TREATMENT

Acute Adrenal Insufficiency

Acute adrenal insufficiency requires immediate initiation of rehydration, usually carried out by saline infusion at initial rates of 1 L/h with continuous cardiac monitoring. Glucocorticoid replacement should be initiated by bolus injection of 100 mg hydrocortisone, followed by the administration of 200 mg hydrocortisone over 24 h, preferably by continuous infusion or alternatively by bolus IV or IM injections. Mineralocorticoid replacement can be initiated once the daily hydrocortisone dose has been reduced to <50 mg because at higher doses hydrocortisone provides sufficient stimulation of MRs.

Glucocorticoid replacement for the treatment of chronic adrenal insufficiency should be administered at a dose that replaces the physiologic daily cortisol production, which is usually achieved by the oral administration of 15–25 mg hydrocortisone in two to three divided doses. Pregnancy may require an increase in hydrocortisone dose by 50% during the last trimester. In all patients, at least one-half of the daily dose should be administered in the morning. Currently available glucocorticoid preparations fail to mimic the physiologic cortisol secretion rhythm (Fig. 386-3). Long-acting glucocorticoids such as prednisolone or dexamethasone are not preferred because they result in increased glucocorticoid exposure due to extended GR activation at times of physiologically low cortisol secretion. There are no well-established dose equivalencies, but as a guide, equipotency can be assumed for 1 mg hydrocortisone, 1.6 mg cortisone acetate, 0.2 mg prednisolone, 0.25 mg prednisone, and 0.025 mg dexamethasone.

Monitoring of glucocorticoid replacement is mainly based on the history and examination for signs and symptoms suggestive of glucocorticoid over- or underreplacement, including assessment of body weight and blood pressure. Plasma ACTH, 24-h urinary free cortisol, or serum cortisol day curves reflect whether hydrocortisone has been taken or not but do not convey reliable information about replacement quality. In patients with isolated primary adrenal insufficiency, monitoring should include screening for autoimmune thyroid disease, and female patients should be made aware of the possibility of premature ovarian failure. Supraphysiologic glucocorticoid treatment with doses equivalent to 30 mg hydrocortisone or more will affect bone metabolism, and these patients should undergo regular bone mineral density evaluation. All patients with adrenal insufficiency need to be instructed about the requirement for stress-related glucocorticoid dose adjustments. These generally consist of doubling the routine oral glucocorticoid dose in the case of intercurrent illness with fever and bed rest and the need for immediate IV or IM injection of 100 mg hydrocortisone followed by intravenous infusion of 200 mg hydrocortisone/24 h in cases of prolonged vomiting, surgery, or trauma. All patients, but in particular those living or traveling in regions with delayed access to acute health care, should carry a hydrocortisone self-injection emergency kit, in addition to their usual steroid emergency cards and bracelets, and should receive training in its use.

Mineralocorticoid replacement in primary adrenal insufficiency should be initiated at a dose of 100–150 μg fludrocortisone. The adequacy of treatment can be evaluated by measuring blood pressure, sitting and standing, to detect a postural drop indicative of hypovolemia. In addition, serum sodium, potassium, and plasma renin should be measured regularly. Renin levels should be kept in the upper normal reference range. Changes in glucocorticoid dose may also impact on mineralocorticoid replacement as cortisol also binds the MR; 40 mg of hydrocortisone is equivalent to 100 μg of fludrocortisone. It is important to note that prednisone and prednisolone have reduced mineralocorticoid activity and dexamethasone has none. In patients living or traveling in areas with hot or tropical weather conditions, the fludrocortisone dose should be increased by 50–100 μg during the summer. Mineralocorticoid dose may also need to be adjusted during pregnancy due to the antimineralocorticoid activity of progesterone, but this is less often required

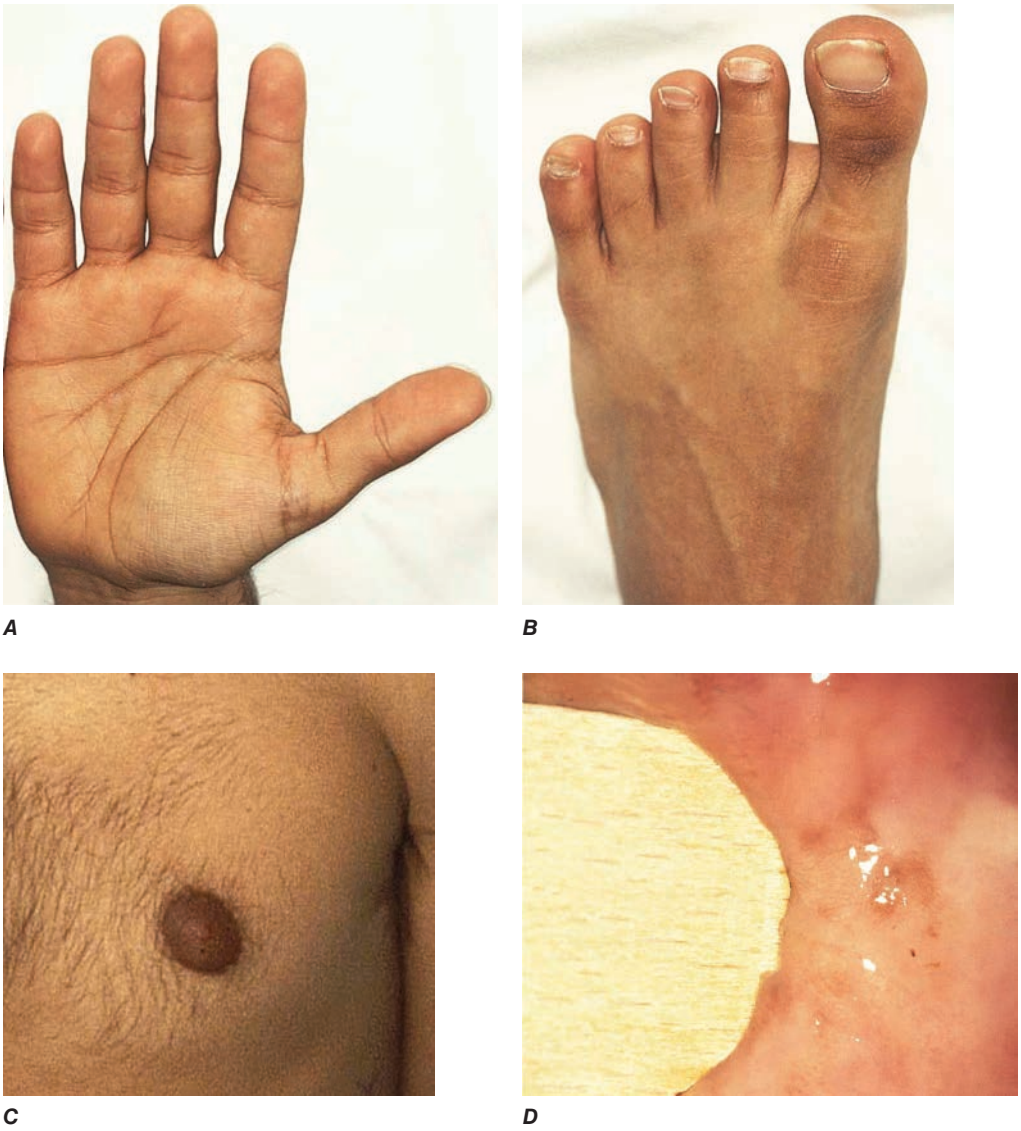

FIGURE 386-15 Clinical features of Addison's disease. Note the hyperpigmentation in areas of increased friction including (***A***) palmar creases, (***B***) dorsal foot, (***C***) nipples and axillary region, and (***D***) patchy hyperpigmentation of the oral mucosa.

than hydrocortisone dose adjustment. Plasma renin cannot serve as a monitoring tool during pregnancy because renin rises physiologically during gestation.

Adrenal androgen replacement is an option in patients with lack of energy, despite optimized glucocorticoid and mineralocorticoid replacement. It may also be indicated in women with features of androgen deficiency, including loss of libido. Adrenal androgen replacement can be achieved by once-daily administration of 25–50 mg DHEA. Treatment is monitored by measurement of DHEAS, androstenedione, testosterone, and sex hormone–binding globulin (SHBG) 24 h after the last DHEA dose.

CONGENITAL ADRENAL HYPERPLASIA

(See also Chap. 390) CAH is caused by mutations in genes encoding steroidogenic enzymes involved in glucocorticoid synthesis (*CYP21A2, CYP17A1, HSD3B2, CYP11B1*) or in the cofactor enzyme P450 oxidoreductase that serves as an electron donor to CYP21A2 and CYP17A1 (Fig. 386-1). Invariably, patients affected by CAH exhibit glucocorticoid deficiency. Depending on the exact step of enzymatic block, they may also have excess production of mineralocorticoids or deficient production of sex steroids (Table 386-10). The diagnosis of CAH is readily established by measurement of the steroids accumulating before the distinct enzymatic block, either in serum or in urine, preferably by the use of mass spectrometry–based assays (Table 386-10).

Mutations in *CYP21A2* are the most prevalent cause of CAH, responsible for 90–95% of cases. 21-Hydroxylase deficiency disrupts glucocorticoid and mineralocorticoid synthesis (Fig. 386-1), resulting in diminished negative feedback via the HPA axis. This leads to increased pituitary ACTH release, which drives increased synthesis of adrenal androgen precursors and subsequent androgen excess. The degree of impairment of glucocorticoid and mineralocorticoid secretion depends on the severity of mutations. Major loss-of-function mutations result in combined glucocorticoid and mineralocorticoid deficiency (classic CAH, neonatal presentation), whereas less severe mutations affect glucocorticoid synthesis only (simple virilizing CAH, neonatal or early childhood presentation). The mildest mutations result in the least severe clinical phenotype, nonclassic CAH, usually presenting during adolescence and early adulthood and with preserved glucocorticoid production.

Androgen excess is present in all patients and manifests with broad phenotypic variability, ranging from severe virilization of the external genitalia in neonatal girls (e.g., 46,XX disordered sex development [DSD]) to hirsutism and oligomenorrhea resembling a polycystic ovary syndrome phenotype in young women with nonclassic CAH. In countries without neonatal screening for CAH, boys with classic CAH usually present with life-threatening adrenal crisis in the first few weeks of life (salt-wasting crisis); a simple-virilizing genotype manifests with precocious pseudopuberty and advanced bone age in early childhood, whereas men with nonclassic CAH are usually detected only through family screening.

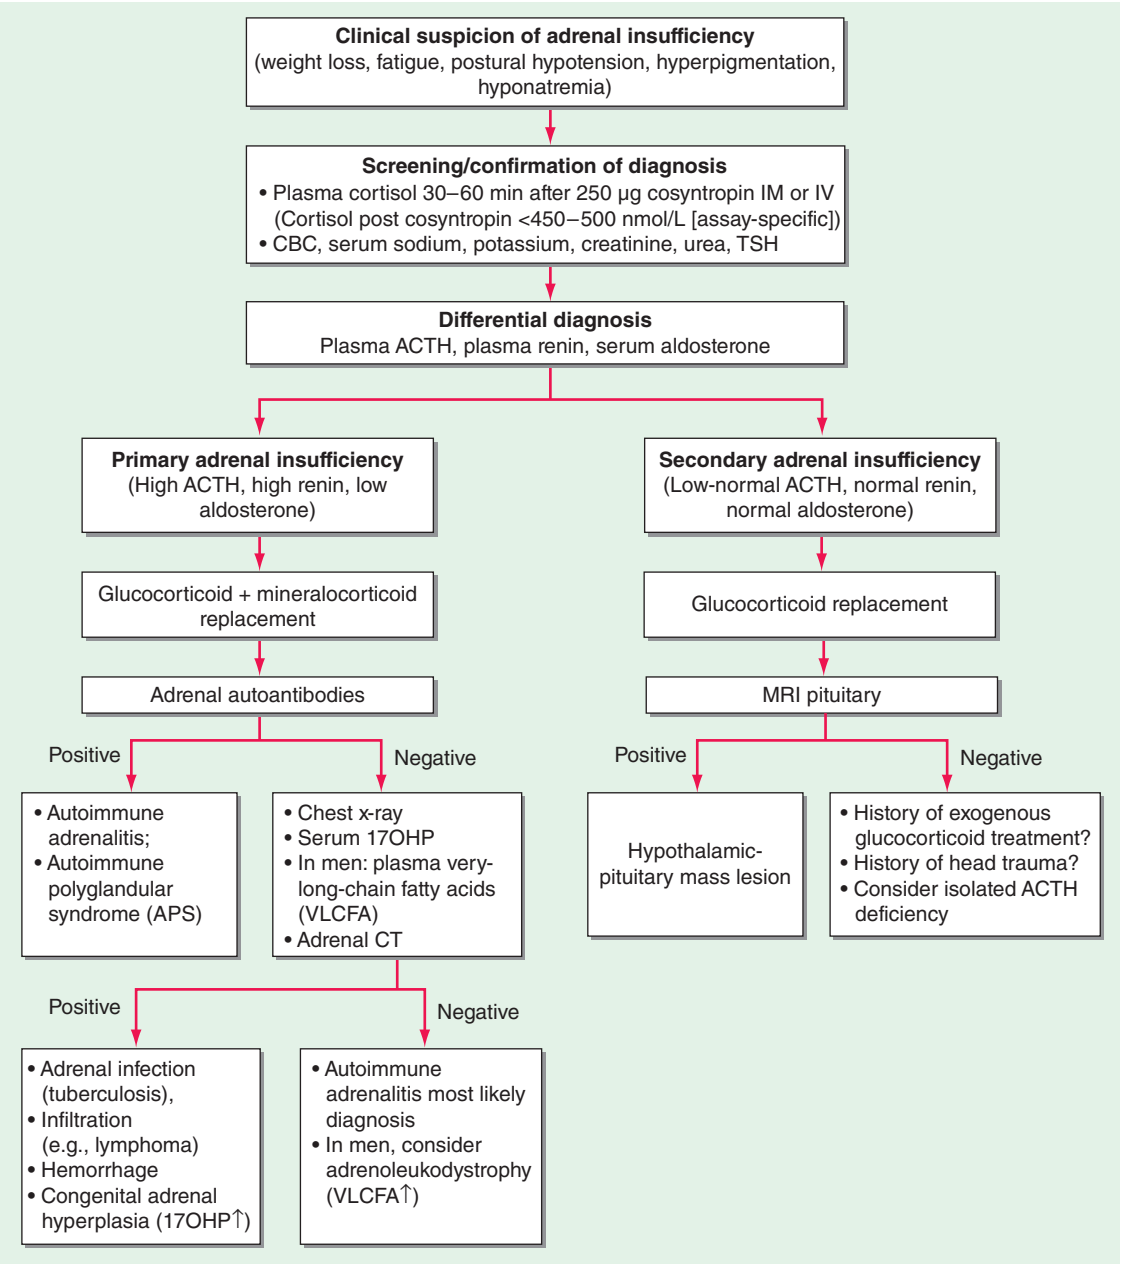

FIGURE 386-16 Management of the patient with suspected adrenal insufficiency. ACTH, adrenocorticotropic hormone; CBC, complete blood count; MRI, magnetic resonance imaging; PRA, plasma renin activity; TSH, thyroid-stimulating hormone.

TABLE 386-10 Variants of Congenital Adrenal Hyperplasia

VARIANT	GENE	IMPACT ON STEROID SYNTHESIS	DIAGNOSTIC MARKER STEROIDS IN SERUM (AND URINE)
21-Hydroxylase deficiency (21OHD)	*CYP21A2*	Glucocorticoid deficiency, mineralocorticoid deficiency, adrenal androgen excess	17-Hydroxyprogesterone, 21-deoxycortisol (pregnanetriol, 17-hydroxypregnanolone, pregnanetriolone)
11β-Hydroxylase deficiency (11OHD)	*CYP11B1*	Glucocorticoid deficiency, mineralocorticoid excess, adrenal androgen excess	11-Deoxycortisol, 11-deoxycorticosterone (tetrahydro-11-deoxycortisol, tetrahydro-11-deoxycorticosterone)
17α-Hydroxylase deficiency (17OHD)	*CYP17A1*	(Glucocorticoid deficiency), mineralocorticoid excess, androgen deficiency	11-Deoxycorticosterone, corticosterone, pregnenolone, progesterone (tetrahydro-11-deoxycorticosterone, tetrahydrocorticosterone, pregnenediol, pregnanediol)
3β-Hydroxysteroid dehydrogenase deficiency (3bHSDD)	*HSD3B2*	Glucocorticoid deficiency, (mineralocorticoid deficiency), adrenal androgen excess (females and males), gonadal androgen deficiency (males)	17-Hydroxypregnanolone (pregnanetriol)
P450 oxidoreductase deficiency (PORD)	*POR*	Glucocorticoid deficiency, (mineralocorticoid excess), prenatal androgen excess and postnatal androgen deficiency, skeletal malformations	Pregnenolone, progesterone, 17-hydroxyprogesterone (pregnanediol, pregnanetriol)

Magnetic resonance imaging scan with T1-weighted (***C***) and T2-weighted (***D***) images showing bilateral testicular adrenal rest tumors (*arrows*) in a young patient with salt-wasting CAH. *(Used with permission from N. Reisch.)*

Glucocorticoid treatment is more complex than for other causes of primary adrenal insufficiency as it not only needed to replace missing glucocorticoids but also to control the increased ACTH drive and subsequent androgen excess. Current treatment is hampered by the lack of glucocorticoid preparations that mimic the diurnal cortisol secretion profile, resulting in a prolonged period of ACTH stimulation and subsequent androgen production during the early morning hours. In childhood, optimization of growth and pubertal development are important goals of glucocorticoid treatment, in addition to prevention of adrenal crisis and treatment of 46,XX DSD. In adults, the focus shifts to preserving fertility and preventing side effects of glucocorticoid overtreatment, namely, the metabolic syndrome and osteoporosis. Fertility can be compromised in women due to oligomenorrhea/amenorrhea with chronic anovulation as a consequence of androgen excess. Men may develop testicular adrenal rest tissue (TART) **(Fig. 386-17)** consisting of hyperplastic cells with shared adrenal and gonadal characteristics located in the rete testis, which should not be confused with testicular tumors. TART can compromise sperm production and induce testicular fibrosis that may be irreversible.

TREATMENT

Congenital Adrenal Hyperplasia

Hydrocortisone is a good treatment option for the prevention of adrenal crisis, but longer acting prednisolone may be needed to control androgen excess. In children, hydrocortisone is given in divided doses at 1–1.5 times the normal cortisol production rate (~10–13 mg/m^2 per day). In adults, if hydrocortisone does not suffice, intermediate-acting glucocorticoids (e.g., prednisone) may be given, using the lowest dose necessary to suppress excess androgen production. For achieving fertility, dexamethasone treatment may be required but should only be given for the shortest possible time period to limit adverse metabolic side effects. The recent introduction of modified and delayed-release hydrocortisone, which mimics the endogenous physiologic cortisol release pattern, is promising, providing effective control of steroid precursor excess while the daily hydrocortisone dose is lower than required for immediate-release hydrocortisone.

Biochemical monitoring should include androstenedione and testosterone, aiming for the normal sex-specific reference range. 17OHP is a useful marker of overtreatment, indicated by 17OHP levels within the normal range of healthy controls. Glucocorticoid overtreatment may suppress the hypothalamic-pituitary-gonadal axis. Thus, treatment needs to be carefully titrated against clinical features of disease control. Stress-dose glucocorticoids should be given at double or triple the daily dose for surgery, acute illness, or severe trauma. Poorly controlled CAH can result in adrenocortical hyperplasia, which gave the disease its name, and may present as macronodular hyperplasia subsequent to long-standing ACTH excess (Fig. 386-17). The nodular areas can develop autonomous adrenal androgen production and may be unresponsive to glucocorticoid treatment. The prevalence of adrenomyelolipomas is increased in CAH; these are benign but can require surgical intervention due to lack of self-limiting growth.

Mineralocorticoid requirements change during life and are higher in children, explained by relative mineralocorticoid resistance that diminishes with ongoing maturation of the kidney. Children with CAH usually receive mineralocorticoid and salt replacement. However, young adults with CAH should undergo reassessment of their mineralocorticoid reserve. Plasma renin should be regularly monitored and kept within the upper half of the normal reference range.

387 Pheochromocytoma

Hartmut P. H. Neumann

Pheochromocytomas and paragangliomas are catecholamine-producing tumors derived from the sympathetic or parasympathetic nervous system. These tumors may arise sporadically or be inherited as features of multiple endocrine neoplasia type 2 (MEN 2), von Hippel–Lindau (VHL) disease, or several other pheochromocytoma-associated syndromes. The diagnosis of pheochromocytomas identifies a potentially correctable cause of hypertension, and their removal can prevent hypertensive crises that can be lethal. The clinical presentation is variable, ranging from an adrenal incidentaloma to a hypertensive crisis with associated cerebrovascular or cardiac complications.

EPIDEMIOLOGY

Pheochromocytoma is estimated to occur in 2–8 of 1 million persons per year, and ~0.1% of hypertensive patients harbor a pheochromocytoma. The mean age at diagnosis is ~40 years, although the tumors can occur from early childhood until late in life. The classic "rule of tens" for pheochromocytomas states that ~10% are bilateral, 10% are extra-adrenal, and 10% are metastatic.

ETIOLOGY AND PATHOGENESIS

Pheochromocytomas and paragangliomas are well-vascularized tumors that arise from cells derived from the sympathetic (e.g., adrenal medulla or sympathetic trunk) or parasympathetic (e.g., carotid body, glomus tympanicum, glomus jugulare, glomus vagale) paraganglia **(Fig. 387-1)**. The name *pheochromocytoma* reflects the formerly used black-colored staining caused by chromaffin oxidation of catecholamines; although a variety of terms have been used to describe these tumors, most clinicians use this designation to describe symptomatic catecholamine-producing tumors, including those in extra-adrenal retroperitoneal, pelvic, and thoracic sites. The term *paraganglioma* is used to describe catecholamine-producing tumors in the skull base and neck; these tumors may secrete little or no catecholamine. In contrast to common clinical parlance, the World Health Organization (WHO) restricts the term *pheochromocytoma* to adrenal tumors and applies the term *paraganglioma* to tumors at all other sites.

The etiology of sporadic pheochromocytomas and paragangliomas is unknown. However, 25–33% of patients have an inherited condition, including germline mutations in the classically recognized *RET* (*re*arranged during *t*ransfection), *VHL, NF1* (neurofibromatosis type 1), *SDHB, SDHC,* and *SDHD* (subunits of SDH) genes or in the more recently recognized *SDHA, SDHAF2*, *TMEM127* (transmembrane protein 127), *MAX* (myc-associated factor X), *FH* (fumarate hydratase), *PDH1, PDH2* (pyruvate dehydrogenase), *HIF1α* and *HIF2α* (hypoxia-inducible factor), *MDH2* (malate dehydrogenase), *KIF1Bβ* (kinesin family member), *IDH1*, (isocitrate dehydrogenase 1), *SLC25A11* (oxoglutarate/malate), *H-RAS* (transforming protein p21), and *DNMTA3* (DNA methyltransferase 3 alpha) genes. Biallelic gene inactivation, a characteristic of tumor-suppressor genes, has been demonstrated for the *VHL, NF1, SDHx, TMEM127, MAX, FH, PDH1, PDH2, MDH2*, and *KIF1Bβ* genes. In contrast, *RET* is a protooncogene, and mutations activate receptor tyrosine kinase activity. Succinate dehydrogenase (SDH) is an enzyme of the Krebs cycle and the mitochondrial respiratory chain. The VHL protein is a component of a ubiquitin E3 ligase. *VHL* mutations reduce protein degradation, resulting in upregulation of components involved in cell-cycle progression, glucose metabolism, and oxygen sensing. In addition to germline mutations, somatic mutations have been observed in >20 genes, broadly grouped into three different clusters of pathogenetically relevant genes: cluster 1, the pseudohypoxia group comprising mainly the genes *SDHx* (subunits of SDH), *FH*, *VHL*, and *HIF2A*; cluster 2, the kinase signaling group (*RET*, *NF1*, *TMEM127*, *MAX*, *HRAS, KIF1Bβ, PDH*); and cluster 3, the Wnt signaling group (*CSDE1*, *MAML3*).

CLINICAL FEATURES

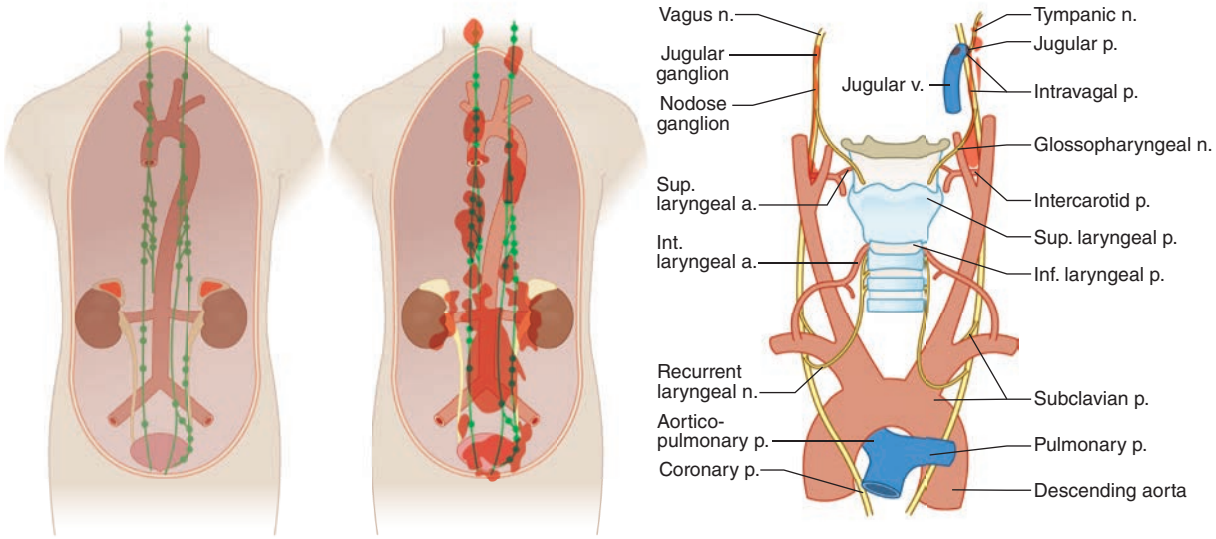
Its clinical presentation is so variable that pheochromocytoma has been termed "the great masquerader" **(Table 387-1)**. Among the presenting manifestations, episodes of palpitation, headache, and profuse sweating are typical, and these manifestations constitute a classic triad. The presence of all three manifestations in association with hypertension makes pheochromocytoma a likely diagnosis. However, a pheochromocytoma can be asymptomatic for years, and some tumors grow to a considerable size before patients note symptoms.

The dominant sign is hypertension. Classically, patients have episodic hypertension, but sustained hypertension is also common. Catecholamine crises can lead to heart failure, pulmonary edema, arrhythmias, and intracranial hemorrhage. During episodes of hormone release, which can occur at widely divergent intervals, patients are anxious and pale, and they experience tachycardia and palpitations. These paroxysms generally last <1 h and may be precipitated by surgery, positional changes, exercise, pregnancy, urination (particularly with bladder pheochromocytomas), and various medications (e.g., tricyclic antidepressants, opiates, metoclopramide).

DIAGNOSIS

The diagnosis is based on documentation of catecholamine excess by biochemical testing and localization of the tumor by imaging. These two criteria are of equal importance, although measurement of catecholamines or metanephrines (their methylated metabolites) is traditionally the first step in diagnosis.

Biochemical Testing Pheochromocytomas and paragangliomas synthesize and store catecholamines, which include norepinephrine (noradrenaline), epinephrine (adrenaline), and dopamine. Elevated



A Adrenal pheochromocytoma

B Extra-adrenal pheochromocytoma

C Head and neck paraganglioma

FIGURE 387-1 The paraganglial system and topographic sites (in red) of pheochromocytomas and paragangliomas. *(Figures A, B reproduced with permission from WM Manger, RW Gifford: Clinical and experimental pheochromocytoma. Cambridge: Blackwell Science; 1996.)*

plasma and urinary levels of catecholamines and metanephrines form the cornerstone of diagnosis. The characteristic fluctuations in the hormonal activity of tumors result in considerable variation in serial catecholamine measurements. However, most tumors continuously leak O-methylated metabolites, which are detected by measurement of metanephrines.

Catecholamines and metanephrines can be measured by different methods, including high-performance liquid chromatography, enzyme-linked immunosorbent assay, and liquid chromatography/mass spectrometry. When pheochromocytoma is suspected on clinical grounds (i.e., when values are three times the upper limit of normal), this diagnosis is highly likely regardless of the assay used. However, as summarized in **Table 387-2**, the sensitivity and specificity of available biochemical tests vary greatly, and these differences are important in assessing patients with borderline elevations of different compounds. Urinary tests for metanephrines (total or fractionated) and catecholamines are widely available and are used commonly for initial evaluation. Among these tests, those for the fractionated metanephrines and catecholamines are the most sensitive. Plasma tests are more convenient and include measurements of catecholamines and metanephrines. Measurements of plasma metanephrine are the most sensitive and are less susceptible to false-positive elevations from stress, including venipuncture. Although the incidence of false-positive test results has been reduced by the introduction of newer assays, physiologic stress responses and medications that increase catecholamine levels still can confound testing. Because the tumors are relatively rare, borderline elevations are likely to represent false-positive results. In this circumstance, it is important to exclude dietary or drug-related factors (withdrawal of levodopa or use of sympathomimetics, diuretics, tricyclic antidepressants, alpha and beta blockers) that might cause false-positive results and then to repeat testing or perform a clonidine suppression test (i.e., the measurement of plasma normetanephrine 3 h after oral administration of 300 μg of clonidine). Other pharmacologic tests, such as the phentolamine test and the glucagon provocation test, are of relatively low sensitivity and are not recommended.

TABLE 387-1 Clinical Features Associated with Pheochromocytoma, Listed by Frequency of Occurrence

1. Headaches	10. Weight loss
2. Profuse sweating	11. Paradoxical response to antihypertensive drugs
3. Palpitations and tachycardia	12. Polyuria and polydipsia
4. Hypertension, sustained or paroxysmal	13. Constipation
5. Anxiety and panic attacks	14. Orthostatic hypotension
6. Pallor	15. Dilated cardiomyopathy
7. Nausea	16. Erythrocytosis
8. Abdominal pain	17. Elevated blood sugar
9. Weakness	18. Hypercalcemia

Diagnostic Imaging A variety of methods have been used to localize pheochromocytomas and paragangliomas (Table 387-2, **Figs. 387-2, 387-3, and 387-4**). CT and MRI are similar in sensitivity and should be performed with contrast. T2-weighted MRI with gadolinium contrast is optimal for detecting pheochromocytomas and is somewhat better than CT for imaging extra-adrenal pheochromocytomas and paragangliomas. About 5% of adrenal incidentalomas, which usually are detected by CT or MRI, prove to be pheochromocytomas upon endocrinologic evaluation, but the presence of pheochromocytomas is unlikely if unenhanced CT reveals an attenuation of <10 HU.

Tumors also can be localized by procedures using radioactive tracers, including ^{131}I- or ^{123}I-metaiodobenzylguanidine (MIBG) scintigraphy, ^{111}In-somatostatin analogue scintigraphy, ^{18}F-DOPA positron emission tomography (PET), ^{68}Ga-DOTATATE PET, or ^{18}F-fluorodeoxyglucose

TABLE 387-2 Biochemical and Imaging Methods Used for Diagnosis of Pheochromocytoma and Paraganglioma

DIAGNOSTIC METHOD	SENSITIVITY	SPECIFICITY
24-h urinary tests		
Catecholamines	+++	+++
Fractionated metanephrines	++++	++
Total metanephrines	+++	++++
Plasma tests		
Catecholamines	+++	++
Free metanephrines	++++	+++
Imaging		
CT	++++	+++
MRI	++++	+++

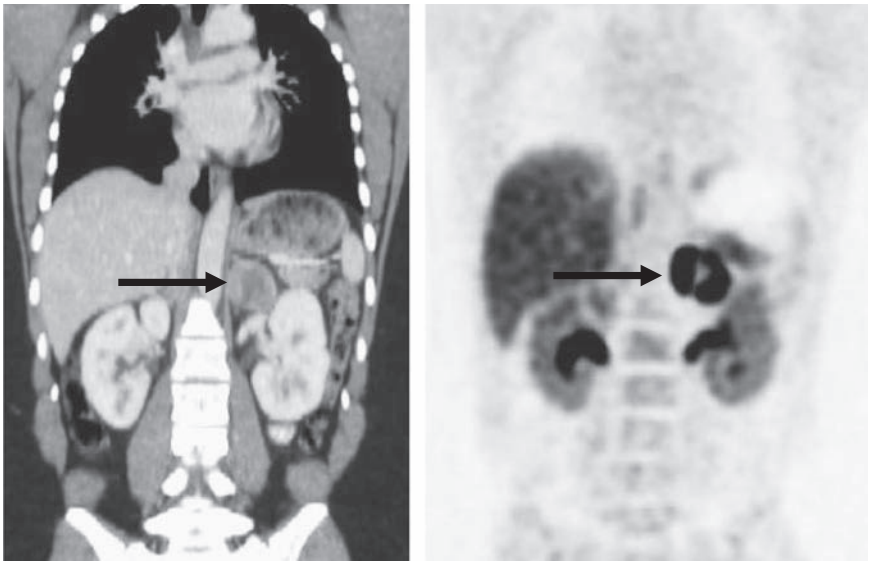
[a]Values are particularly high in head and neck paragangliomas.

Abbreviations: MIBG, metaiodobenzylguanidine; PET/CT, positron emission tomography plus CT. For the biochemical tests, the ratings correspond globally to sensitivity and specificity rates as follows: ++, <85%; +++, 85–95%; and ++++, >95%.



A B

FIGURE 387-2 Typical pheochromocytoma (adrenal unilateral). ***A.*** MRI. ***B.*** ^{18}F-DOPA positron emission tomography (PET). Tumor marked by *arrows. (Part A was provided courtesy of Dr. Tobias Krauss, Freiburg. Part B was provided courtesy of Dr. Juri Ruf, Freiburg.)*

(FDG) PET (Fig. 387-2*B* and 387-4*A* and *B*). For PET-CT with both ^{68}Ga-DOTATATE and ^{18}F-DOPA, the sensitivity and specificity are very high (>95%). These agents are particularly useful in the documentation of hereditary syndromes but also in metastatic pheochromocytoma, because uptake is exhibited also in paragangliomas and metastases.

Pathology Pheochromocytomas and paragangliomas are found at the classical sites of the adrenal medulla (Fig. 387-2) and paraganglia (Fig. 387-3). Histologically, the tumors often show a characteristic "Zellballen" pattern, consisting of nests of neuroendocrine chief cells with peripheral glial-like sustentacular cells. However, a broad spectrum of architectural and cytologic features can be seen. Immunohistochemistry is positive for chromogranin and synaptophysin in the chief cells and S-100 in the sustentacular cells **(Fig. 387-5*A-D*)**. Increasingly, staining with antibodies against the proteins encoded by susceptibility genes for hereditary pheochromocytomas, such as SDHB, is used to histologically demonstrate defects of these proteins, thereby making germline mutations more likely **(Fig. 387-5*E* and *F*)**.

Differential Diagnosis When the possibility of a pheochromocytoma is being entertained, other disorders to consider include essential hypertension, anxiety attacks, use of cocaine or amphetamines, mastocytosis or carcinoid syndrome (usually without hypertension), intracranial lesions, clonidine withdrawal, autonomic epilepsy, and factitious crises (usually from use of sympathomimetic amines). When an asymptomatic adrenal mass is identified, likely diagnoses other than pheochromocytoma include a nonfunctioning adrenal adenoma, an aldosteronoma, and a cortisol-producing adenoma (Cushing's syndrome).

TREATMENT

Pheochromocytoma

Complete tumor removal, the ultimate therapeutic goal, can be achieved by partial or total adrenalectomy. It is important to preserve the normal adrenal cortex in order to prevent Addison's disease, particularly in hereditary disorders in which bilateral pheochromocytomas are most likely. Preoperative preparation of the patient has to be considered, and blood pressure should be consistently <160/90 mmHg. Classically, blood pressure has been

A patient with the *SDHD* W5X mutation and PGL1 ^{68}Ga-DOTATATE positron emission tomography (PET) demonstrating tumor uptake in the right jugular glomus, the right and left carotid body, both adrenal glands, and an interaortocaval paraganglion (*arrows*). Note the physiologic accumulation of the radiopharmaceutical agent in the kidneys and the liver. ***B.*** ^{18}F-DOPA PET of a patient with metastatic pheochromocytoma. Several metastases marked by *arrows*. *(Parts A and B were provided courtesy of Dr. Juri Ruf, Freiburg.)*

controlled by α-adrenergic blockers (oral phenoxybenzamine, 0.5–4 mg/kg of body weight). Because patients are volume-constricted, liberal salt intake and hydration are necessary to avoid severe orthostasis. Oral prazosin or intravenous phentolamine can be used to manage paroxysms while adequate alpha blockade is awaited. Beta blockers (e.g., 10 mg of propranolol three or four times per day) can then be added. Other antihypertensives, such as calcium channel blockers or angiotensin-converting enzyme inhibitors, have also been used effectively.

Surgery should be performed by teams of surgeons and anesthesiologists with experience in the management of pheochromocytomas. Blood pressure can be labile during surgery, particularly at the outset of intubation or when the tumor is manipulated. Nitroprusside infusion is useful for intraoperative hypertensive crises, and hypotension usually responds to volume infusion. The latter side effect can, however, be avoided in normotensive pheochromocytoma patients by having only standby intraoperative nitroprusside, which has been shown to be safe and avoids postoperative hypotension often caused by alpha blockers; the long-lasting guideline for obligatory preoperative treatment with alpha blockers is under discussion.

Minimally invasive techniques (laparoscopy or retroperitoneoscopy) have become the standard approaches in pheochromocytoma surgery. They are associated with fewer complications, a faster recovery, and optimal cosmetic results. Extra-adrenal abdominal and most thoracic pheochromocytomas can also be removed endoscopically. Postoperatively, catecholamine normalization should be documented. An adrenocorticotropic hormone (ACTH) test should be used to exclude cortisol deficiency when bilateral adrenal cortex–sparing surgery has been performed.

Head and neck paragangliomas are a challenge for surgeons, since damage of adjacent tissue, mainly vessels or cranial nerves, is a frequent permanent side effect. Careful consideration of best management is important, and radiotherapy may be an alternative, especially for large head and neck paragangliomas.

METASTATIC PHEOCHROMOCYTOMA

About 5–10% of pheochromocytomas and paragangliomas are metastatic. The diagnosis of malignant pheochromocytoma is problematic. The typical histologic criteria of cellular atypia, presence of mitoses, and invasion of vessels or adjacent tissues are insufficient for the diagnosis of malignancy in pheochromocytoma. Thus, the term *malignant pheochromocytoma* has been replaced by *metastatic pheochromocytoma* as suggested by the WHO and is restricted to tumors with lymph node or distant metastases, the latter most commonly found by nuclear medicine imaging in lungs, bone, or liver locations suggesting a vascular pathway of spread (Fig. 387-4*B*). Because hereditary syndromes are associated with multifocal tumor sites, these features should be anticipated in patients with germline mutations, especially of *RET, VHL, SDHD*, or *SDHB*. However, distant metastases also occur in these syndromes, especially in carriers of *SDHB* mutations.

Treatment of metastatic pheochromocytoma or paraganglioma is challenging. Options include tumor mass reduction, alpha blockers for symptoms, chemotherapy, nuclear medicine radiotherapy, and stereotactic radiation. The first-line choice is nuclear medicine therapy for scintigraphically documented metastases, preferably with ^{131}I-MIBG in 100–300 mCi doses over 3–6 cycles. Other options for radionuclide treatment are somatostatin receptor ligands, e.g., DOTATOC labeled with yttrium-90 or lutetium-177, both for palliative outcomes. Averbuch's chemotherapy protocol includes dacarbazine (600 mg/m^2 on days 1 and 2), cyclophosphamide (750 mg/m^2 on day 1), and vincristine (1.4 mg/m^2 on day 1), all repeated every 21 days for 3–6 cycles. Palliation (stable disease to shrinkage) is achieved in about one-half of patients. Due to increasing insights in the genetics of pheochromocytoma and their molecular pathways, new targeted chemotherapeutic options such as

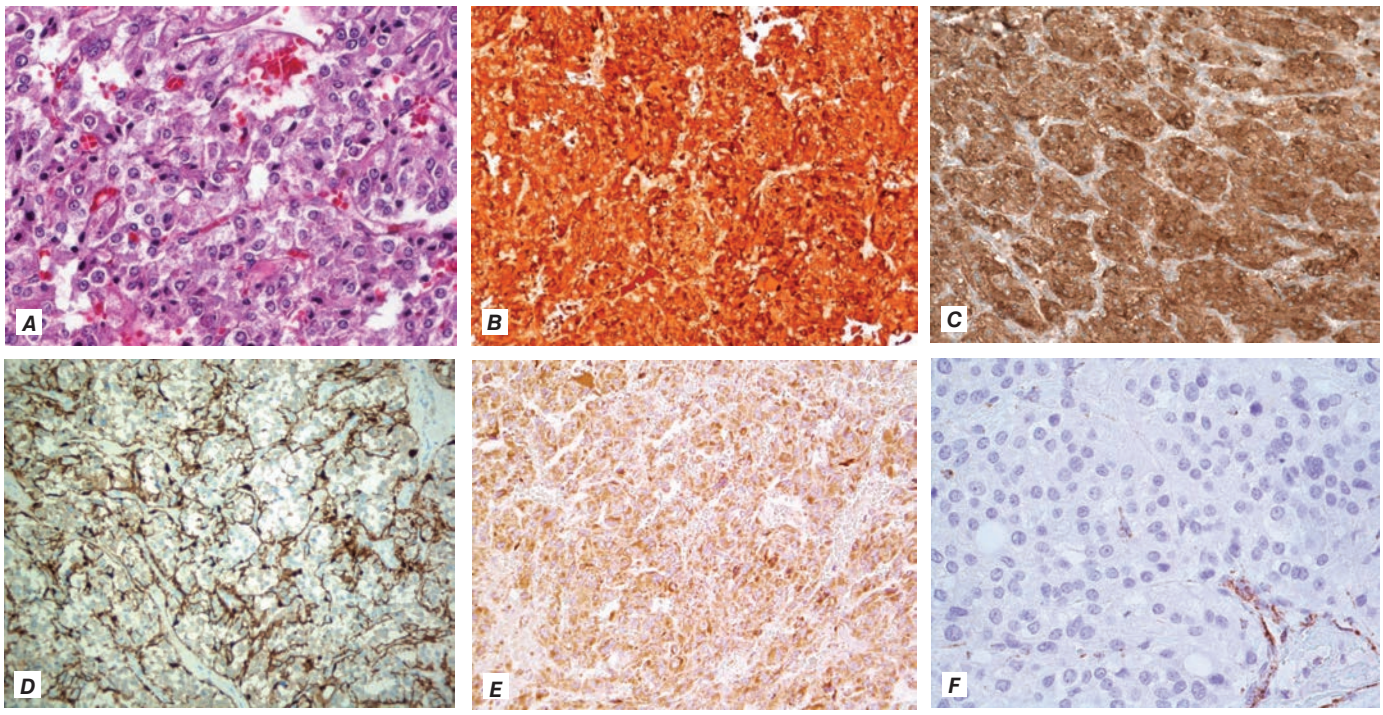

FIGURE 387-5 Histology and immunohistochemistry of pheochromocytoma. ***A.*** Hematoxylin and eosin, ***B.*** chromogranin, ***C.*** synaptophysin, ***C*** and ***B*** stain chief cells; ***D.*** S-100 stains sustentacular cells. ***E, F.*** Immunohistochemistry with SDHB antibody: positive staining (granular cytoplasmic staining) indicates intact SDHB (***E***), whereas negative staining (endothelial cells positive as internal control) (***F***) indicates structurally changed or absent SDHB due to a germline mutation in the *SDHB* gene, which was confirmed by molecular genetic analysis of a blood sample. *(Parts A–D and F were used with permission from Dr Helena Leijon, Helsinki. Part E was provided courtesy of Dr. Kurt Werner Schmid, Essen.)*

sunitinib and temozolomide/thalidomide are under development. The prognosis of metastatic pheochromocytoma or paraganglioma is variable, with 5-year survival rates of 30–60%.

PHEOCHROMOCYTOMA IN PREGNANCY

Pheochromocytomas occasionally are diagnosed in pregnancy and can be very challenging to manage. Endoscopic removal, preferably in the fourth to sixth month of gestation, is possible and can be followed by uneventful childbirth. Regular screening in families with inherited pheochromocytomas provides an opportunity to identify and remove such tumors in women of reproductive age.

PHEOCHROMOCYTOMA-ASSOCIATED SYNDROMES

About 25–33% of patients with a pheochromocytoma or paraganglioma have an inherited syndrome. At diagnosis, patients with inherited syndromes are a mean of ~15 years younger than patients with sporadic tumors.

The best-known pheochromocytoma-associated syndrome is the autosomal dominant disorder MEN 2 **(Chap. 388)**. Both types of MEN 2 (2A and 2B) are caused by mutations in *RET*, which encodes a tyrosine kinase. The locations of *RET* mutations correlate with the severity of disease and the type of MEN 2 **(Chap. 388)**. MEN 2A is characterized by medullary thyroid carcinoma (MTC), pheochromocytoma, and hyperparathyroidism; MEN 2B also includes MTC and pheochromocytoma as well as multiple mucosal neuromas, marfanoid habitus, and other developmental disorders, although it typically lacks hyperparathyroidism. MTC is found in virtually all patients with MEN 2, but pheochromocytoma occurs in only ~50% of these patients. Nearly all pheochromocytomas in MEN 2 are benign and located in the adrenals, often bilaterally. Pheochromocytoma may be symptomatic before MTC. Prophylactic thyroidectomy is being performed in many carriers of *RET* mutations; pheochromocytomas should be excluded before any surgery in these patients.

VHL is an autosomal dominant disorder that predisposes to retinal and cerebellar hemangioblastomas, which also occur in the brainstem and spinal cord **(Fig. 387-6)**. Other important features of VHL are clear cell renal carcinomas, pancreatic neuroendocrine tumors, endolymphatic sac tumors of the inner ear, cystadenomas of the epididymis and broad ligament, and multiple pancreatic or renal cysts. Although the *VHL* gene can be inactivated by all types of mutations, patients with pheochromocytoma predominantly have missense mutations. About 20–30% of patients with VHL have pheochromocytomas, but in some families, the incidence can reach 90%. The recognition of pheochromocytoma as a VHL-associated feature provides an opportunity to diagnose retinal, central nervous system, renal, and pancreatic tumors at a stage when effective treatment may still be possible.

NF1 was the first described pheochromocytoma-associated syndrome. The *NF1* gene functions as a tumor suppressor by regulating the Ras signaling cascade. Classic features of neurofibromatosis include multiple neurofibromas, café au lait spots, axillary freckling of the skin, and Lisch nodules of the iris. Pheochromocytomas occur in only ~1% of these patients and are located predominantly in the adrenals. Metastatic pheochromocytoma is not uncommon in NF1.

The *paraganglioma syndromes* (PGLs) have been classified by genetic analyses of families with head and neck paragangliomas. The susceptibility genes encode subunits of the enzyme SDH, a component in the Krebs cycle and the mitochondrial electron transport chain. SDH is formed by four subunits (A–D). Mutations of *SDHA* (PGL5), *SDHB* (PGL4), *SDHC* (PGL3), *SDHD* (PGL1), and *SDHAF2* (PGL2) predispose to the PGLs. The transmission of the disease in carriers of *SDHA*, *SDHB*, and *SDHC* germline mutations is autosomal dominant. In contrast, in virtually all *SDHD* and *SDHAF2* families, only the progeny of affected fathers develop tumors if they inherit the mutation. PGL1 is most common, followed by PGL4; PGL2, PGL3, and PGL5 are rare. Adrenal, extra-adrenal abdominal, and thoracic pheochromocytomas, which are components of PGL1, PGL4, and PGL5, are rare in PGL3 and absent in PGL2 (Fig. 387-4*A*). About one-third of patients with PGL4 develop metastases, which is the highest rate in pheochromocytoma-associated syndromes. Other syndromes with metastatic pheochromocytomas are mainly VHL, NF1, and PGL1.

Other familial pheochromocytoma has been attributed to hereditary, mainly adrenal tumors in patients with germline mutations in the genes *TMEM127* and *MAX*. Transmission is also autosomal dominant, and mutations of *MAX*, like those of *SDHD*, cause tumors only if inherited from the father.

GENETIC SCREENING OF PATIENTS WITH PHEOCHROMOCYTOMA OR PARAGANGLIOMA

Effective preventive medicine for pheochromocytoma and pheochromocytoma-associated diseases requires management according to identified germline mutations in susceptibility genes. In addition to family history, general features suggesting an inherited syndrome include young age, multifocal tumors, extra-adrenal tumors, and metastatic tumors (Table 387-3 and Fig. 387-7). Because of the relatively high prevalence of familial syndromes among patients who present with pheochromocytoma or paraganglioma, it is useful to identify germline mutations even in patients without a known family history. A first step is to search for clinical features of inherited syndromes and

to obtain an in-depth, multigenerational family history. Each of these syndromes exhibits autosomal dominant transmission with variable penetrance, but a proband with a mother affected by paraganglial tumors is not predisposed to PLG1 and PGL2 (*SDHD* and *SDHAF2* mutation carrier). Cutaneous neurofibromas, café au lait spots, and axillary freckling suggest neurofibromatosis. Germline mutations in *NF1* have nearly never been reported in patients with sporadic pheochromocytomas. Thus, *NF1* testing is not needed in the absence of other clinical features of neurofibromatosis. A personal or family history of MTC or an elevation of serum calcitonin strongly suggests MEN 2 and should prompt testing for *RET* mutations. A history of visual impairment or tumors of the cerebellum, brain stem, spinal

cord or the kidney suggests the possibility of VHL. A personal and/or family history of head and neck paraganglioma suggests PGL1 or PGL4.

A single adrenal pheochromocytoma in a patient with an otherwise unremarkable history may still be associated with mutations of *VHL, RET, SDHB*, or *SDHD* (in decreasing order of frequency). Two-thirds of extra-adrenal tumors are associated with one of these syndromes, and multifocal tumors occur with decreasing frequency in carriers of *RET, SDHD, VHL*, *SDHB*, and *MAX* mutations. About 30% of head and neck paragangliomas are associated with germline mutations of one of the SDH subunit genes (most often *SDHD*) and are rare in carriers of *VHL, RET, MAX*, and *TMEM127* mutations. Immunohistochemistry is helpful in the preselection of hereditary pheochromocytoma. Negative immunostaining with antibodies to SDHB (Fig. 387-5*F*), TMEM127, and MAX may predict mutations of the *SDHx* (PGL1-5), *TMEM127*, and *MAX* genes, respectively.

Whole genome sequence analysis is increasingly replacing targeted Sanger sequencing. It is now possible to search for germline mutations in a set of genes, such that all susceptibility genes for pheochromocytoma-associated syndromes could be analyzed in one procedure. Of note, sequencing protocols may not detect large deletions of one or more exons.

Once the underlying syndrome is diagnosed, the benefit of genetic testing can be extended to relatives. For this purpose, it is necessary to identify the germline mutation in the proband and, after genetic counseling, to perform DNA sequence analyses of the responsible gene in relatives to determine whether they are affected. Other family members may benefit when individuals who carry a germline mutation are biochemically screened for paraganglial tumors.

Asymptomatic paraganglial tumors, now often detected in patients with hereditary tumors and their relatives, are challenging to manage. Watchful waiting strategies have been introduced. Head and neck paragangliomas—mainly carotid body, jugular, and vagal tumors—are increasingly treated by radiation, since surgery is frequently associated with permanent palsy of cranial nerves II, VII, IX, X, XI, and XII. Nevertheless, tympanic paragangliomas are symptomatic early, and most of these tumors can easily be resected, with subsequent improvement of hearing and alleviation of tinnitus.

388 Multiple Endocrine Neoplasia Syndromes

R. V. Thakker

Multiple endocrine neoplasia (MEN) is characterized by a predilection for tumors involving two or more endocrine glands. Four major forms of MEN are recognized and referred to as MEN types 1–4 (MEN 1–4) **(Table 388-1)**. Each type of MEN is inherited as an autosomal dominant syndrome or may occur sporadically, that is, without a family history. However, this distinction between familial and sporadic forms is often difficult because family members with the disease may have died before symptoms developed. In addition to MEN 1–4, at least six other syndromes are associated with multiple endocrine and other organ neoplasias (MEONs) **(Table 388-2)**. These MEONs include the hyperparathyroidism-jaw tumor (HPT-JT) syndrome, Carney complex, von Hippel–Lindau disease **(Chap. 387)**, neurofibromatosis type 1 **(Chap. 90)**, Cowden's syndrome (CWS), and McCune-Albright syndrome (MAS) **(Chap. 412)**; all of these are inherited as autosomal dominant disorders, except for MAS, which is caused by mosaic expression of a postzygotic somatic cell mutation (Table 388-2).

A diagnosis of a MEN or MEON syndrome may be established in an individual by one of three criteria: (1) clinical features (two or more of the associated tumors [or lesions] in an individual); (2) familial pattern (one of the associated tumors [or lesions] in a first-degree relative of a patient with a clinical diagnosis of the syndrome); and (3) genetic analysis (a germline mutation in the associated gene in an individual, who may be clinically affected or asymptomatic). Mutational analysis in MEN and MEON syndromes is helpful in clinical practice to (1) confirm the clinical diagnosis; (2) identify family members who harbor the mutation and require screening for relevant tumor detection and early/appropriate treatment; and (3) identify the ~50% of family members who do not harbor the germline mutation and can, therefore, be alleviated of the anxiety of developing associated tumors. This latter aspect also helps to reduce health care costs by reducing the need for unnecessary biochemical and radiologic investigations.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

Clinical Manifestations MEN type 1 (MEN 1), which is also referred to as Wermer's syndrome, is characterized by the triad of tumors involving the parathyroids, pancreatic islets, and anterior pituitary. In addition, adrenal cortical tumors, carcinoid tumors usually of the foregut, meningiomas, facial angiofibromas, collagenomas, and lipomas may also occur in some patients with MEN 1. Combinations of the affected glands and their pathologic features (e.g., hyperplastic adenomas of the parathyroid glands) may differ in members of the same family and even between identical twins. In addition, a nonfamilial (e.g., sporadic) form occurs in 8–14% of patients with MEN 1, and molecular genetic studies have confirmed the occurrence of de novo mutations of the *MEN1* gene in ~10% of patients with MEN 1. The prevalence of MEN 1 is ~0.25% based on randomly chosen postmortem studies but is 1–18% among patients with primary hyperparathyroidism, 16–38% among patients with pancreatic islet tumors, and <3% among patients with pituitary tumors. The disorder affects all age groups, with a reported age range of 5–81 years, with clinical and biochemical manifestations developing in the vast majority by the fifth decade. The clinical manifestations of MEN 1 are related to the sites of tumors and their hormonal products. In the absence of treatment, endocrine tumors are associated with an earlier mortality in patients with MEN 1, with a 50% probability of death by the age of 50 years. The cause of death is usually a malignant tumor, often from a pancreatic neuroendocrine tumor (NET) or foregut carcinoid. In addition, the treatment outcomes of patients with MEN 1–associated tumors are not as successful as those in patients with non–MEN 1 tumors. This is because MEN 1–associated tumors, with the exception of pituitary

CWS6	AKT1	14q32.33
CWS7	SEC23B	20p11.23
McCune-Albright syndrome (MAS)	$G_s\alpha$	20q13.32

[a]The inheritance for these disorders is autosomal dominant, except MAS, which is due to mosaicism that results from the postzygotic somatic cell mutation of the *GNAS1* gene, encoding $G_s\alpha$. [b]?, unknown.

NETs, are usually multiple, making it difficult to achieve a successful surgical cure. Occult metastatic disease is also more prevalent in MEN 1, and the tumors may be larger, more aggressive, and resistant to treatment.

Parathyroid Tumors (See also Chap. 410) Primary hyperparathyroidism occurs in ~90% of patients and is the most common feature of MEN 1. Patients may have asymptomatic hypercalcemia or vague symptoms associated with hypercalcemia (e.g., polyuria, polydipsia, constipation, malaise, or dyspepsia). Nephrolithiasis and osteitis fibrosa cystica (less commonly) may also occur. Biochemical investigations reveal hypercalcemia, usually in association with elevated circulating parathyroid hormone (PTH) (Table 388-3). The hypercalcemia is usually mild, and severe hypercalcemia or parathyroid cancer is a rare occurrence. Additional differences in the primary hyperparathyroidism of patients with MEN 1, as opposed to those without MEN 1, include an earlier age at onset (20–25 vs 55 years) and an equal male-to-female ratio (1:1 vs 1:3). Preoperative imaging (e.g., neck ultrasound with ^{99m}Tc-sestamibi parathyroid scintigraphy) is of limited benefit because all parathyroid glands may be affected, and neck exploration may be required irrespective of preoperative localization studies.

TREATMENT

Parathyroid Tumors

Surgical removal of the abnormally overactive parathyroids in patients with MEN 1 is the definitive treatment. However, it is controversial whether to perform subtotal (e.g., removal of 3.5 glands) or total parathyroidectomy with or without autotransplantation of parathyroid tissue in the forearm, and whether surgery should be performed at an early or late stage. Minimally invasive parathyroidectomy is not recommended because all four parathyroid glands are usually affected with multiple adenomas or hyperplasia. Surgical experience should be taken into account given the variability in pathology in MEN 1. Calcimimetics (e.g., cinacalcet), which act via the calcium-sensing receptor, have been used to treat primary hyperparathyroidism in some patients when surgery is unsuccessful or contraindicated.

Pancreatic Tumors (See also Chap. 84) The incidence of pancreatic islet cell tumors, which are NETs, in patients with MEN 1 ranges from 30 to 80% in different series. Most of these tumors (Table 388-1) produce excessive amounts of hormone (e.g., gastrin, insulin, glucagon, vasoactive intestinal polypeptide [VIP]) and are associated with distinct clinical syndromes, although some are nonfunctioning or

TABLE 388-3 Biochemical and Radiologic Screening in Multiple Endocrine Neoplasia Type 1

TUMOR	AGE TO BEGIN (YEARS)	BIOCHEMICAL TEST (PLASMA OR SERUM) ANNUALLY	IMAGING TEST (TIME INTERVAL)
Parathyroid	8	Calcium, PTH	None
Pancreatic NETs			
Gastrinoma	20	Gastrin (± gastric pH)	None
Insulinoma	5	Fasting glucose, insulin	None
Other pancreatic NET	<10	Chromogranin A; pancreatic polypeptide, glucagon, vasoactive intestinal peptide	MRI, CT, or EUS (annually)
Anterior pituitary	5	Prolactin, IGF-I	MRI (every 3 years)
Adrenal	<10	None unless symptoms or signs of functioning tumor and/or tumor >1 cm identified on imaging	MRI or CT (annually with pancreatic imaging)
Thymic and bronchial carcinoid	15	None	CT or MRI (every 1–2 years)

Abbreviations: CT, computed tomography; EUS, endoscopic ultrasound; IGF-I, insulin-like growth factor I; MRI, magnetic resonance imaging; PTH, parathyroid hormone.

Source: Data from PJ Newey, RV Thakker: Role of multiple endocrine neoplasia type 1 mutational analysis in clinical practice. Endocr Pract 17, 2011 and RV Thakker: Multiple endocrine neoplasia type 1 (MEN1). Translational Endocrinology and Metabolism, Vol 2. Chevy Chase, MD: The Endocrine Society; 2011.

nonsecretory. These pancreatic islet cell tumors have an earlier age at onset in patients with MEN 1 than in patients without MEN 1.

Gastrinoma Gastrin-secreting tumors (gastrinomas) are associated with marked gastric acid production and recurrent peptic ulcerations, a combination referred to as Zollinger-Ellison syndrome. Gastrinomas occur more often in patients with MEN 1 who are aged >30 years. Recurrent severe multiple peptic ulcers, which may perforate, and cachexia are major contributors to the high mortality. Patients with Zollinger-Ellison syndrome may also suffer from diarrhea and steatorrhea. The diagnosis is established by demonstration of an elevated fasting serum gastrin concentration in association with increased basal gastric acid secretion (Table 388-3). However, the diagnosis of Zollinger-Ellison syndrome may be difficult in hypercalcemic MEN 1 patients because hypercalcemia can also cause hypergastrinemia. Ultrasonography, endoscopic ultrasonography, computed tomography (CT), nuclear magnetic resonance imaging (MRI), selective abdominal angiography, venous sampling, and somatostatin receptor scintigraphy (SRS) are helpful in localizing the tumor prior to surgery. Gastrinomas represent >50% of all pancreatic NETs in patients with MEN 1, and ~20% of patients with gastrinomas will be found to have MEN 1. Gastrinomas, which may also occur in the duodenal mucosa, are the major cause of morbidity and mortality in patients with MEN 1.

TREATMENT

Gastrinoma

Medical treatment of patients with MEN 1 and Zollinger-Ellison syndrome is directed toward reducing basal acid output to <10 mmol/L. Parietal cell H^+-K^+-adenosine triphosphatase (ATPase) inhibitors (e.g., omeprazole or lansoprazole) reduce acid output and are the drugs of choice for gastrinomas. Some patients may also require additional treatment with the histamine H_2 receptor antagonists cimetidine or ranitidine. The role of surgery in the treatment of gastrinomas in patients with MEN 1 is controversial. The goal of surgery is to reduce the risk of distant metastatic disease and improve survival. For a nonmetastatic gastrinoma situated in the pancreas, surgical excision is often effective. However, the risk of hepatic metastases increases with tumor size, such that 25–40% of patients with pancreatic NETs >4 cm develop hepatic metastases, and 50–70% of patients with tumors 2–3 cm in size have lymph node metastases. Survival in MEN 1 patients with gastrinomas <2.5 cm in size is 100% at 15 years, but 52% at 15 years, if metastatic disease is present. The presence of lymph node metastases does not appear to adversely affect survival. Surgery for gastrinomas that are >2–2.5 cm has been recommended, because the disease-related survival in these patients is improved following surgery. In addition, duodenal gastrinomas, which occur more frequently in patients with MEN 1, have been treated successfully with surgery. However, in most patients with MEN 1, gastrinomas are multiple or extrapancreatic, and with the exception of duodenal gastrinomas, surgery is rarely successful. For example, the results of one study revealed that only ~15% of patients with MEN 1 were free of disease immediately after surgery, and at 5 years, this number had decreased to ~5%; the respective outcomes in patients without MEN 1 were better, at 45 and 40%. Given these findings, most specialists recommend a nonsurgical management for gastrinomas in MEN 1, except as noted earlier for smaller, isolated lesions. Treatment of disseminated gastrinomas is difficult. Chemotherapy with streptozotocin and 5-fluorouracil; hormonal therapy with octreotide or lanreotide, which are human somatostatin analogues (SSAs); selected internal radiation therapy (SIRT); radiofrequency ablation; peptide radio receptor therapy (PRRT); hepatic artery embolization; administration of human leukocyte interferon; and removal of all resectable tumor have been successful in some patients.

Insulinoma These β islet cell insulin-secreting tumors represent 10–30% of all pancreatic tumors in patients with MEN 1. Patients with an insulinoma present with hypoglycemic symptoms (e.g., weakness, headaches, sweating, faintness, seizures, altered behavior, weight gain) that typically develop after fasting or exertion and improve after glucose intake. The most reliable test is a supervised 72-h fast. Biochemical investigations reveal increased plasma insulin concentrations in association with hypoglycemia (Table 388-3). Circulating concentrations of C peptide and proinsulin, which are also increased, are useful in establishing the diagnosis. It also is important to demonstrate the absence of sulfonylureas in plasma and urine samples obtained during the investigation of hypoglycemia (Table 388-3). Surgical success is greatly enhanced by preoperative localization by endoscopic ultrasonography, CT scanning, or celiac axis angiography. Additional localization methods may include preoperative and perioperative percutaneous transhepatic portal venous sampling, selective intraarterial stimulation with hepatic venous sampling, and intraoperative direct pancreatic ultrasonography. Insulinomas occur in association with gastrinomas in 10% of patients with MEN 1, and the two tumors may arise at different times. Insulinomas occur more often in patients with MEN 1 who are aged <40 years, and some arise in individuals aged <20 years. In contrast, in patients without MEN 1, insulinomas generally occur in those aged >40 years. Insulinomas may be the first manifestation of MEN 1 in 10% of patients, and ~4% of patients with insulinomas will have MEN 1.

TREATMENT

Insulinoma

Medical treatment, which consists of frequent carbohydrate meals and diazoxide or octreotide, is not always successful, and surgery is the optimal treatment. Surgical treatment, which ranges from enucleation of a single tumor to a distal pancreatectomy or partial pancreatectomy, has been curative in many patients. Chemotherapy

(streptozotocin, 5-fluorouracil, and doxorubicin), PRRT (e.g., with ^{177}Lu-DOTATATE), or hepatic artery embolization has been used for metastatic disease.

Glucagonoma These glucagon-secreting pancreatic NETs occur in <3% of patients with MEN 1. The characteristic clinical manifestations of a skin rash (necrolytic migratory erythema), weight loss, anemia, and stomatitis may be absent. The tumor may have been detected in an asymptomatic patient with MEN 1 undergoing pancreatic imaging or by the finding of glucose intolerance and hyperglucagonemia.

TREATMENT

Glucagonoma

Surgical removal of the glucagonoma is the treatment of choice. However, treatment may be difficult because ~50–80% of patients have metastases at the time of diagnosis. Medical treatment with SSAs (e.g., octreotide or lanreotide) or chemotherapy with streptozotocin and 5-fluorouracil has been successful in some patients, and hepatic artery embolization has been used to treat metastatic disease.

Vasoactive Intestinal Peptide (VIP) Tumors (VIPomas) VIPomas have been reported in only a few patients with MEN 1. This clinical syndrome is characterized by watery diarrhea, hypokalemia, and achlorhydria (WDHA syndrome), which is also referred to as the Verner-Morrison syndrome, or the VIPoma syndrome. The diagnosis is established by excluding laxative and diuretic abuse, confirming a stool volume in excess of 0.5–1.0 L/d during a fast, and documenting a markedly increased plasma VIP concentration.

TREATMENT

VIPomas

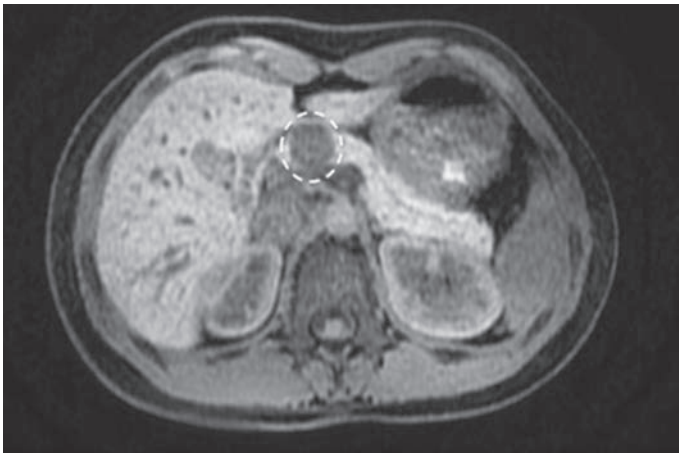
Surgical management of VIPomas, which are mostly located in the tail of the pancreas, can be curative. However, in patients with unresectable tumor, SSAs, such as octreotide and lanreotide, may be effective. Streptozotocin with 5-fluorouracil may be beneficial, along with hepatic artery embolization for the treatment of metastases.

Pancreatic Polypeptide-Secreting Tumors (PPomas) and Nonfunctioning Pancreatic NETs PPomas are found in a large number of patients with MEN 1. No pathologic sequelae of excessive polypeptide (PP) secretion are apparent, and the clinical significance of PP is unknown. Many PPomas may have been unrecognized or classified as nonfunctioning pancreatic NETs, which likely represent the most common enteropancreatic NET associated with MEN 1 (Fig. 388-1). The absence of both a clinical syndrome and specific biochemical abnormalities may result in a delayed diagnosis of nonfunctioning pancreatic NETs, which are associated with a worse prognosis than other functioning tumors, including insulinoma and gastrinoma. The optimum screening method and its timing interval for nonfunctioning pancreatic NETs remain to be established. At present, endoscopic ultrasound likely represents the most sensitive method of detecting small pancreatic tumors, but SRS is the most reliable method for detecting metastatic disease (Table 388-3).

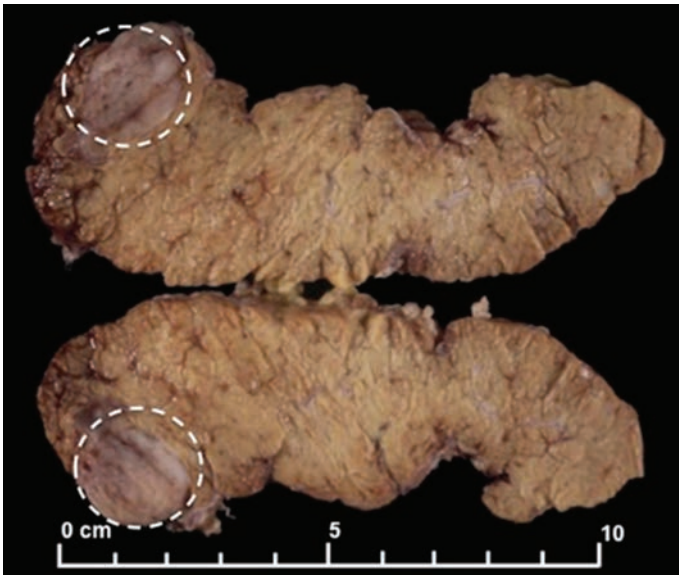
TREATMENT

PPomas and Nonfunctioning Pancreatic NETs

The management of nonfunctioning pancreatic NETs in the asymptomatic patient is controversial. One recommendation is to undertake surgery irrespective of tumor size after biochemical assessment is complete. Alternatively, other experts recommend surgery based on tumor size, using either >1 cm or >2 cm at different centers. Pancreatoduodenal surgery is successful in removing the tumors in 80% of patients, but >40% of patients develop complications, including diabetes mellitus, frequent steatorrhea, early and late dumping syndromes, and other gastrointestinal symptoms. However, ~50–60% of patients treated surgically survive >5 years. When considering these recommendations, it is important to consider that occult metastatic disease (e.g., tumors not detected by imaging investigations) is likely to be present in a substantial proportion of these patients at the time of presentation. Inhibitors of tyrosine kinase receptors (TKRs) and of the mammalian target of rapamycin (mTOR) signaling pathway have been reported to be effective in treating pancreatic NET metastases and in doubling the progression-free survival time. Additional treatments for metastatic disease include PRRT using ^{177}Lu-DOTATATE, chemotherapy, radiofrequency ablation, transarterial chemoembolization, and SIRT.



A



B

FIGURE 388-1 Pancreatic nonfunctioning neuroendocrine tumor (NET) in a 14-year-old patient with multiple endocrine neoplasia type 1 (MEN 1). ***A.*** An abdominal magnetic resonance imaging scan revealed a low-intensity >2.0 cm (anteroposterior maximal diameter) tumor within the neck of pancreas. There was no evidence of invasion of adjacent structures or metastases. The tumor is indicated by *white dashed circle*. ***B.*** The pancreatic NET was removed by surgery, and macroscopic examination confirmed the location of the tumor (*white dashed circles*) in the neck of the pancreas. Immunohistochemistry showed the tumor to immunostain for chromogranin A, but not gastrointestinal peptides or menin, thereby confirming that it was a nonsecreting NET due to loss of menin expression. *(Part A reproduced with permission from PJ Newey et al: Asymptomatic children with multiple endocrine neoplasia type 1 mutations may harbor nonfunctioning pancreatic neuroendocrine tumors. J Clin Endocrinol Metab 94:3640, 2009.)*

Other Pancreatic NETs NETs secreting growth hormone–releasing hormone (GHRH), GHRHomas, have been reported rarely in patients with MEN 1. It is estimated that ~33% of patients with GHRHomas have other MEN 1–related tumors. GHRHomas may be diagnosed by demonstrating elevated serum concentrations of growth hormone and GHRH. More than 50% of GHRHomas occur in the lung, 30% occur in the pancreas, and 10% are found in the small intestine. Somatostatinomas secrete somatostatin, a peptide that inhibits the secretion of a variety of hormones, resulting in hyperglycemia, cholelithiasis, low acid output, steatorrhea, diarrhea, abdominal pain, anemia, and weight loss. Although 7% of pancreatic NETs secrete somatostatin, the clinical features of somatostatinoma syndrome are unusual in patients with MEN 1.

Pituitary Tumors (See also Chap. 380) Pituitary tumors occur in 15–50% of patients with MEN 1 (Table 388-1), and ~75% of these are microadenomas (<1 cm diameter). The tumors occur as early as 5 years of age or as late as the ninth decade. MEN 1 pituitary adenomas are more frequent in women than men, in whom they are often macroadenomas (>1 cm diameter). There are no specific histologic parameters that differentiate between MEN 1 and non–MEN 1 pituitary tumors. Approximately 60% of MEN 1–associated pituitary tumors secrete prolactin, <25% secrete growth hormone, 5% secrete adrenocorticotropic hormone (ACTH), and the remainder appear to be nonfunctioning, with some secreting glycoprotein subunits (Table 388-1). However, pituitary tumors derived from MEN 1 patients may exhibit immunoreactivity to several hormones. In particular, there is a greater frequency of somatolactotrope tumors. Prolactinomas are the first manifestation of MEN 1 in ~15% of patients, whereas somatotrope tumors occur more often in patients aged >40 years. Fewer than 3% of patients with anterior pituitary tumors will have MEN 1. Clinical manifestations are similar to those in patients with sporadic pituitary tumors without MEN 1 and depend on the hormone secreted and the size of the pituitary tumor. Thus, patients may have symptoms of hyperprolactinemia (e.g., amenorrhea, infertility, and galactorrhea in women, or impotence and infertility in men) or have features of acromegaly or Cushing's disease. In addition, enlarging pituitary tumors may compress adjacent structures such as the optic chiasm or normal pituitary tissue, causing visual disturbances and/or hypopituitarism. In asymptomatic patients with MEN 1, periodic biochemical monitoring of serum prolactin and insulin-like growth factor 1 (IGF-1) levels, as well as MRI of the pituitary, can lead to early identification of pituitary tumors (Table 388-3). In patients with abnormal results, hypothalamic-pituitary testing should characterize the nature of the pituitary lesion and its effects on the secretion of other pituitary hormones.

TREATMENT

Pituitary Tumors

Treatment of pituitary tumors in patients with MEN 1 consists of therapies similar to those used in patients without MEN 1 and includes appropriate medical therapy (e.g., bromocriptine or cabergoline for prolactinoma; or octreotide or lanreotide for somatotrope tumors) or selective transsphenoidal adenomectomy, if feasible, with radiotherapy reserved for residual unresectable tumor tissue.

Associated Tumors Patients with MEN 1 may also develop carcinoid tumors, adrenal cortical tumors, facial angiofibromas, collagenomas, thyroid tumors, and lipomatous tumors.

Carcinoid Tumors (See also Chap. 84) Carcinoid tumors occur in >3% of patients with MEN 1 (Table 388-1). The carcinoid tumor may be located in the bronchi, gastrointestinal tract, pancreas, or thymus. At the time of diagnosis, most patients are asymptomatic and do not have clinical features of the carcinoid syndrome. Importantly, no hormonal or biochemical abnormality (e.g., plasma chromogranin A) is consistently observed in individuals with thymic or bronchial carcinoid tumors. Thus, screening for these tumors is dependent on radiologic imaging. The optimum method for screening has not been established. CT and MRI are sensitive for detecting thymic and bronchial tumors (Table 388-3), although repeated CT scanning raises concern about exposure to repeated doses of ionizing radiation. Octreotide scintigraphy may also reveal some thymic and bronchial carcinoids, although there is insufficient evidence to recommend its routine use. Gastric carcinoids, of which the type II gastric enterochromaffin-like (ECL) cell carcinoids (ECLomas) are associated with MEN 1 and Zollinger-Ellison syndrome, may be detected incidentally at the time of gastric endoscopy for dyspeptic symptoms in MEN 1 patients. These tumors, which may be found in >10% of MEN 1 patients, are usually multiple and sized <1.5 cm. Bronchial carcinoids in patients with MEN 1 occur predominantly in women (male-to-female ratio, 1:4). In contrast, thymic carcinoids in European patients with MEN 1 occur predominantly in men (male-to-female ratio, 20:1), with cigarette smokers having a higher risk for these tumors; thymic carcinoids in Japanese patients with MEN 1 have a less marked sex difference (male-to-female ratio 2:1). The course of thymic carcinoids in MEN 1 appears to be particularly aggressive. The presence of thymic tumors in patients with MEN 1 is associated with a median survival after diagnosis of ~9.5 years, with 70% of patients dying as a direct result of the tumor.

TREATMENT

Carcinoid Tumors

If resectable, surgical removal of carcinoid tumors is the treatment of choice. For patients with unresectable tumors and those with metastatic disease, treatment with SSAs, radiotherapy, chemotherapeutic agents (e.g., fluorouracil, temozolomide, cisplatin, etoposide), mTOR inhibitors (e.g., everolimus), or PRRT therapy has resulted in symptom improvement and regression of some tumors. Little is known about the malignant potential of gastric type II ECLomas, but treatment with SSAs has resulted in regression of these ECLomas.

Adrenocortical Tumors (See also Chap. 386) Asymptomatic adrenocortical tumors occur in 20–70% of patients with MEN 1 depending on the radiologic screening methods used (Table 388-1). Most of these tumors, which include cortical adenomas, hyperplasia, multiple adenomas, nodular hyperplasia, cysts, and carcinomas, are nonfunctioning. Indeed, <10% of patients with enlarged adrenal glands have hormonal hypersecretion, with primary hyperaldosteronism and ACTH-independent Cushing's syndrome being encountered most commonly. Occasionally, hyperandrogenemia may occur in association with adrenocortical carcinoma. Pheochromocytoma in association with MEN 1 is rare. Biochemical investigation (e.g., plasma renin and aldosterone concentrations, low-dose dexamethasone suppression test, urinary catecholamines, and/or metanephrines) should be undertaken in those with symptoms or signs suggestive of functioning adrenal tumors or in those with tumors >1 cm. Adrenocortical carcinoma occurs in ~1% of MEN 1 patients but increases to >10% for adrenal tumors >1 cm.

TREATMENT

Adrenocortical Tumors

Consensus has not been reached about the management of MEN 1–associated nonfunctioning adrenal tumors, because the majority are benign. However, the risk of malignancy increases with size, particularly for tumors with a diameter >4 cm. Indications for surgery for adrenal tumors include size >4 cm in diameter, atypical or suspicious radiologic features (e.g., increased Hounsfield unit on unenhanced CT scan) and size of 1–4 cm in diameter, or significant measurable growth over a 6-month period. The treatment of functioning (e.g., hormone-secreting) adrenal tumors is similar to that for tumors occurring in non–MEN 1 patients.

Meningioma Central nervous system (CNS) tumors, including ependymomas, schwannomas, and meningiomas, have been reported in MEN 1 patients (Table 388-1). Meningiomas are found in <10% of patients with other clinical manifestations of MEN 1 (e.g., primary hyperparathyroidism) for >15 years. The majority of meningiomas are not associated with symptoms, and 60% do not enlarge. The treatment of MEN 1–associated meningiomas is similar to that in non–MEN 1 patients.

Lipomas Subcutaneous lipomas occur in >33% of patients with MEN 1 (Table 388-1) and are frequently multiple. In addition, visceral, pleural, or retroperitoneal lipomas may occur in patients with MEN 1. Management is conservative. However, when surgically removed for cosmetic reasons, they typically do not recur.

Facial Angiofibromas and Collagenomas The occurrence of multiple facial angiofibromas in patients with MEN 1 may range from >20 to >90%, and occurrence of collagenomas may range from 0 to >70% (Table 388-1). These cutaneous findings may allow presymptomatic diagnosis of MEN 1 in the relatives of a patient with MEN 1. Treatment for these cutaneous lesions is usually not required.

Thyroid Tumors Thyroid tumors, including adenomas, colloid goiters, and carcinomas, have been reported to occur in >25% of patients with MEN 1. However, the prevalence of thyroid disorders in the general population is high, and it has been suggested that the association of thyroid abnormalities in patients with MEN 1 may be incidental. The treatment of thyroid tumors in MEN 1 patients is similar to that for non–MEN 1 patients.

Genetics and Screening The *MEN1* gene is located on chromosome 11q13 and consists of 10 exons, which encode a 610–amino acid protein, menin, that regulates transcription, genome stability, cell division, and proliferation. The pathophysiology of MEN 1 follows the Knudson two-hit hypothesis with a tumor-suppressor role for menin. Inheritance of a germline *MEN1* mutation predisposes an individual to developing a tumor that arises following a somatic mutation, which may be a point mutation or more commonly a deletion, leading to loss of heterozygosity (LOH) in the tumor DNA. The germline mutations of the *MEN1* gene are scattered throughout the entire 1830-bp coding region and splice sites, and there is no apparent correlation between the location of *MEN1* mutations and clinical manifestations of the disorder, in contrast with the situation in patients with MEN 2 (Table 388-1). More than 10% of *MEN1* germline mutations arise de novo and may be transmitted to subsequent generations. Some families with MEN 1 mutations develop parathyroid tumors as the sole endocrinopathy, and this condition is referred to as familial isolated hyperparathyroidism (FIHP). However, between 5 and 25% of patients with MEN 1 do not harbor germline mutations or deletions of the *MEN1* gene. Such patients with MEN 1–associated tumors but without *MEN1* mutations may represent phenocopies or have mutations involving other genes. Other genes associated with MEN 1–like features include *CDC73*, which encodes parafibromin, whose mutations result in the HPT-JT syndrome; the calcium-sensing receptor gene (*CaSR*), whose mutations result in familial benign hypocalciuric hypercalcemia (FBHH); and the aryl hydrocarbon receptor interacting protein gene (*AIP*), a tumor suppressor located on chromosome 11q13 whose mutations are associated with familial isolated pituitary adenomas (FIPA). Genetic testing to determine the *MEN1* mutation status in symptomatic family members within a MEN 1 kindred, as well as in all index cases (e.g., patients) with two or more endocrine tumors, is advisable. If a *MEN1* mutation is not identified in the index case with two or more endocrine tumors, clinical and genetic tests for other disorders such as HPT-JT syndrome, FBHH, FIPA, MEN 2, or MEN 4 should be considered because these patients may represent phenocopies for MEN 1.

The current guidelines recommend that *MEN1* mutational analysis should be undertaken in (1) an index case with two or more MEN 1–associated endocrine tumors (e.g., parathyroid, pancreatic, or pituitary tumors); (2) asymptomatic first-degree relatives of a known *MEN1* mutation carrier; and (3) first-degree relatives of a *MEN1* mutation carrier with symptoms, signs, or biochemical or radiologic evidence for one or more MEN 1–associated tumors. In addition, *MEN1* mutational analysis should be considered in patients with suspicious or atypical MEN 1. This would include individuals with parathyroid adenomas before the age of 30 years or multigland parathyroid disease; individuals with gastrinoma or multiple pancreatic NETs at any age; or individuals who have two or more MEN 1–associated tumors that are not part of the classical triad of parathyroid, pancreatic islet, and anterior pituitary tumors (e.g., parathyroid tumor plus adrenal tumor). Family members, including asymptomatic individuals who have been identified to harbor a *MEN1* mutation, will require biochemical and radiologic screening (Table 388-3). In contrast, relatives who do not harbor the *MEN1* mutation have a risk of developing MEN 1–associated endocrine tumors that is similar to that of the general population; thus, relatives without the *MEN1* mutation do not require repeated screening.

Mutational analysis in asymptomatic individuals should be undertaken at the earliest opportunity and, if possible, in the first decade of life because tumors have developed in some children by the age of 5 years. Appropriate biochemical and radiologic investigations (Table 388-3) aimed at detecting the development of tumors should then be undertaken in affected individuals. Mutant gene carriers should undergo biochemical screening at least once per annum and also have baseline pituitary and abdominal imaging (e.g., MRI or CT), which should then be repeated at 1- to 3-year intervals (Table 388-3). Screening should commence after 5 years of age and should continue for life because the disease may develop as late as the eighth decade. The screening history and physical examination elicit the symptoms and signs of hypercalcemia; nephrolithiasis; peptic ulcer disease; neuroglycopenia; hypopituitarism; galactorrhea and amenorrhea in women; acromegaly; Cushing's disease; and visual field loss and the presence of subcutaneous lipomas, angiofibromas, and collagenomas. Biochemical screening should include measurements of serum calcium, PTH, gastrointestinal hormones (e.g., gastrin, insulin with a fasting glucose, glucagon, VIP, PP), chromogranin A, prolactin, and IGF-1 in all individuals. More specific endocrine function tests should be undertaken in individuals who have symptoms or signs suggestive of a specific clinical syndrome. Biochemical screening for the development of MEN 1 tumors in asymptomatic members of families with MEN 1 is of great importance to reduce morbidity and mortality from the associated tumors.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2 AND TYPE 3

Clinical Manifestations MEN type 2 (MEN 2), which is also called Sipple's syndrome, is characterized by the association of medullary thyroid carcinoma (MTC), pheochromocytomas, and parathyroid tumors (Table 388-1). Three clinical variants of MEN 2 are recognized: MEN 2A, MEN 2B, and MTC only. MEN 2A, which is often referred to as MEN 2, is the most common variant. In MEN 2A, MTC is associated with pheochromocytomas in 50% of patients (may be bilateral) and with parathyroid tumors in 20% of patients. MEN 2A may rarely occur in association with Hirschsprung's disease, caused by the absence of autonomic ganglion cells in the terminal hindgut, resulting in colonic dilatation, severe constipation, and obstruction. MEN 2A may also be associated with cutaneous lichen amyloidosis, which is a pruritic lichenoid lesion that is usually located on the upper back. MEN 2B, which is also referred to as MEN 3, represents 5% of all cases of MEN 2 and is characterized by the occurrence of MTC and pheochromocytoma in association with a Marfanoid habitus; mucosal neuromas of the lips, tongue, and eyelids; medullated corneal fibers; and intestinal autonomic ganglion dysfunction leading to multiple diverticulae and megacolon. Parathyroid tumors do not usually occur in MEN 2B. MTC only (FMTC) is a variant in which MTC is the sole manifestation of the syndrome. However, the distinction between FMTC and MEN 2A is difficult and should only be considered if there are at least four family members aged >50 years who are affected by MTC but not pheochromocytomas or primary hyperparathyroidism. All of the MEN 2 variants are due to mutations of the rearranged during transfection (*RET*) protooncogene, which encodes a TKR. Moreover, there is a correlation between the locations of *RET* mutations and MEN 2 variants. Thus, ~95% of MEN 2A patients have mutations involving the cysteine-rich

Thyroid 19:565, 2009 and revised from SA Wells Jr et al: Revised American Thyroid Association guidelines for the management of medullary thyroid carcinoma. Thyroid 25:567, 2015. [b]Risk for early development of metastasis and aggressive growth of medullary thyroid cancer: +++, highest; ++, high; and + moderate. [c]Mutations associated with MEN 2A (or medullary thyroid carcinoma only). [d]Timing of surgery to be based on elevation of serum calcitonin and/or joint discussion with pediatrician, surgeon, and parent/family. Later surgery may be appropriate if serum calcitonin and neck ultrasound are normal. [e]Presence of pheochromocytoma must be excluded prior to any surgical intervention, and also in women with *RET* mutation who are planning pregnancy or are pregnant. [f]Surgery earlier than 5 years based on elevation of serum calcitonin. Optimal timing of surgery should be decided by the surgeon and pediatrician, in consultation with the child's parent. [g]Mutations associated with MEN 2B (MEN 3). [h]Not required because PHPT is not a feature of MEN 2B (MEN 3).

Abbreviations: ASAP, as soon as possible; MEN, multiple endocrine neoplasia; PHPT, primary hyperparathyroidism.

extracellular domain, with mutations of codon 634 accounting for ~85% of MEN 2A mutations; FMTC patients also have mutations of the cysteine-rich extracellular domain, with most mutations occurring in codon 618. In contrast, ~95% of MEN 2B/MEN 3 patients have mutations of codon 918 of the intracellular tyrosine kinase domain (Table 388-1 and Table 388-4).

Medullary Thyroid Carcinoma MTC is the most common feature of MEN 2A and MEN 2B and occurs in almost all affected individuals. MTC represents 5–10% of all thyroid gland carcinomas, and 20% of MTC patients have a family history of the disorder. The use of *RET* mutational analysis to identify family members at risk for hereditary forms of MTC has altered the presentation of MTC from that of symptomatic tumors to a preclinical disease for which prophylactic thyroidectomy (Table 388-4) is undertaken to improve the prognosis and ideally result in cure. However, in patients who do not have a known family history of MEN 2A, FMTC, or MEN 2B, and therefore have not had *RET* mutational analysis, MTC may present as a palpable mass in the neck, which may be asymptomatic or associated with symptoms of pressure or dysphagia in >15% of patients. Diarrhea occurs in 30% of patients and is associated either with elevated circulating concentrations of calcitonin or tumor-related secretion of serotonin and prostaglandins. Some patients may also experience flushing. In addition, ectopic ACTH production by MTC may cause Cushing's syndrome. The diagnosis of MTC relies on the demonstration of hypercalcitoninemia (>90 pg/mL in the basal state); stimulation tests using IV pentagastrin (0.5 mg/kg) and or calcium infusion (2 mg/kg) are rarely used now, reflecting improvements in the assay for calcitonin. Neck ultrasonography with fine-needle aspiration of the nodules can confirm the diagnosis. Radionucleotide thyroid scans may reveal MTC tumors as "cold" nodules. Radiography may reveal dense irregular calcification within the involved portions of the thyroid gland and in lymph nodes involved with metastases. Positron emission tomography (PET) may help to identify the MTC and metastases (Fig. 388-2). Metastases of MTC usually occur to the cervical lymph nodes in the early stages and to the mediastinal nodes, lung, liver, trachea, adrenal, esophagus, and bone in later stages. Elevations in serum calcitonin concentrations are often the first sign of recurrence or persistent disease, and the serum calcitonin doubling time is useful for determining prognosis. MTC can have an aggressive clinical course, with early metastases and death in ~10% of patients. A family history of aggressive MTC or MEN 2B may be elicited.

TREATMENT

Medullary Thyroid Carcinoma

Individuals with *RET* mutations who do not have clinical manifestations of MTC should be offered prophylactic surgery between the ages of <1 and 5 years. The timing of surgery will depend on the type of *RET* mutation and its associated risk for early development, metastasis, and aggressive growth of MTC (Table 388-4). Such patients should have a total thyroidectomy with a systematic central neck dissection to remove occult nodal metastasis, although the value of undertaking a central neck dissection has been subject to debate. Prophylactic thyroidectomy, with lifelong thyroxine replacement, has dramatically improved outcomes in patients with MEN 2 and MEN 3, such that ~90% of young patients with *RET* mutations who had a prophylactic thyroidectomy have no evidence

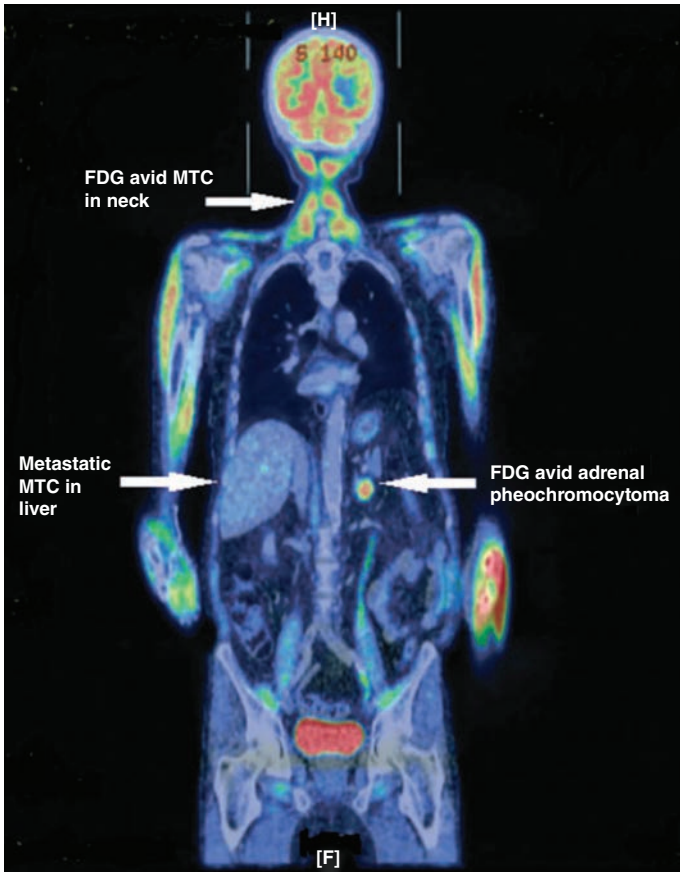

FIGURE 388-2 Fluorodeoxyglucose (FDG) positron emission tomography scan in a patient with multiple endocrine neoplasia type 2A, showing medullary thyroid cancer (MTC) with hepatic and skeletal (left arm) metastasis and a left adrenal pheochromocytoma. Note the presence of excreted FDG compound in the bladder. *(Reproduced with permission from A Naziat et al: Confusing genes: A patient with MEN2A and Cushing's disease. Clin Endocrinol (Oxf) 78:966, 2013.)*

of persistent or recurrent MTC at 7 years after surgery. In patients with clinically evident MTC, a total thyroidectomy with bilateral central resection is recommended, and an ipsilateral lateral neck dissection should be undertaken if the primary tumor is >1 cm in size or there is evidence of nodal metastasis in the central neck. Surgery is the only curative therapy for MTC. The 10-year survival in patients with metastatic MTC is ~20%. For inoperable MTC or metastatic disease, TKR inhibitors (e.g., vandetanib, cabozantinib, selpercatinib) have improved the progression-free survival times. PRRT with ^{177}Lu-DOTATATE has been reported to be beneficial for metastatic MTCs that were found by SRS to express somatostatin receptors. Other types of chemotherapy are of limited efficacy, but radiotherapy may help to palliate local disease.

Pheochromocytoma **(See also Chap. 387)** These noradrenaline- and adrenaline-secreting tumors occur in >50% of patients with MEN 2A and MEN 2B and are a major cause of morbidity and mortality. Patients may have symptoms and signs of catecholamine secretion (e.g., headaches, palpitations, sweating, poorly controlled hypertension), or they may be asymptomatic with detection through biochemical screening based on a history of familial MEN 2A, MEN 2B, or MTC. Pheochromocytomas in patients with MEN 2A and MEN 2B differ significantly in distribution when compared with patients without MEN 2A and MEN 2B. Extra-adrenal pheochromocytomas, which occur in 10% of patients without MEN 2A and MEN 2B, are observed rarely in patients with MEN 2A and MEN 2B. Malignant pheochromocytomas are much less common in patients with MEN 2A and MEN 2B. The biochemical and radiologic investigation of pheochromocytoma in patients with MEN 2A and MEN 2B is similar to that in non–MEN 2 patients and includes the measurement of plasma (obtained from supine patients) and urinary free fractionated metanephrines (e.g., normetanephrine and metanephrines measured separately), CT or MRI scanning, radionuclide scanning with meta-iodo-(^{123}I or ^{131}I)-benzyl guanidine (MIBG), and PET using (^{18}F)-fluorodopamine or (^{18}F)-fluoro-2-dexoxy-D-glucose (Fig. 388-2).

TREATMENT

Pheochromocytoma

Surgical removal of pheochromocytoma, using α and β adrenoreceptor blockade before and during the operation, is the recommended treatment. Other antihypertensive agents, including calcium channel blockers, are sometimes required for adequate blood pressure control. Endoscopic adrenal-sparing surgery, which decreases postoperative morbidity, hospital stay, and expense, as opposed to open surgery, has become the method of choice.

Parathyroid Tumors **(See also Chap. 410)** Parathyroid tumors occur in 10–25% of patients with MEN 2A. However, >50% of these patients do not have hypercalcemia. The presence of abnormally enlarged parathyroids, which are unusually hyperplastic, is often seen in the normocalcemic patient undergoing thyroidectomy for MTC. The biochemical investigation and treatment of hypercalcemic patients with MEN 2A is similar to that of patients with MEN 1.

Genetics and Screening To date, ~50 different *RET* mutations have been reported, and these are located in exons 5, 8, 10, 11, 13, 14, 15, and 16. *RET* germline mutations are detected in >95% of MEN 2A, FMTC, and MEN 2B families, with Cys634Arg being most common in MEN 2A, Cys618Arg being most common in FMTC, and Met918Thr being most common in MEN 2B (Tables 388-1 and 388-4). Between 5 and 10% of patients with MTC or MEN 2A–associated tumors have de novo *RET* germline mutations, and ~50% of patients with MEN 2B have de novo *RET* germline mutations. These de novo *RET* germline mutations always occur on the paternal allele. Approximately 5% of patients with sporadic pheochromocytoma have a germline *RET* mutation, but such germline *RET* mutations do not appear to be associated with sporadic primary hyperparathyroidism. Thus, *RET* mutational analysis should be performed in (1) all patients with MTC who have a family history of tumors associated with MEN 2, FMTC, or MEN 3, such that the diagnosis can be confirmed and genetic testing offered to asymptomatic relatives; (2) all patients with MTC and pheochromocytoma without a known family history of MEN 2 or MEN 3; (3) all patients with MTC, but without a family history of MEN 2, FMTC, or MEN 3, because these patients may have a de novo germline *RET* mutations; (4) all patients with bilateral pheochromocytoma; and (5) patients with unilateral pheochromocytoma, particularly if this occurs with increased calcitonin levels.

Screening for MEN 2/MEN 3–associated tumors in patients with *RET* germline mutations should be undertaken annually and include serum calcitonin measurements, a neck ultrasound for MTC, plasma (or 24-h urinary) fractionated metanephrines for pheochromocytoma, and albumin-corrected serum calcium or ionized calcium with PTH for primary hyperparathyroidism. In patients with MEN 2–associated *RET* mutations, screening for MTC should begin by 1–5 years, for pheochromocytoma by 11–16 years, and for primary hyperparathyroidism by 11–16 years of age (Table 388-4).

MULTIPLE ENDOCRINE NEOPLASIA TYPE 4

Clinical Manifestations Patients with MEN 1–associated tumors, such as parathyroid adenomas, pituitary adenomas, and pancreatic NETs, occurring in association with gonadal, adrenal, renal, and thyroid tumors have been reported to have mutations of the gene encoding the 196–amino acid cyclin-dependent kinase inhibitor (CK1) p27 kip1 (*CDKN1B*). Such families with MEN 1–associated tumors and *CDKN1B* mutations are designated to have MEN 4 (Table 388-1). The investigations and treatments for the MEN 4–associated tumors are similar to those for MEN 1 and non–MEN 1 tumors.

Genetics and Screening To date, 50 MEN patients (from <20 kindreds) with mutations of *CDKN1B*, which is located on chromosome 12p13, have been reported, and all of these are predicted to result in a loss of function. These MEN 4 patients may represent ~3% of the 5–10% of patients with MEN 1 who do not have mutations of the *MEN1* gene. Germline *CDKN1B* mutations may rarely be found in patients with sporadic (i.e., nonfamilial) forms of primary hyperparathyroidism.

HYPERPARATHYROIDISM-JAW TUMOR SYNDROME (SEE ALSO CHAP. 410)

Clinical Manifestations Hyperparathyroidism-jaw tumor (HPT-JT) syndrome is an autosomal dominant disorder characterized by the development of parathyroid tumors (15% are carcinomas) and fibro-osseous jaw tumors. In addition, some patients may also develop Wilms' tumors, renal cysts, renal hamartomas, renal cortical adenomas, renal cell carcinoma (RCC), pancreatic adenocarcinomas, uterine tumors, testicular mixed germ cell tumors with a major seminoma component, and Hürthle cell thyroid adenomas. The parathyroid tumors may occur in isolation and without any evidence of jaw tumors, and this may cause confusion with other hereditary hypercalcemic disorders, such as MEN 1. However, genetic testing to identify the causative mutation will help to establish the correct diagnosis. The investigation and treatment for HPT-JT–associated tumors are similar to those in non-HPT-JT patients, except that early parathyroidectomy is advisable because of the increased frequency of parathyroid carcinoma.

Genetics and Screening The gene that causes HPT-JT is located on chromosome 1q31.2 and encodes a 531–amino acid protein, parafibromin (Table 388-2). Parafibromin is also referred to as cell division cycle protein 73 (CDC73) and has a role in transcription. Genetic testing in families helps to identify mutation carriers who should be periodically screened for the development of tumors **(Table 388-5)**.

VON HIPPEL–LINDAU DISEASE (SEE ALSO CHAP. 387)

Clinical Manifestations von Hippel–Lindau (VHL) disease is an autosomal dominant disorder characterized by hemangioblastomas

TABLE 388-5 HPT-JT Screening Guidelines

TUMOR[a]	TEST	FREQUENCY[b]
Parathyroid	Serum Ca, PTH	6–12 months
Ossifying jaw fibroma	Panoramic jaw x-ray with neck shielding[c]	5 years
Renal	Abdominal MRI[c,d]	5 years
Uterine	Ultrasound (transvaginal or transabdominal) and additional imaging ± D&C if indicated[e]	Annual

[a]Screening for most common HPT-JT–associated tumors is considered. Assessment for other reported tumor types may be indicated (e.g., pancreatic, thyroid, testicular tumors). [b]Frequency of repeating test after baseline tests performed. [c]X-rays and imaging involving ionizing radiation should ideally be avoided to minimize risk of generating subsequent mutations. [d]Ultrasound scan recommended if MRI unavailable. [e]Such selective pelvic imaging should be considered after obtaining a detailed menstrual history.

Abbreviations: Ca, calcium; D&C, dilation and curettage; HPT-JT, hyperparathyroidism-jaw tumor syndrome; MRI, magnetic resonance imaging; PTH, parathyroid hormone.

Source: Reproduced with permission from PJ Newey et al: Cell division cycle protein 73 homolog (CDC73) mutations in the hyperparathyroidism-jaw tumor syndrome (HPT-JT) and parathyroid tumors. Hum Mutat 31:295, 2010.

of the retina and CNS; cysts involving the kidneys, pancreas, and epididymis; RCC; pheochromocytomas; and pancreatic islet cell tumors. The retinal and CNS hemangioblastomas are benign vascular tumors that may be multiple; those in the CNS may cause symptoms by compressing adjacent structures and/or increasing intracranial pressure. In the CNS, the cerebellum and spinal cord are the most frequently involved sites. The renal abnormalities consist of cysts and carcinomas, and the lifetime risk of RCC in VHL is 70%. The endocrine tumors in VHL consist of pheochromocytomas and pancreatic islet cell tumors. The clinical presentation of pheochromocytoma in VHL disease is similar to that in sporadic cases, except that there is a higher frequency of bilateral or multiple tumors, which may involve extra-adrenal sites in VHL disease. The most frequent pancreatic lesions in VHL are multiple cyst-adenomas, which rarely cause clinical disease. However, nonsecreting pancreatic islet cell tumors occur in <10% of VHL patients, who are usually asymptomatic. The pancreatic tumors in these patients are often detected by regular screening using abdominal imaging. Pheochromocytomas should be investigated and treated as described earlier for MEN 2. The pancreatic islet cell tumors frequently become malignant, and early surgery is recommended.

Genetics and Screening The *VHL* gene, which is located on chromosome 3p26-p25, is widely expressed in human tissues and encodes a 213–amino acid protein (pVHL) (Table 388-2). A wide variety of germline *VHL* mutations have been identified. *VHL* acts as a tumor-suppressor gene. A correlation between the type of mutation and the clinical phenotype has been reported; large deletions and protein-truncating mutations are associated with a low incidence of pheochromocytomas, whereas some missense mutations in VHL patients are associated with pheochromocytoma (referred to as VHL type 2C). Other missense mutations may be associated with hemangioblastomas and RCC but not pheochromocytoma (referred to as VHL type 1), whereas distinct missense mutations are associated with hemangioblastomas, RCC, and pheochromocytoma (VHL type 2B). VHL type 2A, which refers to the occurrence of hemangioblastomas and pheochromocytoma without RCC, is associated with rare missense mutations. The basis for these complex genotype-phenotype relationships remains to be elucidated. One major function of pVHL, which is also referred to as elongin, is to downregulate the expression of vascular endothelial growth factor (VEGF) and other hypoxia-inducible mRNAs. Thus, pVHL, in complex with other proteins, regulates the expression of hypoxia-inducible factors (HIF-1 and HIF-2) such that loss of functional pVHL leads to a stabilization of the HIF protein complexes, resulting in VEGF overexpression and tumor angiogenesis. Screening for the development of pheochromocytomas and pancreatic islet cell tumors is as described earlier for MEN 2 and MEN 1, respectively (Tables 388-3 and 388-4).

NEUROFIBROMATOSIS

Clinical Manifestations Neurofibromatosis type 1 (NF1), which is also referred to as von Recklinghausen's disease, is an autosomal dominant disorder characterized by the following manifestations: neurologic (e.g., peripheral and spinal neurofibromas); ophthalmologic (e.g., optic gliomas and iris hamartomas such as Lisch nodules); dermatologic (e.g., café au lait macules); skeletal (e.g., scoliosis, macrocephaly, short stature, pseudoarthrosis); vascular (e.g., stenoses of renal and intracranial arteries); and endocrine (e.g., pheochromocytoma, carcinoid tumors, precocious puberty). Neurofibromatosis type 2 (NF2) is also an autosomal dominant disorder but is characterized by the development of bilateral vestibular schwannomas (acoustic neuromas) that lead to deafness, tinnitus, or vertigo. Some patients with NF2 also develop meningiomas, spinal schwannomas, peripheral nerve neurofibromas, and café au lait macules. Endocrine abnormalities are not found in NF2 and are associated solely with NF1. Pheochromocytomas, carcinoid tumors, and precocious puberty occur in ~1% of patients with NF1, and growth hormone deficiency has also been reported. The features of pheochromocytomas in NF1 are similar to those in non-NF1 patients, with 90% of tumors being located within the adrenal medulla and the remaining 10% at an extra-adrenal location, which often involves the para-aortic region. Primary carcinoid tumors are often periampullary and may also occur in the ileum but rarely in the pancreas, thyroid, or lungs. Hepatic metastases are associated with symptoms of the carcinoid syndrome, which include flushing, diarrhea, bronchoconstriction, and tricuspid valve disease. Precocious puberty is usually associated with the extension of an optic glioma into the hypothalamus with resultant early activation of gonadotropin-releasing hormone secretion. Growth hormone deficiency has also been observed in some NF1 patients, who may or may not have optic chiasmal gliomas, but it is important to note that short stature is frequent in the absence of growth hormone deficiency in patients with NF1. The investigation and treatment for tumors are similar to those undertaken for each respective tumor type in non-NF1 patients.

Genetics and Screening The *NF1* gene, which is located on chromosome 17q11.2 and acts as a tumor suppressor, consists of 60 exons that span >350 kb of genomic DNA (Table 388-2). Mutations in *NF1* are of diverse types and are scattered throughout the exons. The NF1 gene product is the protein neurofibromin, which has homologies to the p120GAP (GTPase activating protein) and acts on p21ras by converting the active GTP bound form to its inactive GDP form. Mutations of *NF1* impair this downregulation of the p21ras signaling pathways, which in turn results in abnormal cell proliferation. Screening for the development of pheochromocytomas and carcinoid tumors is as described earlier for MEN 2 and MEN 1, respectively (Tables 388-3 and 388-4).

CARNEY COMPLEX

Clinical Manifestations Carney complex (CNC) is an autosomal dominant disorder characterized by spotty skin pigmentation (usually of the face, labia, and conjunctiva), myxomas (usually of the eyelids and heart, but also the tongue, palate, breast, and skin), psammomatous melanotic schwannomas (usually of the sympathetic nerve chain and upper gastrointestinal tract), and endocrine tumors that involve the adrenals, Sertoli cells, somatotropes, thyroid, and ovary. Cushing's syndrome, the result of primary pigmented nodular adrenal disease (PPNAD), is the most common endocrine manifestation of CNC and may occur in one-third of patients. Patients with CNC and Cushing's syndrome often have an atypical appearance by being thin (as opposed to having truncal obesity). In addition, they may have short stature, muscle and skin wasting, and osteoporosis. These patients often have levels of urinary free cortisol that are normal or increased only marginally. Cortisol production may fluctuate periodically with days or weeks of hypercortisolism; this pattern is referred to as "periodic Cushing's syndrome." Patients with Cushing's syndrome usually have loss of the circadian rhythm of cortisol production. Acromegaly, the

result of a somatotrope tumor, affects ~10% of patients with CNC. Testicular tumors may also occur in one-third of patients with CNC. These may either be large-cell calcifying Sertoli cell tumors, adrenocortical rests, or Leydig cell tumors. The Sertoli cell tumors occasionally may be estrogen-secreting and lead to precocious puberty or gynecomastia. Some patients with CNC have been reported to develop thyroid follicular tumors, ovarian cysts, or breast duct adenomas.

Genetics and Screening CNC type 1 (CNC1) is due to mutations of the protein kinase A (PKA) regulatory subunit 1 α (R1α) (*PRAKAR1A*), a tumor suppressor, whose gene is located on chromosome 17q.24.2 (Table 388-2). The gene causing CNC type 2 (CNC2) is located on chromosome 2p16 and has not yet been identified. It is interesting to note, however, that some tumors do not show LOH of 2p16 but instead show genomic instability, suggesting that this CNC gene may not be a tumor suppressor. Screening and treatment of these endocrine tumors are similar to those described earlier for patients with MEN 1 and MEN 2 (Tables 388-3 and 388-4).

COWDEN'S SYNDROME

Clinical Manifestations Multiple hamartomatous lesions, especially of the skin, mucous membranes (e.g., buccal, intestinal, colonic), breast, and thyroid, are characteristic of Cowden's syndrome (CWS), which is an autosomal dominant disorder. Thyroid abnormalities occur in two-thirds of patients with CWS, and these usually consist of multinodular goiters or benign adenomas, although <10% of patients may have a follicular thyroid carcinoma. Breast abnormalities occur in >75% of patients and consist of either fibrocystic disease or adenocarcinomas. The investigation and treatment for CWS tumors are similar to those undertaken for non-CWS patients.

Genetics and Screening CWS is genetically heterogenous, and seven types (CWS1–7) are recognized (Table 388-2). CWS1 is due to mutations of the phosphate and tensin homologue deleted on chromosome 10 (*PTEN*) gene, located on chromosome 10q23.31. CWS2 is caused by mutations of the succinate dehydrogenase subunit B (*SDHB*) gene, located on chromosome 1p36.13; and CWS3 is caused by mutations of the *SDHD* gene, located on chromosome 11q13.1. *SDHB* and *SDHD* mutations are also associated with pheochromocytoma. CWS4 is caused by hypermethylation of the Killin (*KLLN*) gene, the promoter of which shares the same transcription site as *PTEN* on chromosome 10q23.31. CWS5 is caused by mutations of the phosphatidylinositol 3-kinase catalytic alpha (*PIK3CA*) gene on chromosome 3q26.32. CWS6 is caused by mutations of the V-Akt murine thymoma viral oncogene homolog 1 (*AKT1*) gene on chromosome 14q32.33, and CWS7 is caused by mutations of the saccharomyces cerevisiae homology of B (*SEC23B*) gene on chromosome 20p11.23. Screening for thyroid abnormalities entails neck ultrasonography and fine-needle aspiration with analysis of cell cytology.

MCCUNE-ALBRIGHT SYNDROME (SEE ALSO CHAP. 412)

Clinical Manifestations McCune-Albright syndrome (MAS) is characterized by the triad of polyostotic fibrous dysplasia, which may be associated with hypophosphatemic rickets; café au lait skin pigmentation; and peripheral precocious puberty. Other endocrine abnormalities include thyrotoxicosis, which may be associated with a multinodular goiter, somatotrope tumors, and Cushing's syndrome (due to adrenal tumors). Investigation and treatment for each endocrinopathy are similar to those used in patients without MAS.

Genetics and Screening MAS is a disorder of mosaicism that results from postzygotic somatic cell mutations of the G protein α-stimulating subunit ($G_s\alpha$), encoded by the *GNAS1* gene, located on chromosome 20q13.32 (Table 388-2). The $G_s\alpha$ mutations, which include Arg201Cys, Arg201His, Glu227Arg, or Glu227His, are activating and are found only in cells of the abnormal tissues. Screening for hyperfunction of relevant endocrine glands and development of hypophosphatemia, which may be associated with elevated serum fibroblast growth factor 23 (FGF23) concentrations, is undertaken in MAS patients.

389 Autoimmune Polyendocrine Syndromes

Peter A. Gottlieb, Aaron W. Michels

Polyglandular deficiency syndromes have been given many different names, reflecting the wide spectrum of disorders that have been associated with these syndromes and the heterogeneity of their clinical presentations. The name used in this chapter for this group of disorders is *autoimmune polyendocrine syndrome* (APS). In general, these disorders are divided into two major categories, APS type 1 (APS-1) and APS type 2 (APS-2). Some groups have further subdivided APS-2 into APS type 3 (APS-3) and APS type 4 (APS-4) depending on the type of autoimmunity involved. For the most part, this additional classification does not clarify our understanding of disease pathogenesis or prevention of complications in individual patients. Importantly, there are many nonendocrine disease associations included in these syndromes, suggesting that although the underlying autoimmune disorder predominantly involves endocrine targets, it does not exclude other tissues. The disease associations found in APS-1 and APS-2 are summarized in Table 389-1. Understanding these syndromes and their disease manifestations can lead to early diagnosis and treatment of additional disorders in patients and their family members.

APS-1

APS-1 (Online Mendelian Inheritance in Man [OMIM] 240300) has also been called autoimmune polyendocrinopathy–candidiasis–ectodermal

TABLE 389-1 Disease Associations with Autoimmune Polyendocrine Syndromes

AUTOIMMUNE POLYENDOCRINE SYNDROME TYPE 1	AUTOIMMUNE POLYENDOCRINE SYNDROME TYPE 2	OTHER AUTOIMMUNE POLYENDOCRINE DISORDERS
Endocrine	**Endocrine**	IPEX (immune dysfunction polyendocrinopathy X-linked)
Addison's disease	Addison's disease	Thymic tumors
Hypoparathyroidism	Type 1 diabetes	Anti-insulin receptor antibodies
Hypogonadism	*Graves' disease or autoimmune thyroiditis*	POEMS syndrome
Graves' disease or autoimmune thyroiditis	*Hypogonadism*	Insulin autoimmune syndrome (Hirata's syndrome)
Type 1 diabetes		Adult combined pituitary hormone deficiency (CPHD) with anti-Pit1 autoantibodies
		Kearns-Sayre syndrome
		DIDMOAD syndrome
Nonendocrine	**Nonendocrine**	Congenital rubella associated with thyroiditis and/or diabetes
Mucocutaneous candidiasis	Celiac disease, dermatitis herpetiformis	
Chronic active hepatitis	Pernicious anemia	
Pernicious anemia	Vitiligo	
Vitiligo	*Alopecia*	
Asplenism	*Myasthenia gravis*	
Ectodermal dysplasia	*IgA deficiency*	
Alopecia	*Parkinson's disease*	
Malabsorption syndromes	*Idiopathic thrombocytopenia*	
IgA deficiency

Note: Italics denote less common disorders.

dystrophy (APECED). Mucocutaneous candidiasis, hypoparathyroidism, and Addison's disease form the three major components of this disorder. However, as summarized in Table 389-1, many other organ systems can be involved over time. APS-1 is rare, with <500 cases reported in the literature.

The classical form of APS-1 is an autosomal recessive disorder caused by mutations in the *AIRE* gene (autoimmune regulator gene) found on chromosome 21. This gene is most highly expressed in thymic medullary epithelial cells (mTECs) where it controls the expression of tissue-specific self-antigens (e.g., insulin). Deletion of this regulator leads to decreased expression of tissue-specific self-antigens and is hypothesized to allow autoreactive T cells to avoid central deletion, which normally occurs during T-cell maturation in the thymus. The *AIRE* gene is also expressed in epithelial cells found in peripheral lymphoid organs, but its role in these extrathymic cells remains controversial. To date, >100 mutations have been described in this gene, and there is a higher frequency within certain ethnic groups including Iranian Jews, Sardinians, Finns, Norwegians, and Irish. Recently, several autosomal dominant mutations have been identified and are localized primarily in the PHD1 domain of the *AIRE* gene, rather than the CARD region, where the autosomal recessive mutations have been found. Individuals with this nonclassical form of APS-1 may have a later onset of symptoms and less aggressive disease, without the full spectrum of autoimmune components being expressed.

TABLE 389-2 Comparison of APS-1 and APS-2

APS-1	APS-2
Early onset: infancy	Later onset
Siblings often affected and at risk	Multigenerational
Equivalent sex distribution	Females > males affected
Monogenic: *AIRE* gene, chromosome 21, autosomal recessive	Polygenic: *HLA, MICA, PTNP22, CTLA4*
Not HLA associated for entire syndrome, some specific component risk	DR3/DR4 associated; other HLA class III gene associations noted
Autoantibodies to type 1 interferons and IL-17 and IL-22	No autoantibodies to cytokines
Autoantibodies to specific target organs	Autoantibodies to specific target organs
Asplenism	No defined immunodeficiency
Mucocutaneous candidiasis	Association with other nonendocrine immunologic disorders like myasthenia gravis and idiopathic thrombocytopenic purpura

Abbreviations: APS, autoimmune polyendocrine syndrome; HLA, human leukocyte antigen; IL, interleukin.

Clinical Manifestations Classical APS-1 develops very early in life, often in infancy (Table 389-2). Chronic mucocutaneous candidiasis without signs of systemic disease is often the first manifestation. It affects the mouth and nails more frequently than the skin and esophagus. Chronic oral candidiasis can result in atrophic disease with areas suggestive of leukoplakia, which can pose a risk for future carcinoma. The etiology is associated with anticytokine autoantibodies (anti-interleukin [IL] 17A, IL-17F, and IL-22) related to T helper (T_H) 17 T cells and depressed production of these cytokines by peripheral blood mononuclear cells. Hypoparathyroidism usually develops next, followed by adrenal insufficiency. The time from development of one component of the disorder to the next can be many years, and the order of disease appearance is variable.

Chronic candidiasis is nearly always present and is not very responsive to treatment. Hypoparathyroidism is found in >85% of cases, and Addison's disease is found in nearly 80%. Gonadal failure appears to affect women more than men (70 vs 25%, respectively), and hypoplasia of the dental enamel also occurs frequently (77% of patients). Other endocrine disorders that occur less frequently include type 1 diabetes (23%) and autoimmune thyroid disease (18%). Nonendocrine manifestations that present less frequently include alopecia (40%), vitiligo (26%), intestinal malabsorption (18%), pernicious anemia (31%), chronic active hepatitis (17%), and nail dystrophy. An unusual and debilitating manifestation of the disorder is the development of refractory diarrhea/obstipation that may be related to autoantibody-mediated destruction of enterochromaffin or enterochromaffin-like cells. The incidence rates for many of these disorders peak in the first or second decade of life, but the individual disease components continue to emerge over time. Therefore, prevalence rates may be higher than originally reported.

Diagnosis The diagnosis of APS-1 is usually made clinically when two of the three major component disorders are found in an individual patient. Siblings of individuals with APS-1 should be considered affected even if only one component disorder has been detected due to the known inheritance of the syndrome. Genetic analysis of the *AIRE* gene should be undertaken to identify mutations. Detection of anti–interferon α and anti–interferon ω antibodies can identify nearly 100% of cases with APS-1. The autoantibody arises independent of the type of *AIRE* gene mutation and is not found in other autoimmune disorders.

Diagnosis of each underlying disorder should be done based on their typical clinical presentations (Table 389-3). Mucocutaneous candidiasis may present throughout the gastrointestinal tract, and it may be detected in the oral mucosa or from stool samples. Evaluation by a gastroenterologist to examine the esophagus for candidiasis or secondary stricture may be merited based on symptoms. Other gastrointestinal

TABLE 389-3 Clinical Features and Recommended Follow-Up for APS-1 and APS-2

COMPONENT DISEASE	RECOMMENDED EVALUATION
APS-1	
Addison's disease	Sodium, potassium, ACTH, cortisol, 21- and 17-hydroxylase autoantibodies
Diarrhea	History
Ectodermal dysplasia	Physical examination
Hypoparathyroidism	Serum calcium, phosphate, PTH
Hepatitis	Liver function tests
Hypothyroidism/Graves' disease	TSH; thyroid peroxidase and/or thyroglobulin autoantibodies and anti-TSH receptor Ab
Male hypogonadism	FSH/LH, testosterone
Malabsorption	Physical examination, anti-IL-17 and anti-IL-22 autoantibodies
Mucocutaneous candidiasis	Physical examination, mucosal swab, stool samples
Obstipation	History
Ovarian failure	FSH/LH, estradiol
Pernicious anemia	CBC, vitamin B_{12} levels
Splenic atrophy	Blood smear for Howell-Jolly bodies; platelet count; ultrasound if positive
Type 1 diabetes	Glucose, hemoglobin A_{1c}, diabetes-associated autoantibodies (insulin, GAD65, IA-2, ZnT8)
APS-2	
Addison's disease	21-Hydroxylase autoantibodies, ACTH stimulation testing if positive
Alopecia	Physical examination
Autoimmune hyper- or hypothyroidism	TSH; thyroid peroxidase and/or thyroglobulin autoantibodies, anti-TSH receptor Ab
Celiac disease	Transglutaminase autoantibodies; small intestine biopsy if positive
Cerebellar ataxia	Dictated by signs and symptoms of disease
Chronic inflammatory demyelinating polyneuropathy	Dictated by signs and symptoms of disease
Hypophysitis	Dictated by signs and symptoms of disease, anti-Pit1 autoantibody
Idiopathic heart block	Dictated by signs and symptoms of disease
IgA deficiency	IgA level
Myasthenia gravis	Dictated by signs and symptoms of disease, antiacetylcholinesterase Ab
Myocarditis	Dictated by signs and symptoms of disease
Pernicious anemia	Anti–parietal cell autoantibodies
	CBC, vitamin B_{12} levels if positive
Serositis	Dictated by signs and symptoms of disease
Stiff man syndrome	Dictated by signs and symptoms of disease
Vitiligo	Physical examination, NALP-1 polymorphism

Abbreviations: Ab, antibody; ACTH, adrenocorticotropic hormone; APS, autoimmune polyendocrine syndrome; CBC, complete blood count; FSH, follicle-stimulating hormone; IL, interleukin; LH, luteinizing hormone; PTH, parathyroid hormone; TSH, thyroid-stimulating hormone.

manifestations of APS-1, including malabsorption and obstipation, may also bring these young patients to the attention of gastroenterologists for first evaluation. Specific physical examination findings of hyperpigmentation, vitiligo, alopecia, tetany, and signs of hyper- or hypothyroidism should be considered as signs of development of component disorders.

The development of disease-specific autoantibody assays can help confirm disease and also detect risk for future disease. For example, where possible, detection of anticytokine antibodies to IL-17 and IL-22 would confirm the diagnosis of mucocutaneous candidiasis due to APS-1. The presence of anti-21-hydroxylase antibody or anti-17-hydroxylase antibody (which may be found more commonly in adrenal insufficiency associated with APS-1) would confirm the presence or risk for Addison's disease. Other autoantibodies found in type 1 diabetes (e.g., anti-GAD65), pernicious anemia, and other component conditions should be screened for on a regular basis (6- to 12-month intervals depending on the age of the subject).

Laboratory tests, including a complete metabolic panel, phosphorous and magnesium, thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH; morning), hemoglobin A_{1c}, plasma vitamin B_{12} level, and complete blood count with peripheral smear looking for Howell-Jolly bodies (asplenism), should also be performed at these time points. Detection of abnormal physical findings or test results should prompt subsequent examinations of the relevant organ system (e.g., presence of Howell-Jolly bodies indicates need for ultrasound of spleen).

TREATMENT

APS-1

Therapy of individual disease components is carried out as outlined in other relevant chapters. Replacement of deficient hormones (e.g., adrenal, pancreas, ovaries/testes) will treat most of the endocrinopathies noted. Several unique issues merit special emphasis. Adrenal insufficiency can be masked by primary hypothyroidism by prolonging the half-life of cortisol. The caveat therefore is that replacement therapy with thyroid hormone can precipitate an adrenal crisis in an undiagnosed individual. Hence, all patients with hypothyroidism and the possibility of APS should be screened for adrenal insufficiency to allow treatment with glucocorticoids prior to the initiation of thyroid hormone replacement. Treatment of mucocutaneous candidiasis with ketoconazole in an individual with subclinical adrenal insufficiency may also precipitate adrenal crisis. Furthermore, mucocutaneous candidiasis may be difficult to eradicate entirely. Severe cases of disease involvement may require systemic immunomodulatory therapy, but this is not commonly needed.

APS-2

APS-2 (OMIM 269200) is more common than APS-1, with a prevalence of 1–2 in 100,000. It has a gender bias and occurs more often in female patients, with a ratio of at least 3:1 compared to male patients. In contrast to APS-1, APS-2 often has its onset in adulthood, with a peak incidence between 20 and 60 years of age. It shows a familial, multigenerational heritage (Table 389-2). The presence of two or more of the following endocrine deficiencies in the same patient defines the presence of APS-2: primary adrenal insufficiency (Addison's disease; 50–70%), Graves' disease or autoimmune thyroiditis (15–69%), type 1 diabetes mellitus (T1D; 40–50%), and primary hypogonadism. Frequently associated autoimmune conditions include celiac disease (3–15%), myasthenia gravis, vitiligo, alopecia, serositis, and pernicious anemia. These conditions occur with increased frequency in affected patients but are also are found in their family members (Table 389-3).

Genetic Considerations The overwhelming risk factor for APS-2 has been localized to the genes in the human lymphocyte antigen (HLA) complex on chromosome 6. Primary adrenal insufficiency in APS-2, but not APS-1, is strongly associated with both HLA-DR3 and HLA-DR4. Other class I and class II genes and alleles, such as HLA-B8, HLA-DQ2 and HLA-DQ8, and HLA-DR subtypes such as DRB1*04:04, appear to contribute to organ-specific disease susceptibility (Table 389-4). HLA-B8- and HLA-DR3-associated illnesses include selective IgA deficiency, juvenile dermatomyositis, dermatitis herpetiformis, alopecia, scleroderma, autoimmune thrombocytopenia purpura, hypophysitis, metaphyseal osteopenia, and serositis.

Several other immune genes have been proposed to be associated with Addison's disease and therefore with APS-2 (Table 389-3). The "5.1" allele of a major histocompatibility complex (MHC) gene is an atypical class I HLA molecule MIC-A. The MIC-A5.1 allele has a very strong association with Addison's disease that is not accounted for by linkage disequilibrium with DR3 or DR4. Its role is complicated because certain HLA class I genes can offset this effect. *PTPN22* codes for a polymorphism in a protein tyrosine phosphatase, which acts on

TABLE 389-4 APS-2 and Other Polyendocrine Disorder Associations

DISEASE	HLA ASSOCIATION	INITIATING FACTOR	MECHANISM	AUTOANTIGEN
Graves' disease	DR3	Iodine Anti-CD52	Antibody	TSH receptor
Myasthenia gravis	DR3, DR7	Thymoma Penicillamine	Antibody	Acetylcholine receptor
Anti-insulin receptor	?	SLE or other autoimmune disease	Antibody	Insulin receptor
Hypoparathyroidism	?	?	Antibody	Cell surface inhibitor
Insulin autoimmune syndrome	DR4, DRB1*0406	Methimazole Sulfhydryl-containing drugs	Antibody	Insulin
Celiac disease	DQ2/DQ8	Gluten diet	T cell	Transglutaminase
Type 1 diabetes	DR3/DR4 DQ2/DQ8	? Congenital rubella	T cell	Insulin, GAD65, IA-2, ZnT8, IGRP
Addison's disease	DR3/DR4 DRB1*0404	Unknown	T cell	21-Hydroxylase P450-5cc
Thyroiditis	DR3/DQB1*0201 DQA1*0301	Iodine Interferon α	T cell	Thyroglobulin Thyroid peroxidase
Pernicious anemia	?	?	T cell	Intrinsic factor H+/K+ ATPase
Vitiligo	?	Melanoma Antigen Immunization	?	Melanocyte
Chromosome dysgenesis–trisomy 21 and Turner's syndrome	DQA1*0301	?	?	Thyroid, islet, transglutaminase
Hypophysitis	?	Pit-1, TDRD6	?	Pituitary, Pit-1

Abbreviations: APS, autoimmune polyendocrine syndrome; SLE, systemic lupus erythematosus; TSH, thyroid-stimulating hormone.

intracellular signaling pathways in both T and B lymphocytes. It has been implicated in T1D, Addison's disease, and other autoimmune conditions. *CTLA4* is a receptor on the T-cell surface that modulates the activation state of the cell as part of the signal 2 pathway (i.e., binding to CD80/86 on antigen presenting cells). Polymorphisms of this gene appear to cause downregulation of the cell surface expression of the receptor, leading to decreased T-cell activation and proliferation. This appears to contribute to Addison's disease and potentially other components of APS-2. Allelic variants of the IL-2Rα are linked to development of T1D and autoimmune thyroid disease and could contribute to the phenotype of APS-2 in certain individuals.

Diagnosis When one of the component disorders is present, a second associated disorder occurs more commonly than in the general population (Table 389-3). There is controversy as to which tests to use and how often to screen individuals for disease. A strong family history of autoimmunity should raise suspicion in an individual with an initial component diagnosis. The development of a rarer form of autoimmunity, such as Addison's disease, should prompt more extensive screening for other linked disorders, as ~50% of Addison's disease patients develop another autoimmune disease during their lifetime.

Circulating autoantibodies, as previously discussed, can precede the development of clinical disease by many years but would allow the clinician to follow the patient and identify the disease onset at its earliest time point (Tables 389-3 and 389-4). For each of the endocrine components of the disorder, appropriate autoantibody assays are listed and, if positive, should prompt physiologic testing to diagnose clinical or subclinical disease. For Addison's disease, antibodies to 21-hydroxylase antibodies are highly diagnostic for risk of adrenal insufficiency. However, individuals may take many years to develop overt symptoms of hypoadrenalism. Screening of 21-hydroxylase antibody–positive patients can be performed measuring morning ACTH and cortisol on a yearly basis. Rising ACTH values over time or low morning cortisol in association with signs or symptoms of adrenal insufficiency should prompt testing via the cosyntropin stimulation test **(Chap. 386)**. T1D can be screened for by measuring autoantibodies directed against insulin, GAD65, IA-2, and ZnT8. Risk for progression to disease is based on the number of antibodies (≥2 islet autoantibodies with normal glucose tolerance is now defined as stage 1 of T1D as the lifetime risk for developing clinical symptoms is nearly 100%) and metabolic factors (impaired oral glucose tolerance test). Many efforts are ongoing and underway to screen relatives of T1D patients and those in the general population for islet autoantibodies to identify prediabetic individuals who may qualify for intervention trials to change the course of the disease prior to clinical onset.

Screening tests for thyroid disease can include anti–thyroid peroxidase (TPO) or anti-thyroglobulin autoantibodies or anti-TSH receptor antibodies for Graves' disease. Yearly measurements of TSH can then be used to follow these individuals. Celiac disease can be screened for using the anti–tissue transglutaminase (tTg) antibody test. For those <20 years of age, testing every 1–2 years should be performed, whereas less frequent testing is indicated after the age of 20 because the majority of individuals who develop celiac disease have the antibody earlier in life. Positive tTg antibody test results should be confirmed on repeat testing, followed by small-bowel biopsy to document pathologic changes of celiac disease. Many patients have asymptomatic celiac disease that is nevertheless associated with osteopenia and impaired growth. If left untreated, symptomatic celiac disease has been reported to be associated with an increased risk of gastrointestinal malignancy, especially lymphoma, and osteoporosis later in life.

The knowledge of the particular disease associations should guide other autoantibody or laboratory testing. A complete history and physical examination should be performed every 1–3 years including CBC, metabolic panel, TSH, and vitamin B_{12} levels to screen for most of the possible abnormalities. More specific tests should be based on specific findings from the history and physical examination.

TREATMENT

APS-2

With the exception of Graves' disease, the management of each endocrine component of APS-2 involves hormone replacement and is covered in detail in the chapters on adrenal **(Chap. 386)**, thyroid **(Chap. 382)**, gonadal **(Chaps. 391 and 392)**, and parathyroid diseases **(Chap. 410)**. As noted for APS-1, adrenal insufficiency can be masked by primary hypothyroidism and should be considered and treated as discussed above. In patients with T1D, decreasing insulin requirements or hypoglycemia, without obvious secondary causes, may indicate the emergence of adrenal insufficiency. Hypocalcemia in APS-2 patients is more likely due to malabsorption, potentially from undiagnosed celiac disease, than hypoparathyroidism.

Immunotherapy for autoimmune endocrine disease has been reserved for T1D, for the most part, reflecting the lifetime burden of the disease for the individual patient and society. Although several immunotherapies (e.g., modified anti-CD3, rituximab, abatacept, alefacept, low-dose antithymocyte globulin) can prolong the honeymoon phase of T1D, none has achieved long-term success. The anti-CD3 monoclonal antibody (teplizumab) does delay the onset of clinical diabetes by an average of 2 years when administered to individuals with stage 2 T1D (e.g., those with autoantibodies and

impaired glucose tolerance). Active basic and clinical research using new approaches and combination therapy may change the treatment of this disease or other autoimmune conditions that share similar pathways.

IMMUNE CHECKPOINT INHIBITOR–INDUCED ENDOCRINE AUTOIMMUNITY

Therapies that block immune checkpoints, such as programmed cell death protein 1 (PD-1), its ligand (PD-L1), or CTLA-4, are beneficial immunotherapies for many advanced-stage cancers. These immune checkpoint inhibitors (ICIs) block negative immune regulation, thereby allowing for an immune response directed against tumor cells. However, immune-related adverse events also occur, especially autoimmunity directed toward self-tissues. ICI-induced T1D, thyroid disease, hypophysitis, and adrenal insufficiency have all been reported with these therapies. Hypothyroidism occurs in ~8% and T1D in 1% of those receiving monoclonal antibodies directed against PD-1 or PD-L1, and hypophysitis and adrenal insufficiency occur in <1% of treated patients. These autoimmune side effects can develop during or after therapy, mostly within a few weeks to months following the start of therapy. ICI-induced T1D has a very rapid onset, presents with diabetic ketoacidosis, is permanent, and requires lifelong exogenous insulin therapy for treatment. There is a genetic association with HLA-DR4 and islet autoantibodies in ~40–50% of patients at diagnosis. The pathogenesis is immune mediated as T lymphocyte infiltration has been documented in the pancreatic islets of an ICI-T1D patient. Determining the mechanisms of autoimmune disease development following ICI therapies and developing biomarkers to stratify risk for autoimmune side effects prior to therapy are active areas of research.

IPEX

*I*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, and *X*-linked disease (IPEX; OMIM 304790) is a rare X-linked recessive disorder. The disease onset is in infancy and is characterized by severe enteropathy, T1D, and skin disease, as well as variable association with several other autoimmune disorders. Many infants die within the first days of life, but the course is variable, with some children surviving for 12–15 years. Early onset of T1D, often at birth, is highly suggestive of the diagnosis because nearly 80% of IPEX patients develop T1D. Although treatment of the individual disorders can temporarily improve the situation, treatment of the underlying immune deficiency is required and includes immunosuppressive therapy generally followed by hematopoietic stem cell transplantation. Transplantation is the only life-saving form of therapy and can be fully curative by normalizing the imbalanced immune system found in this disorder.

IPEX is caused by mutations in the *FOXP3* gene, which is also mutated in the Scurfy mouse, an animal model that shares much of the same phenotype of IPEX patients. The FOXP3 transcription factor is expressed in regulatory T cells designated CD4+CD25+FOXP3+ (Treg). Lack of this factor causes a profound deficiency of this Treg population and results in rampant autoimmunity due to the lack of peripheral tolerance normally provided by these cells. Certain mutations may lead to varying forms of expression of the full syndrome, and there are rare cases where the *FOXP3* gene is intact but other genes involved in this pathway (e.g., CD25, IL-2Rα) may be causative. Future therapy with autologous CD4+ T cells transfected with a functioning *FOXP3* gene may offer a better long-term outcome than has been seen in those treated with stem cell transplantation.

THYMIC TUMORS

Thymomas and thymic hyperplasia are associated with several autoimmune diseases, with the most common being myasthenia gravis (44%) and red cell aplasia (20%). Graves' disease, T1D, and Addison's disease may also be associated with thymic tumors. Patients with myasthenia gravis and thymoma may have unique anti–acetylcholine receptor autoantibodies. Most thymomas lack AIRE expression within the thymoma, and this could be a potential factor in the development of autoimmunity. In support of this concept, thymoma is the one other disease with "frequent" development of anticytokine antibodies and mucocutaneous candidiasis in adults. The majority of tumors are malignant, and temporary remissions of the autoimmune condition can occur with resection of the tumor.

ANTI-INSULIN RECEPTOR ANTIBODIES

This is a very rare disorder where severe insulin resistance (type B) is caused by the presence of anti-insulin receptor antibodies. It is associated with acanthosis nigricans, which can also be associated with other forms of less severe insulin resistance. About one-third of patients have an associated autoimmune illness such as systemic lupus erythematosus or Sjögren's syndrome. Therefore, the presence of antinuclear antibodies, elevated erythrocyte sedimentation rate, hyperglobulinemia, leukopenia, and hypocomplementemia may accompany the presentation. The presence of anti-insulin receptor autoantibodies leads to marked insulin resistance, requiring >100,000 units of insulin to be given daily with only partial control of hyperglycemia. Patients can also have severe hypoglycemia due to partial activation of the insulin receptor by the antibody. The course of the disease is variable, and several patients have had spontaneous remissions. A therapeutic approach that targets B lymphocytes, including rituximab, cyclophosphamide, and pulse steroids, has been validated in follow-on case reports to induce remission of the disease.

INSULIN AUTOIMMUNE SYNDROME (HIRATA'S SYNDROME)

The insulin autoimmune syndrome, associated with Graves' disease and methimazole therapy (or other sulfhydryl-containing medications), is of particular interest due to a remarkably strong association with a specific HLA haplotype. Such patients with elevated titers of anti-insulin antibodies frequently present with hypoglycemia. In Japan, the disease is restricted to HLA-DR4-positive individuals with DRB1*04:06, while Caucasian patients predominantly have DRB1*04:03 (which is related to DRB1*04:06). In Hirata's syndrome, the anti-insulin antibodies are often polyclonal. Discontinuation of the medication generally leads to resolution of the syndrome over time. There are very rare cases of insulin autoimmune syndrome not associated with sulfhydryl-containing medications that result in profound, life-threatening hypoglycemia. Treatment involves treating the underlying condition that causes anti-insulin antibodies, such as a B lymphocyte lymphoma (tend to have monoclonal insulin antibodies) or systemic lupus erythematosus. As hypoglycemia is profound when elevated titers of high affinity insulin antibodies bind secreted insulin and then release it into circulation, treatment that begins with high-dose glucocorticoids and rituximab to target B lymphocytes has been shown to be effective.

POEMS SYNDROME

POEMS (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-protein, and *s*kin changes; also known as Crow-Fukase syndrome; OMIM 192240) patients usually present with a progressive sensorimotor polyneuropathy, diabetes mellitus (50%), primary gonadal failure (70%), and a plasma cell dyscrasia with sclerotic bony lesions. Associated findings can be hepatosplenomegaly, lymphadenopathy, and hyperpigmentation. Patients often present in the fifth to sixth decade of life and have a median survival after diagnosis of <3 years. The syndrome is assumed to be secondary to circulating immunoglobulins, but patients have excess vascular endothelial growth factor as well as elevated levels of other inflammatory cytokines such as IL1-β, IL-6, and tumor necrosis factor α. Patients have been treated with thalidomide, and more recently lenalidomide, leading to a decrease in vascular endothelial growth factor. Hyperglycemia responds to small, subcutaneous doses of insulin. The hypogonadism is due to primary gonadal disease with elevated plasma levels of follicle-stimulating hormone and luteinizing hormone. Temporary resolution of the features of POEMS, including normalization of blood glucose, may occur after radiotherapy for localized plasma cell lesions of bone or after chemotherapy, lenalidomide and dexamethasone, or autologous stem cell transplantation.

OTHER DISORDERS

Other diseases can exhibit polyendocrine deficiencies, including Kearns-Sayre syndrome, DIDMOAD syndrome (*d*iabetes *i*nsipidus, *d*iabetes *m*ellitus, progressive bilateral *o*ptic *a*trophy, and sensorineural *d*eafness; also termed Wolfram's syndrome), Down's syndrome or trisomy 21 (OMIM 190685), Turner's syndrome (monosomy X, 45,X0), and congenital rubella.

Kearns-Sayre syndrome (OMIM 530000) is a rare mitochondrial DNA disorder characterized by myopathic abnormalities leading to ophthalmoplegia and progressive weakness in association with several endocrine abnormalities, including hypoparathyroidism, primary gonadal failure, diabetes mellitus, and hypopituitarism. Crystalline mitochondrial inclusions are found in muscle biopsy specimens, and such inclusions have also been observed in the cerebellum. Antiparathyroid antibodies have not been described; however, antibodies to the anterior pituitary gland and striated muscle have been identified, and the disease may have autoimmune components. These mitochondrial DNA mutations occur sporadically and do not appear to be associated with a familial syndrome.

Wolfram's syndrome (OMIM 222300, chromosome 4; OMIM 598500, mitochondrial) is a rare autosomal recessive disease that is also called DIDMOAD. Neurologic and psychiatric disturbances are prominent in most patients and can cause severe disability. The disease is caused by defects in the *Wolfram syndrome 1* (*WFS1*) gene, which encodes a 100-kDa transmembrane protein that has been localized to the endoplasmic reticulum and is found in neuronal and neuroendocrine tissue. Its expression induces ion channel activity with a resultant increase in intracellular calcium and may play an important role in intracellular calcium homeostasis. Wolfram's syndrome appears to be a slowly progressive neurodegenerative process, and there is nonautoimmune selective destruction of the pancreatic beta cells. Diabetes mellitus with an onset in childhood is usually the first manifestation. Diabetes mellitus and optic atrophy are present in all reported cases, but expression of the other features is variable. Treatments targeting endoplasmic reticulum dysfunction are being tested and may be a bridge until gene therapy can be developed to treat the most severely affected cases.

Down's syndrome, or trisomy 21 (OMIM 190685), is associated with the development of T1D, thyroiditis, and celiac disease. Patients with Turner's syndrome also appear to be at increased risk for the development of thyroid disease and celiac disease. It is recommended to screen patients with trisomy 21 and Turner's syndrome for associated autoimmune diseases on a regular basis.

GLOBAL CONSIDERATIONS

Identification of these syndromes requires access to central laboratories with the ability to detect unique autoantibodies and to sequence the specific genes that may underlie these disorders. Early recognition of the clinical features of these disorders and timely referral and/or consultation with tertiary care centers to confirm the diagnosis and initiate therapy are important to improving outcomes. The *AIRE* recessive gene mutations found in APS-1 were originally described in high frequency in several populations including Finns, Iranian Jews, Sardinians, Norwegians, and Irish. Although individuals from many other countries have now been found to have these mutations and the newly identified dominant *AIRE* gene mutations, understanding the frequency in the background population may raise the clinician's level of suspicion for these rare disorders. Hirata's syndrome was originally reported in Japanese populations but also may be found in other populations, as noted.

Section 2 Sex- and Gender-Based Medicine

390 Sex Development

Courtney Finlayson, J. Larry Jameson, John C. Achermann

Sex development begins in utero but continues into young adulthood with the achievement of sexual maturity and reproductive capability. The major determinants of sex development can be divided into three components: chromosomal sex, gonadal sex (sex determination), and phenotypic sex (sex differentiation) (Fig. 390-1). Variations at each of these stages can result in differences (or disorders) of sex development (DSDs) (Table 390-1). In the newborn period, ~1 in 5000 babies undergo investigation because of atypical or ambiguous genitalia. Urgent assessment is indicated, because some causes such as congenital adrenal hyperplasia (CAH) can be associated with life-threatening adrenal crises. An experienced multidisciplinary team is important for counseling, planning appropriate investigations, discussing long-term well-being, supporting parents, and providing clear communication about the diagnosis and management options. DSDs can also present at other ages and to a range of health professionals (Table 390-2). Subtler forms of gonadal dysfunction (e.g., Klinefelter syndrome [KS], Turner syndrome [TS]) often are diagnosed later in life by internists. Because DSDs are associated with a variety of psychological, reproductive, and potential medical consequences, an open dialogue must be established between the patient and health care providers to ensure continuity and attention to these issues across the life span. Gender variance and gender dysphoria are more common among some individuals with DSD than in the general population. Thus, attention to and comfort discussing gender identity is important. Support groups also have a valuable role to play for many patients and families.

Care of individuals with DSDs has evolved from primarily focusing on medical and surgical intervention to "genitalia" to a more holistic approach involving medical, surgical, and psychosocial care, acknowledging that the best way to care for individuals with DSD is not always clear and should be individualized. This includes many controversies, particularly concerning whether genitoplasty or prophylactic gonadectomy in selected conditions should be performed for infants and young children prior to the age of consent. Accepted nomenclature is also controversial. Previous terms such as *intersex* and *hermaphrodite* were

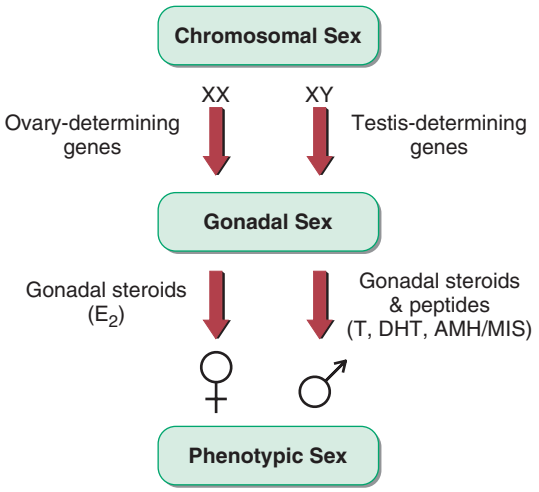

FIGURE 390-1 Sex development can be divided into three major components: chromosomal sex, gonadal sex, and phenotypic sex. AMH, anti-müllerian hormone also known as Müllerian-inhibiting substance, MIS; DHT, dihydrotestosterone; T, testosterone.

TABLE 390-1 Classification of Disorders of Sex Development (DSDs)[a]

SEX CHROMOSOME DSD	46,XY DSD (SEE TABLE 390-3)	46,XX DSD (SEE TABLE 390-4)
47,XXY (Klinefelter syndrome and variants)	**Disorders of gonadal (testis) development**	**Disorders of gonadal (ovary) development**
45,X (Turner syndrome and variants)	Complete or partial gonadal dysgenesis (e.g., *SRY, SOX9, SF1, WT1, DMRT1, DHH, GATA4, ZFPM2, MAP3K1, ESR2, ZNRF3, SOX8, DHX37*)	Gonadal dysgenesis
45,X/46,XY mosaicism (mixed gonadal dysgenesis)	Impaired fetal Leydig cell function (e.g., *SF1/NR5A1, CXorf6/MAMLD1, HHAT, SAMD9*)	Ovotesticular DSD
46,XX/46,XY (chimerism/mosaicism)	Ovotesticular DSD	Testicular DSD (e.g., *SRY+*, dup *SOX9, RSPO1, SF1/NR5A1, NR2F2, WT1*)
	Testis regression	**Androgen excess**
	Disorders in androgen synthesis or action	Fetal
	Disorders of androgen biosynthesis	3β-Hydroxysteroid dehydrogenase II (*HSD3β2*)
	LH receptor (*LHCGR*)	21-Hydroxylase (*CYP21A2*)
	Smith-Lemli-Opitz syndrome (*DHCR7*)	P450 oxidoreductase (*POR*)
	Steroidogenic acute regulatory (*StAR*) protein	11β-Hydroxylase (*CYP11B1*)
	Cholesterol side-chain cleavage (*CYP11A1*)	Fetoplacental
	3β-Hydroxysteroid dehydrogenase II (*HSD3B2*)	Aromatase deficiency (*CYP19*)
	17α-Hydroxylase/17,20-lyase (*CYP17A1*)	Oxidoreductase deficiency (*POR*)
	P450 oxidoreductase (*POR*)	Maternal
	Cytochrome b5 (*CYB5A*)	Maternal virilizing tumors (e.g., luteomas)
	17β-Hydroxysteroid dehydrogenase III (*HSD17B3*)	Androgenic drugs
	5α-Reductase II (*SRD5A2*)	**Other**
	Aldo-keto reductase 1C2 (*AKR1C2*)	Syndromic associations (e.g., cloacal anomalies)
	Disorders of androgen action	Müllerian agenesis/hypoplasia (e.g., MRKH)
	Androgen insensitivity syndrome	Uterine abnormalities (e.g., MODY5)
	Drugs and environmental modulators	Vaginal atresia (e.g., McKusick-Kaufman)
	Other	Labial adhesions
	Syndromic associations of male genital development	
	Associated with fetal growth restriction	
	Persistent müllerian duct syndrome	
	Vanishing testis syndrome	
	Isolated hypospadias	
	Congenital hypogonadotropic hypogonadism	
	Cryptorchidism	
	Environmental influences	

[a]Some experts and patient advocacy groups prefer to define DSD as *differences of sex development* rather than *disorders of sex development*.

Abbreviations: LH, luteinizing hormone; MODY, maturity-onset diabetes of the young; MRKH, Mayer-Rokitansky-Küster-Hauser syndrome.

Source: Reproduced with permission from IA Hughes et al: Consensus statement on management of intersex disorders. J Pediatr Urol 2:148, 2006.

changed by the 2006 Consensus Statement to *disorder of sex development* and *ovotesticular DSD*, but these terms are not universally accepted.

SEX DEVELOPMENT

Chromosomal sex, defined by a karyotype, describes the X and/or Y chromosome complement (46,XY; 46,XX) established at the time of fertilization. The presence of a normal Y chromosome determines that testis development will occur even in the presence of multiple X chromosomes (e.g., 47,XXY). Loss of an X chromosome impairs gonad development (45,X or 45,X/46,XY mosaicism). Fetuses with no X chromosome (45,Y) are not viable.

Gonadal sex refers to the histologic and functional characteristics of gonadal tissue as testis or ovary. The embryonic gonad is initially "bipotential" and can develop (from ~42 days after conception) into

TABLE 390-2 Presentation of Disorders of Sex Development (DSD) at Different Stages of Life

PRESENTATION	FEATURES	PROFESSIONAL	EXAMPLES
Prenatal	Karyotype-phenotype discordance	Obstetrician; fetal medicine	Many
Neonatal	Atypical genitalia	Obstetrician; neonatal medicine	Many
	Salt-losing crisis	Pediatrician	CAH *(CYP21)*
Childhood	Hernia	Surgeon	CAIS
	Androgenization	Endocrinologist	CAH *(CYP21, CYP11B1)*
	Poor growth	Pediatrician	Turner, 45,X/46,XY
	Associated features	Oncologist/nephrologist	Wilms' tumor
Puberty	Androgenization	Endocrinologist	17β-HSD, 5α-reductase, SF1
	Estrogenization	Endocrinologist	Ovotestis
	Absent puberty	Endocrinologist	Gonadal dysgenesis, CAH *(CYP17A1)*, Turner
Post-puberty	Amenorrhea	Gynecologist	CAIS
Adult	Infertility	Andrologist	Klinefelter, 45,X/46,XY, SF1

Abbreviations: CAH, congenital adrenal hyperplasia; CAIS, complete androgen insensitivity syndrome; 17β-HSD, 17β-hydroxysteroid dehydrogenase deficiency; SF1, steroidogenic factor 1 (*NR5A1*).

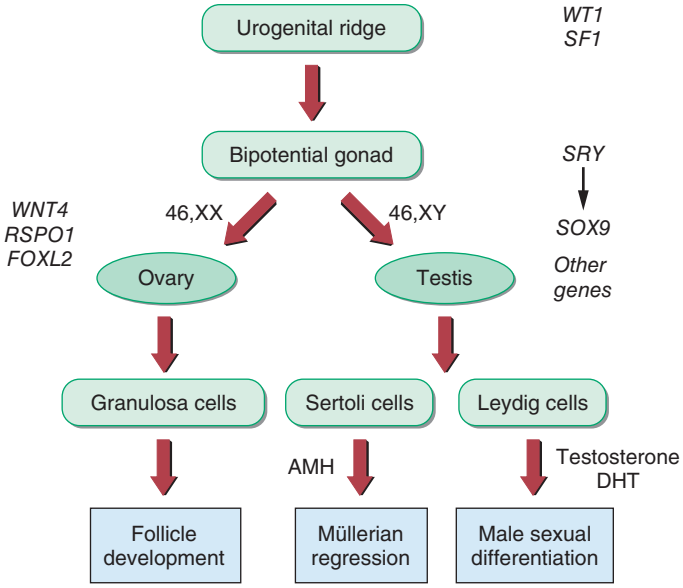

FIGURE 390-2 The genetic regulation of gonadal development. See text for additional genes involved. AMH, anti-müllerian hormone (müllerian-inhibiting substance); DHT, dihydrotestosterone; *FOXL2*, forkhead transcription factor L2; *RSPO1*, R-spondin 1; *SF1*, steroidogenic factor 1 (also known as NR5A1); *SOX9*, *SRY*-related HMG-box gene 9; *SRY*, sex-determining region on the Y chromosome; *WNT4*, wingless-type MMTV integration site 4; *WT1*, Wilms' tumor–related gene 1.

either a testis or an ovary (Fig. 390-2). Testis development is initiated by expression of the gene *SRY* (sex-determining region on the Y chromosome). Disruption of *SRY* prevents testis development in 46,XY individuals, whereas translocation of *SRY* in 46,XX individuals induces testis development and a male phenotype. The main target of SRY is *SOX9* (*SRY*-related HMG-box gene 9). *SOX9* is upregulated in the developing testis but is suppressed in the ovary. Many other genes are involved in testis development, including in Sertoli cell maturation and Leydig cell differentiation/steroidogenesis. In addition to transcription factors, these genes encode an array of signaling molecules and paracrine growth factors, some of which influence other organ systems. For example, *WT1* (Wilms' tumor–related gene 1) acts early in the genetic pathway and also regulates kidney development, whereas steroidogenic factor 1 (*SF1*, *NR5A1*) influences both gonad and adrenal development. Pathogenic variants causing loss of function of *SF1* are found in ~10% of XY patients with gonadal dysgenesis and impaired androgenization. Of note, duplication of a related gene *DAX1*/*NR0B1* impairs testis development, revealing the exquisite sensitivity of the testis-determining pathway to gene dosage effects.

Although ovarian development once was considered a "default" genetic pathway, it is now clear that specific genes are expressed during the earliest stages of ovary development. Some of these factors may repress testis development (e.g., WNT4, R-spondin-1) (Fig. 390-2). Once the ovary has formed, additional factors are required for normal follicular development (e.g., follicle-stimulating hormone [FSH] receptor). Steroidogenesis in the ovary requires the development of follicles that contain granulosa cells and theca cells surrounding the oocytes (Chap. 392). Thus, there is relatively limited ovarian steroidogenesis until puberty.

Germ cells also develop in a sex dimorphic manner. In the developing ovary, primordial germ cells (PGCs) proliferate and enter meiosis, whereas they proliferate and then undergo mitotic arrest in the developing testis. PGC entry into meiosis is potentially initiated by retinoic acid. The developing testis produces high levels of CYP26B1, an enzyme that degrades retinoic acid, preventing PGC entry into meiosis. Approximately 7 million germ cells are present in the fetal ovary in the second trimester, and 1 million remain at birth. Only 400 are ovulated during a woman's reproductive life span (Chap. 392).

Phenotypic sex refers to the structures of the external and internal genitalia and secondary sex characteristics. In addition to bipotential gonads in the fetuses, they also initially possess internal and external genitalia, which can develop along a male- or female-typical pathway, with sex-specific development occurring as a result of hormone action (Fig. 390-3). The developing testis releases anti-müllerian hormone (AMH; also known as müllerian-inhibiting substance [MIS]) from Sertoli cells and testosterone from Leydig cells. AMH acts through specific receptors to cause regression of the müllerian structures from 60–80 days after conception. At ~60–140 days after conception, testosterone supports the maintenance of wolffian structures, including the epididymides, vasa deferentia, and seminal vesicles. Testosterone is the precursor for dihydrotestosterone (DHT), a potent androgen that promotes development of the external genitalia, including the penis and scrotum (60–100 days, and thereafter) (Fig. 390-3). The urogenital sinus develops into the prostate and prostatic urethra in the male and into the urethra and lower portion of the vagina in the female. The genital tubercle becomes the glans penis in the male and the clitoris in the female. The urogenital swellings form the scrotum or the labia majora, and the urethral folds fuse to form the shaft of the penis and the male urethra or the labia minora. In the female, wolffian ducts regress and the müllerian ducts form the fallopian tubes, uterus, and upper segment of the vagina. A female phenotype will develop in the absence of the gonad, but estrogen is needed for maturation of the uterus and breast at puberty.

The prenatal hormone environment is likely one of many factors influencing aspects of gender identity and behavior. This is an area of ongoing research and is beyond the scope of this chapter.

DISORDERS OF CHROMOSOMAL SEX

Variations in sex chromosome number and structure can present as DSDs (e.g., 45,X/46,XY). KS (47,XXY) and TS (45,X) do not usually present with genital ambiguity but are associated with gonadal dysfunction (Table 390-3).

KLINEFELTER SYNDROME (47,XXY)

Pathophysiology The classic form of KS (47,XXY) occurs after meiotic nondisjunction of the sex chromosomes during gametogenesis (40% during spermatogenesis, 60% during oogenesis). Other forms of KS (including mosaic 46,XY/47,XXY [10–20%], 48,XXYY, and 48,XXXY) are less common. KS has an incidence of at least 1 in 1000 men, but ~75% of cases are not diagnosed. Of those diagnosed, historically only 10% were identified prepubertally. However, the advent of noninvasive prenatal testing is leading to increased detection at an earlier age.

Clinical Features KS is most commonly characterized by small testes, infertility, gynecomastia, tall stature/increased leg length, and hypogonadism in phenotypic males. At birth, most infants with KS do not have clinical features, although there are higher rates of cryptorchidism and hypospadias. Most patients present in puberty with arrested pubertal development caused by testicular insufficiency. Others are diagnosed after puberty, based on low androgens, gynecomastia, or infertility. Testes are small and firm (median length 2.5 cm [4 mL volume]; almost always <3.5 cm [12 mL]) and typically seem inappropriately small for the degree of androgenization. Biopsies are not usually necessary but typically reveal seminiferous tubule hyalinization and azoospermia. Other clinical features of KS are listed in Table 390-3. Plasma concentrations of FSH and luteinizing hormone (LH) are increased in most adults with 47,XXY, and plasma testosterone is decreased (50–75%), reflecting primary gonadal insufficiency. Estradiol is often increased, resulting in gynecomastia (Chap. 391). Patients with mosaic forms of KS have less severe clinical features, have larger testes, and sometimes achieve spontaneous fertility.

TREATMENT

Klinefelter Syndrome

Growth, endocrine function, and bone mineralization should be monitored, especially from adolescence. Educational and psychological support is important for many individuals with

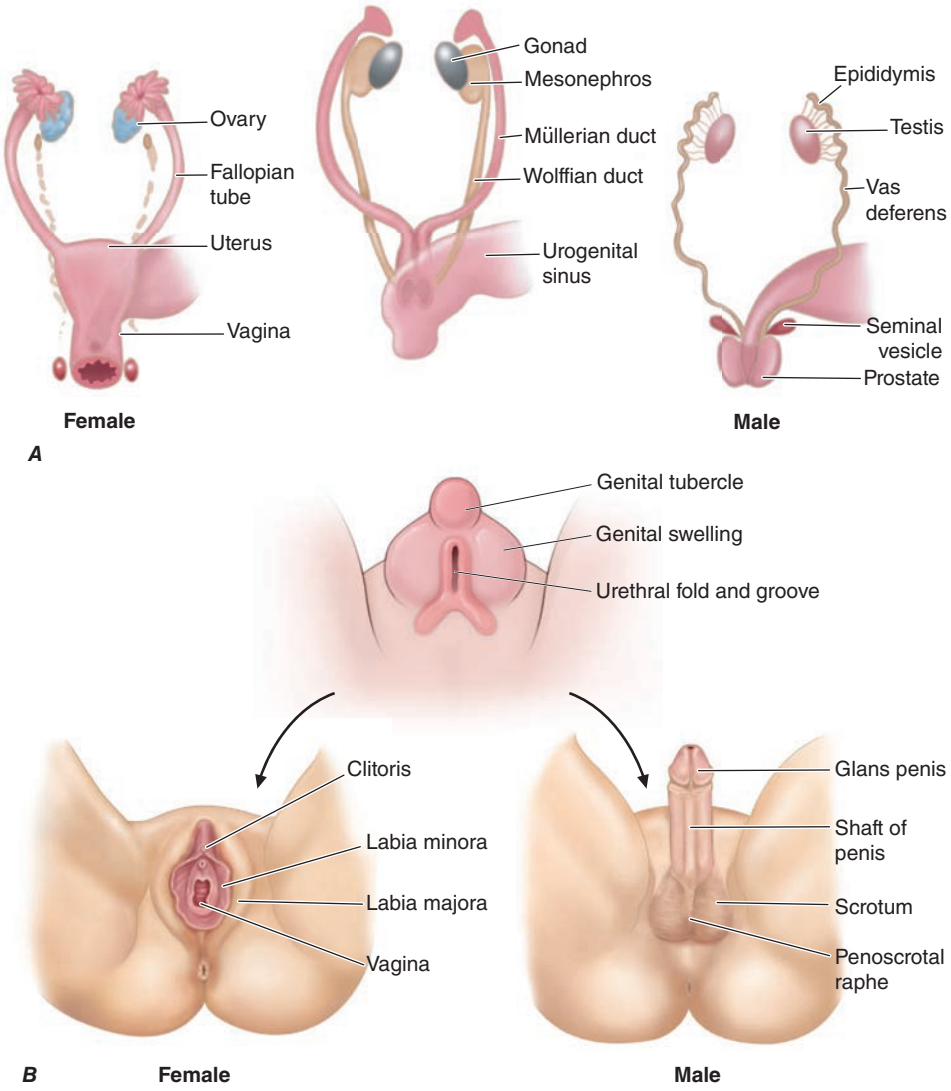

FIGURE 390-3 Sex development. ***A.*** Internal urogenital tract. ***B.*** External genitalia.

KS. Androgen supplementation improves virilization, libido, energy, hypofibrinolysis, and bone mineralization in men with low testosterone levels but may occasionally worsen gynecomastia (Chap. 391). Gynecomastia can be treated by surgical reduction if it causes concern (Chap. 391). Fertility has been achieved by using in vitro fertilization in men with oligospermia or with intracytoplasmic sperm injection (ICSI) after retrieval of spermatozoa by testicular sperm extraction techniques. In specialized centers, successful spermatozoa retrieval using this technique is possible in >50% of men with nonmosaic KS. Results may be better in younger men. After ICSI and embryo transfer, successful pregnancies can be achieved in ~50% of these cases. The risk of transmitting chromosomal anomalies needs to be considered and counseling provided, although this outcome is much less common than originally predicted. Long-term monitoring of men with KS is important given the increased risk of breast cancer, cardiovascular disease, metabolic syndrome, osteoporosis, and autoimmune disorders. Because most men with KS are never diagnosed, it is important that all internists consider this diagnosis in men with these features who might be seeking medical advice for other conditions.

TURNER SYNDROME (GONADAL DYSGENESIS; 45,X)

Pathophysiology TS is caused by complete or partial loss of one X chromosome and affects ~1 in 2500 women. Approximately one-half of women with TS have a 45,X karyotype, ~20% have 45,X/46,XX mosaicism, and the remainder have structural abnormalities of the X chromosome such as X fragments, isochromosomes, rings, or Y chromosome material. The clinical features of TS result from haploinsufficiency of multiple X chromosomal genes (e.g., short stature homeobox, *SHOX*), either directly or through effects on autosomal gene expression. However, imprinted genes are also proposed to be affected when the inherited X has different parental origins.

Clinical Features TS is characterized by female external genitalia, short stature, hypergonadotropic hypogonadism, infertility, and other phenotypic features (Table 390-3). Infants may present with lymphedema, nuchal folds, low hairline, or left-sided cardiac defects or later in childhood with unexplained growth failure or delayed puberty. Although limited spontaneous pubertal development occurs in up to 30% of girls with TS (10%, 45,X; 60%, 45,X/46,XX) and up to 20% have menarche, the vast majority of women with TS develop complete ovarian insufficiency. Therefore, this diagnosis should be considered in all women who present with primary or secondary amenorrhea and elevated gonadotropin levels.

TREATMENT

Turner Syndrome

The management of girls and women with TS requires a multidisciplinary approach to address many potentially affected organ systems according to TS practice guidelines. Individuals require long-term monitoring by an experienced cardiologist to follow

TABLE 390-3 Possible Associated Clinical Features of Chromosomal Disorders of Sex Development (DSDs)

DISORDER	COMMON CHROMOSOMAL COMPLEMENT	GONAD	GENITALIA		BREAST DEVELOPMENT
			EXTERNAL	INTERNAL	
Klinefelter syndrome	47,XXY or 46,XY/47,XXY	Hyalinized testes	Male	Male	Gynecomastia
	Clinical Features				
	Small testes, azoospermia, decreased facial and axillary hair, decreased libido, tall stature and increased leg length, decreased penile length, increased risk of breast tumors, thromboembolic disease, learning difficulties, anxiety, speech delay and decreased verbal IQ, obesity, diabetes mellitus, metabolic syndrome, varicose veins, hypothyroidism, systemic lupus erythematosus, epilepsy				
Turner syndrome	45,X or 45,X/46,XX	Streak gonad or immature ovary	Female	Hypoplastic female	Immature female
	Clinical Features				
	Infancy: lymphedema, web neck, shield chest, low-set hairline, cardiac defects and coarctation of the aorta, urinary tract malformations, and horseshoe kidney				
	Childhood: short stature, cubitus valgus, short neck, short fourth metacarpals, hypoplastic nails, micrognathia, scoliosis, otitis media and sensorineural hearing loss, ptosis and amblyopia, multiple nevi and keloid formation, autoimmune thyroid disease, visuospatial learning difficulties				
	Adulthood: absent puberty and primary amenorrhea, hypertension, obesity, dyslipidemia, impaired glucose tolerance and insulin resistance, autoimmune thyroid disease, cardiovascular disease, aortic root dilation, osteoporosis, inflammatory bowel disease, chronic hepatic dysfunction, increased risk of colon cancer, hearing loss				
45,X/46,XY mosaicism	45,X/46,XY	Testis or streak gonad	Variable	Variable	Usually male
	Clinical Features				
	Short stature, increased risk of gonadal tumors, some Turner syndrome features				
Ovotesticular DSD	46,XX/46,XY	Testis and ovary or ovotestis	Variable	Variable	Gynecomastia
	Clinical Features				
	Possible increased risk of gonadal tumors				

congenital heart defects (CHDs) (30%) (bicuspid aortic valve, 30–50%; coarctation of the aorta, 30%; aortic root dilation, 5%), antibiotic prophylaxis for dental or surgical procedures, and serial magnetic resonance imaging (MRI) of aortic root dimensions, as progressive aortic root dilation is associated with increased risk of aortic dissection. Individuals found to have congenital renal and urinary tract malformations (30%) are at risk for urinary tract infections, hypertension, and nephrocalcinosis. Hypertension can occur independently of cardiac and renal malformations and should be monitored and treated as in other patients with essential hypertension. Regular assessment of thyroid function, weight, dentition, hearing, speech, vision, and educational issues should be performed during childhood. Counseling about long-term growth and fertility issues should be provided. Patient support groups are active throughout the world and can play an invaluable role.

Short stature is common, and untreated final height rarely exceeds 150 cm in nonmosaic 45,X TS. Recombinant growth hormone has been used in an attempt to increase growth, sometimes with oxandrolone in older children. Girls with evidence of ovarian insufficiency require estrogen replacement to induce breast and uterine development, support growth, and maintain bone mineralization. Most physicians now initiate low-dose estrogen therapy to induce puberty at an age-appropriate time (~11 years). Doses of estrogen are increased gradually to allow development over a 2- to 4-year period. Progestins are added later to regulate withdrawal bleeds. A very small percentage of women with TS have had spontaneous pregnancy, whereas others have achieved successful pregnancy after ovum donation and in vitro fertilization, but the risks of cardiac complications are high, and expert counseling and management are needed. Long-term follow-up of women with TS includes careful surveillance of sex hormone replacement and reproductive function, bone mineralization, cardiac function and aortic root dimensions, blood pressure, weight and glucose tolerance, hepatic and lipid profiles, thyroid function, skin examination, and hearing. This service is provided by a dedicated TS clinic in some centers.

45,X/46,XY MOSAICISM

The phenotype of individuals with 45,X/46,XY mosaicism (sometimes called *mixed gonadal dysgenesis*) can vary considerably. Some have a predominantly female phenotype (see TS above). Most 45,X/46,XY individuals have a male phenotype and testes, and the diagnosis is made incidentally after amniocentesis or during investigation of infertility. In practice, most newborns referred for assessment have atypical genitalia and variable somatic features. There is often marked asymmetry, with a streak gonad and hemiuterus on one side and a partially descended dysgenetic testis and hemiscrotum on the other side. Many children are raised as boys, but in some children, sex designation (whether to raise the baby as male or female) must be decided by parents and the multidisciplinary team. In these children, gender identity may be harder to predict. There is an increased risk of germ cell cancer (GCC), up to 35% in intraabdominal gonads, so prophylactic removal of intraabdominal gonads is usually considered. Individuals raised as males often have reconstructive surgery for hypospadias and removal of dysgenetic or streak gonads if the gonads cannot be brought down into the scrotum. Scrotal testes can be preserved but require regular examination for tumor development and sonography at the time of puberty. Biopsy for carcinoma in situ is recommended in adolescence, and testosterone supplementation may be required to support androgenization in puberty or if low testosterone is detected in adulthood. As 45,X/46,XY mosaicism can be associated with other features (e.g., cardiac, renal), individuals should be monitored according to TS guidelines. Infertility is typical, but non-azoospermia or focal spermatogenesis has been reported, highlighting the importance of individualized approaches to management.

OVOTESTICULAR DSD

Ovotesticular DSD (OTDSD) is a condition in which an individual has both ovarian and testicular tissue, either by having both an ovary and a testis or by having an ovotestis. Most individuals with this diagnosis have a 46,XX karyotype (especially in individuals of African ancestry), although 46,XX/46,XY chimerism and rarely a 46,XY karyotype is also possible. OTDSD usually presents with atypical genitalia at birth

and sometimes breast development, cyclical hematuria, and/or phallic development at puberty. Progressive regression of the ovarian and/or testicular component can occur over time. Gender identity varies in OTDSD but often aligns with assigned sex. Risk of GCC is also elevated in OTDSD (~3%) and may occur in the ovarian or testicular component. Infertility is typical (especially in 46,XX testes with no Y chromosome), but births have occurred via ovum or sperm from individuals with other forms of OTDSD.

DISORDERS OF GONADAL AND PHENOTYPIC SEX

Disorders of gonadal and phenotypic sex can result in reduced androgen production or action in individuals with a 46,XY karyotype (46,XY DSD) or excess androgen production in individuals with a 46,XX karyotype (46,XX DSD) (Table 390-1). These conditions cover a spectrum of phenotypes ranging from phenotypic females with a Y chromosome to phenotypic males with a 46,XX karyotype to individuals with atypical genitalia. Karyotype is a useful starting investigation for diagnosis but does not define an individual's gender.

46,XY DSD

Underandrogenization of the 46,XY fetus reflects defects in androgen production or action. It can result from disorders of testis development, defects of androgen synthesis, or resistance to testosterone and DHT (Table 390-1).

Disorders of Testis Development • TESTICULAR DYSGENESIS *Complete gonadal dysgenesis* (CGD, *Swyer's syndrome*) is associated with streak gonads, müllerian structures (due to insufficient AMH/MIS secretion), and a complete absence of androgenization. Phenotypic females with this condition often present because of absent pubertal development and are found to have a 46,XY karyotype. Serum sex steroids, AMH/MIS, and inhibin B are low, and LH and FSH are elevated. Individuals with CGD typically identify as female. The risk of GCC is high, and intraabdominal gonads should be removed. In contrast, patients with *partial gonadal dysgenesis* (PGD, *dysgenetic testes*) may produce enough MIS to regress the uterus and sufficient testosterone for partial androgenization and, therefore, usually present in the newborn period with atypical genitalia, highlighting the spectrum of features that are typically seen with many DSDs.

Testicular dysgenesis can result from disruption of testis-promoting genes (e.g., *WT1*, *SF1*, *SRY*, *SOX9*, *MAP3K1*, *DHH*, *DHX37*, and others) or, rarely, duplication of chromosomal loci containing "antitestis" genes (e.g., *DAX1*) **(Table 390-4)**. Among these, deletions or mutations of *SRY* and heterozygous mutations of *SF1* (*NR5A1*) or *DHX37* appear to be most common but still account collectively for <30% of cases. Associated clinical features may be present, reflecting additional functional roles for these genes. For example, renal dysfunction occurs in patients with specific *WT1* mutations (Denys-Drash and Frasier's syndromes), primary adrenal insufficiency occurs in a minority of patients with disruption of *SF1*, and severe cartilage abnormalities (campomelic dysplasia) are the predominant clinical feature of pathogenic variants in *SOX9*. A family history of DSD, hypospadias, infertility, or early menopause is important because variations in some genes (e.g., *SF1*/*NR5A1*, *SOX8*) can be associated with a range of reproductive phenotypes. *SF1* variants are sometimes inherited from a mother in a sex-limited dominant manner (which can mimic X-linked inheritance), and a woman may later develop primary ovarian insufficiency because of the effect of *SF1* on the ovary. Gender identity can be variable in PGD. Dysgenetic testes have an increased risk of GCC. For descended testes, monitoring via physical examination is appropriate. If testes are intraabdominal and not able to be brought down, they may be removed to prevent GCC (risk up to 35% if intraabdominal). Dysgenetic testes may or may not produce sufficient testosterone for puberty. In those who identify as male, testosterone replacement may be needed. In those who identify as female, estrogen replacement will be needed for female-typical pubertal development and ongoing sex steroid requirements. *Absent (vanishing) testis syndrome* (*bilateral anorchia*) reflects regression of the testis during development. The absence of müllerian structures indicates adequate secretion of AMH early in utero. Usually, androgenization of the external genitalia is normal. The etiology is often unknown but sometimes associated with pathogenic variants in *DHX37*. These individuals can be offered testicular prostheses and androgen replacement in adolescence and typically identify as male.

Disorders of Androgen Synthesis Defects in the pathway that regulates androgen synthesis **(Fig. 390-4)** cause underandrogenization of the 46,XY fetus (Table 390-1). Müllerian regression is unaffected because Sertoli cell function is preserved, and no uterus is found. These conditions can present with a spectrum of genital appearances, ranging from female-typical external genitalia or clitoromegaly in some individuals to penoscrotal hypospadias or a small phallus in others.

LH RECEPTOR Mutations in the LH receptor (LHCGR) cause Leydig cell hypoplasia and androgen deficiency, due to impaired actions of human chorionic gonadotropin in utero and LH late in gestation and during the neonatal period. As a result, testosterone and DHT synthesis are reduced.

STEROIDOGENIC ENZYME PATHWAYS Mutations in *steroidogenic acute regulatory protein* (*StAR*) and *CYP11A1* affect both adrenal and gonadal steroidogenesis (Fig. 390-4) **(Chap. 386)**. Affected individuals (46,XY) usually have severe early-onset salt-losing adrenal failure and a female phenotype, although later-onset milder variants are increasingly reported. Defects in *3β-hydroxysteroid dehydrogenase type 2* (*HSD3B2*) also cause adrenal insufficiency in severe cases, but the accumulation of dehydroepiandrosterone (DHEA) has a mild androgenizing effect, resulting in atypical genitalia or hypospadias. Salt loss occurs in many but not all children. Patients with CAH due to *17α-hydroxylase (CYP17A1) deficiency* have variable underandrogenization and develop hypertension and hypokalemia due to the potent salt-retaining effects of corticosterone and 11-deoxycorticosterone. Patients with complete loss of 17α-hydroxylase function often present as phenotypic females who do not enter puberty and are found to have inguinal testes and hypertension in adolescence. Some mutations in *CYP17* selectively impair 17,20-lyase activity without altering 17α-hydroxylase activity, leading to underandrogenization without mineralocorticoid excess and hypertension. Disruption of the coenzyme, *cytochrome b5* (*CYB5A*), can present similarly, and methemoglobinemia is usually present. Mutations in *P450 oxidoreductase* (*POR*) affect multiple steroidogenic enzymes, leading to reduced androgen production and a biochemical pattern of apparent combined 21-hydroxylase and 17α-hydroxylase deficiency, sometimes with skeletal abnormalities (Antley-Bixler craniosynostosis). Defects in *17β-hydroxysteroid dehydrogenase type 3* (*HSD17B3*) and *5α-reductase type 2* (*SRD5A2*) interfere with the synthesis of testosterone and DHT, respectively. These conditions are characterized by minimal or absent androgenization in utero, but some phallic development can occur during adolescence due to the action of other enzyme isoforms. Individuals with 5α-reductase type 2 deficiency have normal wolffian structures and usually do not develop breast tissue. At puberty, the increase in testosterone induces muscle mass and other virilizing features despite DHT deficiency. DHT gel can improve prepubertal phallic growth in patients raised as male. Prevention of testosterone exposure (by gonadectomy or pubertal suppression) in adolescence and estrogen replacement at puberty can be considered in individuals who identify as female. Disruption of alternative pathways to fetal DHT production might also present with 46,XY DSD (*AKR1C2*/*AKR1C4*).

Disorders of Androgen Action • ANDROGEN INSENSITIVITY SYNDROME Pathogenic variants in the androgen receptor cause resistance to androgen (testosterone, DHT) action or the *androgen insensitivity syndrome* (*AIS*). AIS is a spectrum of disorders that affects at least 1 in 100,000 46,XY individuals. Because the androgen receptor is X-linked, only 46,XY offspring are affected. The condition is usually inherited from a mother who carries the sequence variant but can also arise de novo. XY individuals with *complete AIS* (formerly called *testicular feminization syndrome*) have a female phenotype, normal breast development (due to aromatization of testosterone), a short vagina but no uterus (because AMH/MIS production is normal), scanty pubic

TABLE 390-4 Selected Genetic Causes of 46,XY Disorders of Sex Development (DSDs)

GENE	INHERITANCE	GONAD	UTERUS	EXTERNAL GENITALIA	ASSOCIATED FEATURES
Disorders of Testis Development					
WT1	AD	Dysgenetic testis	+/–	Female or ambiguous	Wilms' tumor, renal abnormalities, gonadal tumors (WAGR, Denys-Drash and Frasier's syndromes)
SF1/NR5A1	AR/AD (SL)	Dysgenetic testis/Leydig dysfunction	+/–	Female, ambiguous or male	Primary adrenal failure (rare); hyposplenia (rare); primary ovarian insufficiency in female (46,XX) relatives
SRY	Y	Dysgenetic testis or ovotestis	+/–	Female or ambiguous	
SOX9	AD	Dysgenetic testis or ovotestis	+/–	Female or ambiguous	Campomelic dysplasia
MAP3K1	AD (SL)	Dysgenetic testis	+/–	Female or ambiguous	
DHX37	AD	Dysgenetic testis	+/–	Female, ambiguous or male	Testicular regression syndrome
DHH	AR	Dysgenetic testis/Leydig dysfunction	+	Female	Minifascicular neuropathy
Other causes of testicular dysgenesis include: *DMRT1, CBX2, SOX8, ZNRF3, GATA4,* and *ZFPM2* (congenital heart disease); *ARX* (X-linked lissencephaly); *TSPYL1* (sudden infant death); *MYRF* (diaphragmatic hernia); *ESR2/NR3A2, SAMD9* (MIRAGE syndrome); *MAMLD1*, dupXp21, dup1p35, del9p24, del10q23					
Disorders of Androgen Synthesis					
LHCGR	AR	Testis	–	Female, ambiguous or micropenis	Leydig cell hypoplasia
DHCR7	AR	Testis	–	Variable	Smith-Lemli-Opitz syndrome: coarse facies, second-third toe syndactyly, failure to thrive, developmental delay, cardiac and visceral abnormalities
STAR	AR	Testis	–	Female or ambiguous	Congenital lipoid adrenal hyperplasia (primary adrenal insufficiency)
CYP11A1	AR	Testis	–	Female or ambiguous	Primary adrenal insufficiency
HSD3B2	AR	Testis	–	Ambiguous	CAH, primary adrenal insufficiency ± salt loss, partial androgenization due to ↑ DHEA
CYP17A1	AR	Testis	–	Female or ambiguous	CAH, hypertension due to ↑ corticosterone and 11-deoxycorticosterone, except in isolated 17,20-lyase deficiency
CYB5A	AR	Testis	–	Ambiguous	Apparent isolated 17,20-lyase deficiency; methemoglobinemia
POR	AR	Testis	–	Ambiguous or male	Mixed features of 21-hydroxylase deficiency and 17α-hydroxylase/17,20-lyase deficiency, sometimes associated with Antley-Bixler craniosynostosis
HSD17B3	AR	Testis	–	Female or ambiguous	Partial androgenization at puberty, ↑ androstenedione-to-testosterone ratio
SRD5A2	AR	Testis	–	Ambiguous or micropenis	Partial androgenization at puberty, ↑ testosterone-to-dihydrotestosterone ratio
AKR1C2 (*AKR1C4*)	AR	Testis	–	Female or ambiguous	Decreased fetal DHT production
Disorders of Androgen Action					
Androgen receptor	X	Testis	–	Female, ambiguous, micropenis or normal male	Phenotypic spectrum from complete androgen insensitivity syndrome (female external genitalia) and partial androgen insensitivity (ambiguous) to normal male genitalia and infertility

Abbreviations: AD, autosomal dominant; *AKR1C2,* aldo-keto reductase family 1 member 2; AR, autosomal recessive; *ARX,* aristaless related homeobox, X-linked; CAH, congenital adrenal hyperplasia; *CBX2,* chromobox homologue 2; *CYB5A,* cytochrome b5; *CYP11A1,* P450 cholesterol side-chain cleavage; *CYP17A1,* cytochrome P450 family 17 subfamily A member 1; *DAX1,* dosage sensitive sex-reversal, adrenal hypoplasia congenita on the X chromosome, gene 1; DHEA, dehydroepiandrosterone; *DHCR7,* sterol 7 δ reductase; *DHH,* desert hedgehog; *DMRT1,*doublesex and mab3-related transcription factor 1; *GATA4,* GATA binding protein 4; *HSD17B3,* 17β-hydroxysteroid dehydrogenase type 3; *HSD3B2,* 3β-hydroxysteroid dehydrogenase type 2; *LHR,* LH receptor; *MAP3K1,* mitogen-activated protein kinase kinase kinase 1; MIRAGE, myelodysplasia, infection, restriction of growth, adrenal hypoplasia, genital phenotypes, and enteropathy; *MYRF,* myelin regulatory factor; POR, P450 oxidoreductase; *SF1,* steroidogenic factor 1; SL, sex-limited; *SOX8, SRY*-related HMG-box gene 8; *SOX9, SRY*-related HMG-box gene 9; *SRD5A2,* 5α-reductase type 2; *SRY,* sex-related gene on the Y chromosome; *StAR,* steroidogenic acute regulatory protein; *TSPYL1,* testis-specific Y-encoded-like protein 1; WAGR, Wilms' tumor, aniridia, genitourinary anomalies, and mental retardation; *WNT4,* wingless-type mouse mammary tumor virus integration site, 4; *WT1,* Wilms' tumor–related gene 1; *ZFPM2,* zinc finger protein, multitype 2; *ZNRF3,* zinc and ring finger 3.

and axillary hair, and typically a female gender identity and sex role behavior. Gonadotropins and testosterone levels can be low, normal, or elevated, depending on the degree of androgen resistance and the contribution of estradiol to feedback inhibition of the hypothalamic-pituitary-gonadal axis. AMH/MIS levels in childhood are normal or high. CAIS sometimes presents as inguinal hernias (containing testes) in childhood or more often with primary amenorrhea in late adolescence. In the past, gonadectomy was recommended in childhood, but due to the low risk of malignancy (~2%), increasingly this is delayed, and gonads are left in situ until breast development is complete. Subsequently, the adolescent or young adult should be counseled about the risk of malignancy and the option for gonadectomy (with estrogen replacement), especially because early detection of premalignant changes by imaging or biomarkers is currently not possible. The use of graded dilators in adolescence is often sufficient to dilate the vagina for sexual activity.

Partial AIS (*Reifenstein's syndrome*) results from androgen receptor mutations that maintain residual function. Patients often present in infancy with penoscrotal hypospadias and undescended testes and with gynecomastia at the time of puberty. Gender identity can be variable. At puberty, testes produce testosterone with variable phenotypic development. For those who identify as male, high-dose testosterone has been given to support development if puberty does not progress, but long-term data are limited. For those raised as female, testosterone

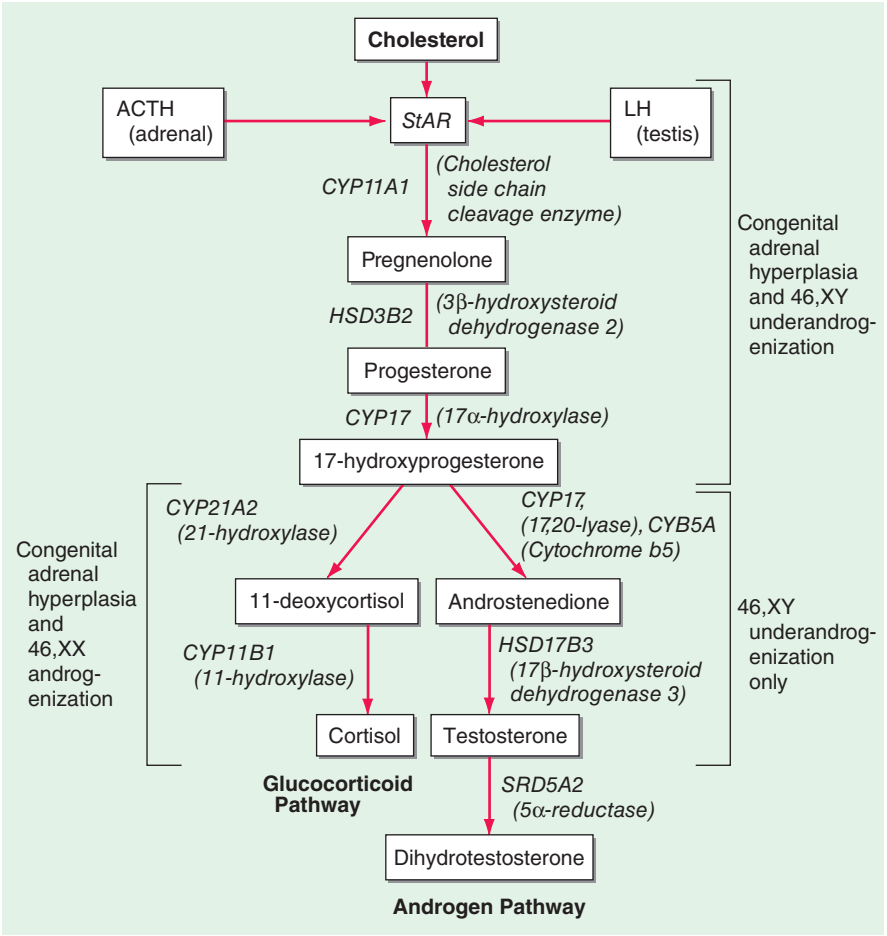

FIGURE 390-4 Simplified overview of glucocorticoid and androgen synthesis pathways. Defects in *CYP21A2* and *CYP11B1* shunt steroid precursors into the androgen pathway and cause androgenization of the 46,XX fetus. Testosterone is synthesized in the testicular Leydig cells and converted to dihydrotestosterone peripherally. Defects in enzymes involved in androgen synthesis result in underandrogenization of the 46,XY fetus. *StAR*, steroidogenic acute regulatory protein.

effects at puberty can be prevented (by gonadectomy or pubertal suppression) and female-typical puberty induced with estrogen. They also have an increased risk of GCC, again raising the question of if and when to perform gonadectomy. *Azoospermia* and male-factor infertility also have been described in association with mild loss-of-function mutations in the androgen receptor.

OTHER DISORDERS AFFECTING 46,XY MALES

Persistent müllerian duct syndrome is the presence of a uterus in an otherwise phenotypic male. This condition can result from pathogenic variants in AMH or its receptor (AMHR2). The uterus may be removed, but only if damage to the vasa deferentia and blood supply to the testes can be avoided. *Isolated hypospadias* occurs in ~1 in 250 males. Most cases are idiopathic, although evidence of penoscrotal hypospadias, poor phallic development, and/or bilateral cryptorchidism requires investigation for an underlying DSD (e.g., partial gonadal dysgenesis, mild defect in testosterone action, or even severe forms of 46,XX CAH). Unilateral undescended testes (cryptorchidism) affect >3% of boys at birth. Orchidopexy should be considered if the testis has not descended by 6–9 months of age. Bilateral cryptorchidism occurs less frequently and should raise suspicion of gonadotropin deficiency or DSD. *Syndromic associations* and *intrauterine growth retardation* also occur relatively frequently in association with impaired testicular function or target tissue responsiveness, but the underlying etiology of many of these conditions is unknown.

46,XX DSD

Androgenization of the 46,XX fetus occurs when the gonad (ovary) contains androgen-secreting testicular tissue or after increased androgen exposure, which is usually adrenal in origin (Table 390-1).

46,XX Testicular DSD Testicular tissue can develop in 46,XX testicular DSD (46,XX males) most often following translocation of *SRY*. This may be diagnosed with karyotype/phenotype discordance or later in life during evaluation for hypogonadism or infertility. Individuals with this condition develop testes with normal testosterone production, leading to external male phenotype in utero, and produce AMH/MIS to regress müllerian structures. They have azoospermia due to lack of the AZF region of the Y chromosome. Progressive testicular regression and hypogonadism are common. Gender identity is typically male.

46,XX OTDSD Ovotestes (or testes) can also develop in individuals with a 46,XX karyotype following upregulation of *SOX9* or *SOX3* or defects in *RSPO1*, *NR2F2*, *WT1*, or *SF1*/*NR5A1* (Table 390-5). OTDSD is discussed above under "Disorders of Chromosomal Sex."

Increased Androgen Exposure • 21-HYDROXYLASE DEFICIENCY (CONGENITAL ADRENAL HYPERPLASIA) The *classic form* of 21-hydroxylase deficiency (21-OHD) is the most common cause of CAH (Chap. 386), and it is the most common cause of androgenization in chromosomal 46,XX females (incidence between 1 in 10,000 and 1 in 15,000) (Table 390-5). Affected individuals are homozygous or compound heterozygous for severely disruptive sequence variants in the gene (*CYP21A2*) encoding the enzyme 21-hydroxylase. Impaired 21-hydroxylase activity prevents adrenal glucocorticoid and mineralocorticoid synthesis, thus shunting steroid precursors into the androgen synthesis pathway (Fig. 390-4). Increased androgen synthesis in utero causes androgenization of the 46,XX fetus in the first trimester. Atypical genitalia are seen at birth, with varying degrees of clitoral enlargement and labial fusion.

A salt-wasting crisis usually manifests between 5 and 21 days of life and is a potentially life-threatening event that requires urgent fluid resuscitation and steroid treatment. Thus, a diagnosis of 21-OHD should be considered in any baby with atypical genitalia with bilateral nonpalpable gonads. Males (46,XY) with 21-OHD have no genital abnormalities at birth but are equally susceptible to adrenal insufficiency and salt-losing crises. Excess androgen production can cause gonadotropin-independent precocious puberty in males with 21-OHD.

Patients with *nonclassic 21-OHD* produce normal amounts of cortisol and aldosterone but at the expense of producing excess androgens. Symptoms may include hirsutism, menstrual dysfunction, subfertility, and recurrent miscarriages. This is one of the most common recessive disorders in humans, with an incidence as high as 1 in 100–500 in many populations and 1 in 27 in Ashkenazi Jews of Eastern European origin.

TREATMENT

Congenital Adrenal Hyperplasia

Acute salt-wasting crises require fluid resuscitation, IV hydrocortisone, and correction of hypoglycemia. Once the patient is stabilized, glucocorticoids must be given to correct the cortisol insufficiency and suppress ACTH stimulation, thereby preventing further virilization, rapid skeletal maturation, adrenal rest tumor formation, and the development of polycystic ovaries. Mineralocorticoid replacement may be needed, along with salt supplements in early life. In childhood, treatment is also titrated carefully to prevent

TABLE 390-5 Selected Genetic Causes of 46,XX Disorders of Sex Development (DSDs)

GENE	INHERITANCE	GONAD	UTERUS	EXTERNAL GENITALIA	ASSOCIATED FEATURES
Testicular/Ovotesticular DSD					
SRY	Translocation	Testis or ovotestis	–	Male or ambiguous	
SOX9	dup17q24	Testis or ovotestis	–	Male or ambiguous	
SF1/NR5A1 (codon 92)	AD	Testis or ovotestis	+/–	Male or ambiguous	
WT1 (zinc finger 4)	AD	Testis or ovotestis	+/–	Male or ambiguous	
Other causes of testicular/ovotesticular DSD include: *COUP-TF2/NR2F2* (congenital heart disease), *RSPO1* (palmar plantar hyperkeratosis, squamous cell skin carcinoma), *WNT4* (SERKAL syndrome), dysregulation/duplication of SOX3 (Xq27)					
Increased Androgen Synthesis					
HSD3B2	AR	Ovary	+	Clitoromegaly	CAH, primary adrenal insufficiency, mild androgenization due to ↑ DHEA
CYP21A2	AR	Ovary	+	Ambiguous	CAH, phenotypic spectrum from severe salt-losing forms associated with adrenal insufficiency to simple virilizing forms with compensated adrenal function, ↑ 17-hydroxyprogesterone
POR	AR	Ovary	+	Ambiguous or female	Mixed features of 21-hydroxylase deficiency and 17α-hydroxylase/17,20-lyase deficiency, sometimes associated with Antley-Bixler craniosynostosis
CYP11B1	AR	Ovary	+	Ambiguous	CAH, hypertension due to ↑ 11-deoxycorticosterone
CYP19	AR	Ovary	+	Ambiguous	Maternal virilization during pregnancy, absent breast development at puberty

Abbreviations: ACTH, adrenocorticotropin; AD, autosomal dominant; AR, autosomal recessive; CAH, congenital adrenal hyperplasia; *COUP-TF2,* chicken ovalbumin upstream promoter transcription factor 2; *CYP11B1,* 11β-hydroxylase; *CYP19,* aromatase; *CYP21A2,* 21-hydroxylase; DHEA, dehydroepiandrosterone; *HSD3B2,* 3β-hydroxysteroid dehydrogenase type 2; *POR,* P450 oxidoreductase; *RSPO1,* R-spondin 1; SERKAL, sex reversion, kidneys, adrenal and lung dysgenesis; *SF1,* steroidogenic factor 1; *SOX3, SRY*-related HMG-box gene 3; *SOX9, SRY*-related HMG-box gene 9; *SRY,* sex-related gene on the Y chromosome; *WT1,* Wilms' tumor–related gene 1.

impairment of linear growth. In the future, different forms of glucocorticoid replacement and multimodal therapies may improve treatment options. **See Chap. 386 for detailed discussion of hormone replacement.**

Individuals with 46,XX CAH due to classic 21-OHD historically underwent genitoplasty in infancy, but if and when these procedures should be performed is debated. Concerns have arisen about the importance of assent/consent by the individual for genital surgery, potential long-term side effects related to sexual function and ability to achieve orgasm, and the increased incidence of nonfemale gender identity. Surgical options include vaginoplasty and clitoroplasty. When vaginoplasty is performed in infancy, surgical revision or vaginal dilation may still be needed in adolescence or adulthood and, if deferred, may be necessary for menstrual flow or intercourse. Current clinical practice guidelines recommend that parents be informed of all surgical options including the option to defer surgery. Women with 21-OHD frequently develop polycystic ovaries and have subfertility. The latter occurs due to multiple factors including anatomic barriers, hormone imbalances, and psychological effects of the condition. Preconception genetic counseling is recommended. Due to concerns about fetal neurologic development, prenatal treatment with dexamethasone to prevent androgenization of a fetus is currently not recommended unless in a study protocol that allows long-term follow-up of all children treated.

The treatment of other forms of CAH (including in 46,XY individuals) includes mineralocorticoid and glucocorticoid replacement for salt-losing conditions (e.g., *StAR*, *CYP11A1*, *HSD3B2*), suppression of ACTH drive with glucocorticoids in disorders associated with hypertension (e.g., *CYP11B1*), and appropriate sex hormone replacement in adolescence and adulthood, when necessary.

OTHER CAUSES Increased androgen synthesis can also occur in CAH due to defects in *POR*, *11β-hydroxylase* (*CYP11B1*), and *3β-hydroxysteroid dehydrogenase type 2* (*HSD3B2*) and with mutations in the genes encoding *aromatase* (*CYP19*). Increased androgen exposure in utero can occur with maternal virilizing tumors, luteomas, and ingestion of androgenic compounds.

OTHER DISORDERS AFFECTING 46,XX FEMALES

Congenital absence of the vagina occurs in association with *müllerian agenesis* or *hypoplasia* as part of the Mayer-Rokitansky-Kuster-Hauser (MRKH) syndrome. This diagnosis should be considered in otherwise phenotypic females with primary amenorrhea. Associated features include renal (agenesis) and cervical spinal abnormalities.

GLOBAL CONSIDERATIONS

The approach to a child or adolescent with atypical genitalia or another DSD requires cultural sensitivity, as the concepts of sex and gender vary widely around the world. Rare genetic DSDs can occur more frequently in specific populations (e.g., *5α-reductase type 2* in the Dominican Republic). Different forms of CAH also show ethnic and geographic variability. In many countries, appropriate biochemical tests may not be readily available, and access to appropriate forms of treatment and support may be limited.

391 Disorders of the Testes and Male Reproductive System

Shalender Bhasin, J. Larry Jameson

The male reproductive system regulates sex differentiation, androgenization, and the hormonal changes that accompany puberty, ultimately leading to spermatogenesis and fertility. Under the control of the pituitary hormones—luteinizing hormone (LH) and follicle-stimulating hormone (FSH)—the Leydig cells of the testes produce testosterone and germ cells are nurtured by Sertoli cells to divide, differentiate, and mature into sperm. During embryonic development, testosterone and dihydrotestosterone (DHT) induce the wolffian duct and virilization of the external genitalia. During puberty, testosterone promotes somatic growth and the development of secondary sex characteristics. In the adult, testosterone is necessary for spermatogenesis, libido and normal sexual function, and maintenance of muscle and bone mass. This chapter focuses on the physiology of the testes and disorders associated with decreased androgen production, which may be caused by gonadotropin deficiency or by primary testis dysfunction. Infertility occurs in ~5% of men and is increasingly amenable to treatment by hormone replacement or by using sperm transfer techniques. **For further discussion of sexual dysfunction, disorders of the prostate, and testicular cancer, see Chaps. 397, 87, and 88, respectively.**

DEVELOPMENT AND STRUCTURE OF THE TESTIS

The fetal testis develops from a single bipotential progenitor cell population in the undifferentiated gonad after expression of a genetic cascade that is initiated by the gene encoding SRY (sex-related gene on the Y chromosome) **(Chap. 390)**. SRY, whose expression is regulated by histone modification and DNA methylation, induces differentiation of Sertoli cells, which surround germ cells and, together with peritubular myoid cells, form testis cords that will later develop into seminiferous tubules. Fetal Leydig cells and endothelial cells migrate into the gonad from the adjacent mesonephros but may also arise from interstitial cells that reside between testis cords. Fetal Leydig cells atrophy after birth and do not contribute to the origin of adult Leydig cells, which originate from undifferentiated progenitor cells that appear in the testis after birth and acquire full steroidogenic function during puberty. Testosterone produced by the fetal Leydig cells supports the growth and differentiation of Wolffian duct structures that develop into the epididymis, vas deferens, and seminal vesicles. Testosterone is also converted to DHT (see below), which induces formation of the prostate and the external male genitalia, including the penis, urethra, and scrotum. Testicular descent through the inguinal canal is controlled in part by Leydig cell production of insulin-like factor 3 (INSL3), which acts via a receptor termed *great* (*G* protein–coupled *re*ceptor *a*ffecting *t*estis descent). Sertoli cells produce Müllerian inhibiting substance (MIS), which causes regression of the Müllerian structures, including the fallopian tube, uterus, and upper segment of the vagina.

NORMAL MALE PUBERTAL DEVELOPMENT

Puberty commonly refers to the maturation of the reproductive axis and the development of secondary sex characteristics. In addition to reproductive hormones, it requires a coordinated response of multiple hormonal systems including metabolic signals (e.g., leptin), as well as the adrenal and growth hormone (GH) axes **(Fig. 391-1)**. The development of secondary sex characteristics is initiated by *adrenarche*, which usually occurs between 6 and 8 years of age when the adrenal gland begins to produce greater amounts of androgens from the zona reticularis, the principal site of dehydroepiandrosterone (DHEA) production. The sex maturation process is greatly accelerated by the activation of the hypothalamic-pituitary axis and the production of gonadotropin-releasing hormone (GnRH). The GnRH pulse generator in the hypothalamus

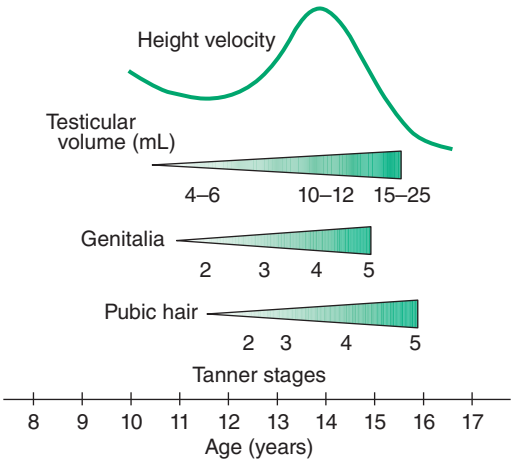

FIGURE 391-1 Pubertal events in males. Sexual maturity ratings for genitalia and pubic hair and divided into five stages.

is active during fetal life and early infancy but is restrained until the early stages of puberty by a neuroendocrine brake imposed by the inhibitory actions of glutamate and γ-aminobutyric acid (GABA) in the mediobasal hypothalamus and neuropeptide Y. Although the pathways that initiate reactivation of the GnRH pulse generator at the onset of puberty remain incompletely understood, mounting evidence supports involvement of GPR54, a G protein–coupled receptor that binds an endogenous ligand, kisspeptin. Individuals with mutations of GPR54 fail to enter puberty, and experiments in primates demonstrate that infusion of the ligand is sufficient to induce premature puberty. Kisspeptin signaling plays an important role in mediating the feedback action of sex steroids on gonadotropin secretion and in regulating the tempo of sexual maturation at puberty. Leptin, a hormone produced by adipose cells, plays a permissive role in the resurgence of GnRH secretion at the onset of puberty, as leptin-deficient individuals also fail to enter puberty **(Chap. 401)**. The adipocyte hormone leptin, the gut hormone ghrelin, neuropeptide Y, and kisspeptin integrate the signals originating in energy stores and metabolic tissues with mechanisms that control onset of puberty through regulation of GnRH secretion. Energy deficit and excess and metabolic stress are associated with disturbed reproductive maturation and timing of puberty.

The early stages of puberty are characterized by nocturnal surges of LH and FSH. Growth of the testes is usually the first clinical sign of puberty, reflecting an increase in seminiferous tubule volume. Increasing levels of testosterone deepen the voice and stimulate muscle growth. Conversion of testosterone to DHT leads to growth of the external genitalia and pubic hair. DHT also stimulates prostate and facial hair growth and initiates recession of the temporal hairline. The growth spurt occurs at a testicular volume of ~10–12 mL. GH increases early in puberty and is stimulated in part by the rise in gonadal steroids. GH increases the level of insulin-like growth factor 1 (IGF-1), which enhances linear bone growth. The prolonged pubertal exposure to gonadal steroids (mainly estradiol) ultimately induces epiphyseal closure and limits further bone growth.

REGULATION OF TESTICULAR FUNCTION

REGULATION OF THE HYPOTHALAMIC-PITUITARY-TESTIS AXIS IN ADULT MAN

Pulsatile secretion of GnRH in the hypothalamus is regulated by the KNDy neurons through the release of kisspeptin, neurokinin B (NKB), and dynorphin **(Fig. 391-2)**. Kisspeptin binds to the kisspeptin (GPR54) receptors in the cell bodies of the GnRH neurons as well as in the GnRH nerve terminals in the median eminence to induce pulsatile GnRH secretion into the portal blood. As a component of this autocrine/paracrine loop, NKB released by the KNDy neurons activates NK3R to stimulate kisspeptin release. KNDy neurons also produce dynorphin A, which inhibits basal as well as NKB-stimulated kisspeptin release through the mediation of K-type opioid receptor. The

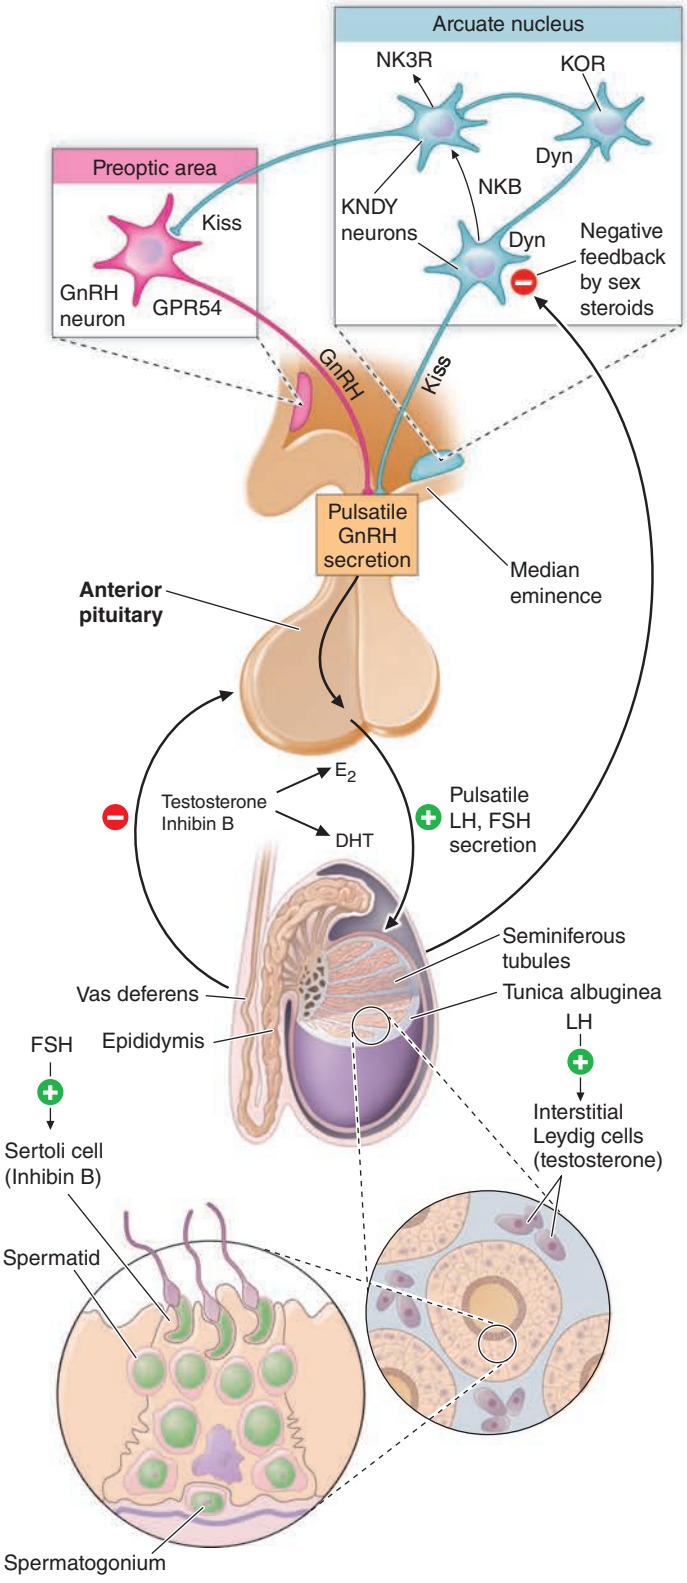

FIGURE 391-2 Hypothalamic-pituitary-gonadotropin axis, structure of testis, seminiferous tubule. DHT, dihydrotestosterone; Dyn, dynorphin A; E_2, 17β-estradiol; FSH, follicle-stimulation hormone; GnRH, gonadotropin-releasing hormone; GPR54, G protein–coupled receptor 54 for kisspeptin; Kiss, kisspeptin; KNDY, kisspeptin, neurokinin B, dynorphin neurons; LH, luteinizing hormone; NKB, neurokinin B; NK3R, neurokinin 3 receptor.

negative feedback effects of testosterone, estradiol, and progesterone are mediated through KNDy neurons in the preoptic area by inhibition of kisspeptin release.

Hypothalamic GnRH regulates the production of the pituitary gonadotropins LH and FSH (Fig. 391-2). GnRH is released in discrete pulses approximately every 2 h, resulting in corresponding pulses of LH and FSH. These dynamic hormone pulses account in part for the wide variations in LH and testosterone, even within the same individual. LH acts primarily on the Leydig cell to stimulate testosterone synthesis. The regulatory control of androgen synthesis is modulated by dynamic integration of the feedforward elements exerted on the testis by LH and FSH and the feedback exerted by testosterone and estrogen on both the hypothalamus and the pituitary. FSH acts on the Sertoli cell to regulate spermatogenesis and the production of Sertoli products such as inhibin B, which acts to selectively suppress pituitary FSH. Despite these somewhat distinct Leydig and Sertoli cell–regulated pathways, testis function is integrated at several levels: GnRH regulates both gonadotropins; spermatogenesis requires high levels of testosterone; and numerous paracrine interactions between Leydig and Sertoli cells are necessary for normal testis function.

THE LEYDIG CELL: ANDROGEN SYNTHESIS

LH binds to its seven-transmembrane G protein–coupled receptor to activate the cyclic AMP pathway. Stimulation of the LH receptor induces *st*eroid *a*cute *r*egulatory (StAR) protein, along with several steroidogenic enzymes involved in androgen synthesis. LH receptor mutations cause Leydig cell hypoplasia or agenesis, underscoring the importance of this pathway for Leydig cell development and function. The rate-limiting process in testosterone synthesis is the transport of intracellular cholesterol by the StAR protein to the inner mitochondrial membrane. Mutations of the StAR protein are associated with congenital lipoid adrenal hyperplasia, a rare form of congenital adrenal hyperplasia (CAH) characterized by very low adrenal and gonadal steroids. Peripheral benzodiazepine receptor, a mitochondrial cholesterol-binding protein, is also an acute regulator of Leydig cell steroidogenesis. The major enzymatic steps involved in testosterone synthesis are summarized in Fig. 391-3. After cholesterol transport into the mitochondrion, the formation of pregnenolone by CYP11A1 (side chain cleavage enzyme) is a limiting enzymatic step. The 17α-hydroxylase and the 17,20-lyase reactions are catalyzed by a single enzyme, CYP17A1; posttranslational modification (phosphorylation) of this enzyme and the presence of specific enzyme cofactors, such as cytochrome B, confer 17,20-lyase activity selectively in the testis and zona reticularis of the adrenal gland. Although CYP17A1 is able to catalyze the conversion of progesterone to 17α-hydroxyprogesterone, most of δ4-androstenedione in humans is not derived from 17α-hydroxyprogesterone but rather from the conversion of 17α-hydroxypregnenolone to DHEA in the δ5 pathway and further conversion of DHEA to δ4-androstenedione. Abiraterone is a dual inhibitor of 17α-hydroxylase and 17,20-lyase activities, which play an important role in androgen synthesis in castration-resistant prostate cancers. Testosterone can be converted to the more potent DHT by a family of steroid 5α-reductase enzymes, or it can be aromatized to estradiol by CYP19 (aromatase). At least two isoforms of steroid 5α-reductase, SRD5A1 and SRD5A2, have been described; all known patients with 5α-reductase deficiency have had mutations in SRD5A2, the predominant form in the prostate and the skin. Finasteride predominantly inhibits SRD5A2, whereas dutasteride is a dual inhibitor of both SRD5A1 and SRD5A2. DHT can also be derived through the backdoor pathway in which 17α-hydroxyprogesterone is converted to androsterone and eventually to DHT. Recent reports of mutations in the *AKR1C2/4* genes in undervirilized 46,XY individuals suggest that the backdoor pathway for DHT formation, which was originally described in the tammar wallaby, is active in the human fetal testis. The placental progesterone serves as a substrate for the synthesis of androsterone via the backdoor pathway, which is then converted to DHT in the genital tubercle.

Testosterone Transport and Metabolism In males, 95% of circulating testosterone is derived from testicular production (3–10 mg/d). Direct secretion of testosterone by the adrenal and the peripheral conversion of androstenedione to testosterone collectively account for another 0.5 mg/d of testosterone. Only a small amount of DHT (70 μg/d) is secreted directly by the testis; most circulating DHT is derived from peripheral conversion of testosterone. Most of the daily production of estradiol (~45 μg/d) in men is derived from aromatase-mediated peripheral conversion of testosterone and androstenedione.

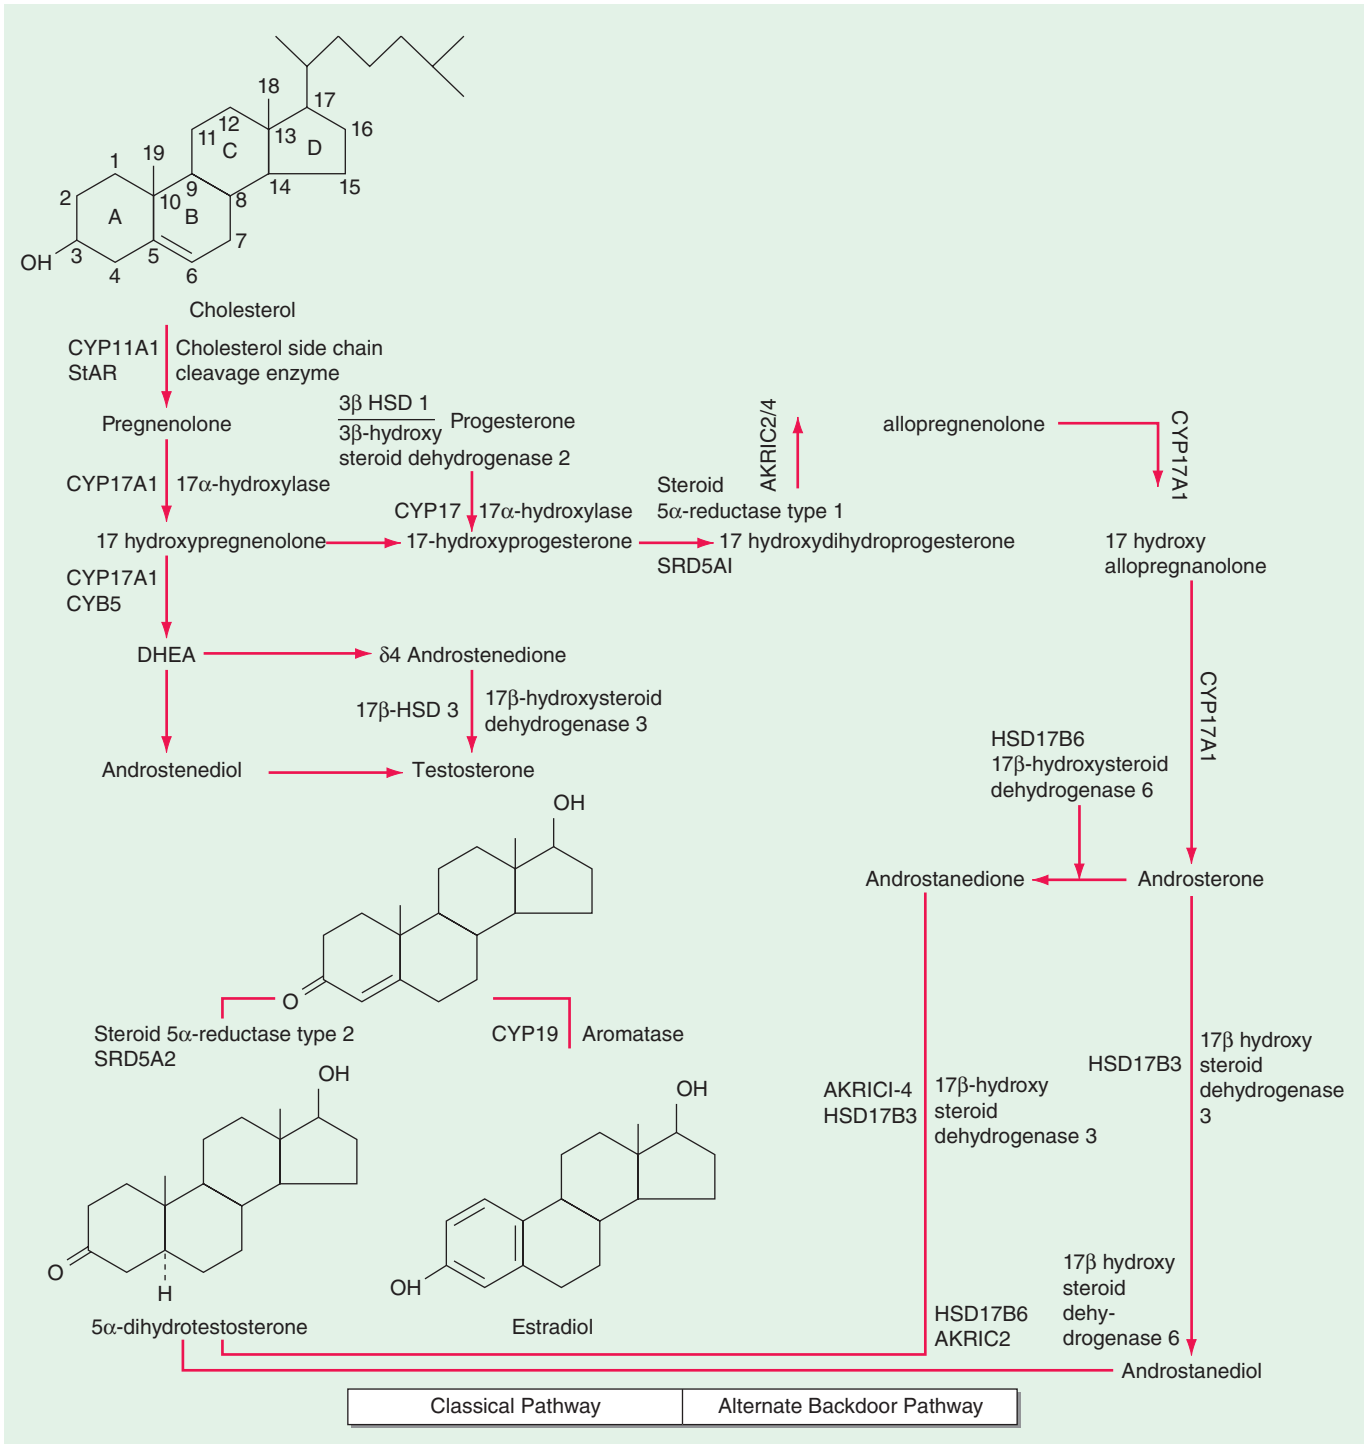

FIGURE 391-3 The biochemical pathway in the conversion of 27-carbon sterol cholesterol to androgens and estrogens.

Circulating testosterone is bound predominantly to sex hormone–binding globulin (SHBG) and albumin **(Fig. 391-4)** and, to a lesser extent, to cortisol-binding globulin (CBG) and orosomucoid. SHBG binds testosterone with much greater affinity than albumin, CBG, and orosomucoid. The binding proteins regulate the transport and bioavailability of testosterone. SHBG circulates as a dimer, and testosterone's binding to SHBG involves intermonomeric allostery such that neither the conformation nor the binding affinity of the two monomers is equivalent. Similarly, estradiol binding to SHBG involves bidirectional, intermonomeric allostery that changes the distribution of both monomers among various energy and conformational states. Intermonomeric allostery offers a mechanism to extend the binding range of SHBG and regulate hormone bioavailability as sex hormone concentrations vary widely during life. Human serum albumin (HSA) contains multiple, allosterically coupled binding sites for testosterone. Testosterone shares these binding sites on HSA with free fatty acids. Commonly used drugs such as ibuprofen and antibiotics can displace testosterone from HSA under various physiologic states or disease conditions, affecting its bioavailability. SHBG concentrations are decreased by androgens, obesity, diabetes mellitus, hypothyroidism, nephrotic syndrome, and genetic factors. Conversely, estrogen administration, hyperthyroidism, many chronic inflammatory illnesses, infections such as HIV or hepatitis B and C, aging, and the use of some anticonvulsants are associated with high SHBG concentrations.

Testosterone is metabolized predominantly in the liver, although some degradation occurs in peripheral tissues, particularly the prostate and the skin. In the liver, testosterone is converted by a series of enzymatic steps that involve 5α- and 5β-reductases, 3α- and 3β-hydroxysteroid dehydrogenases, and 17β-hydroxysteroid dehydrogenase into androsterone, etiocholanolone, DHT, and 3α-androstanediol.

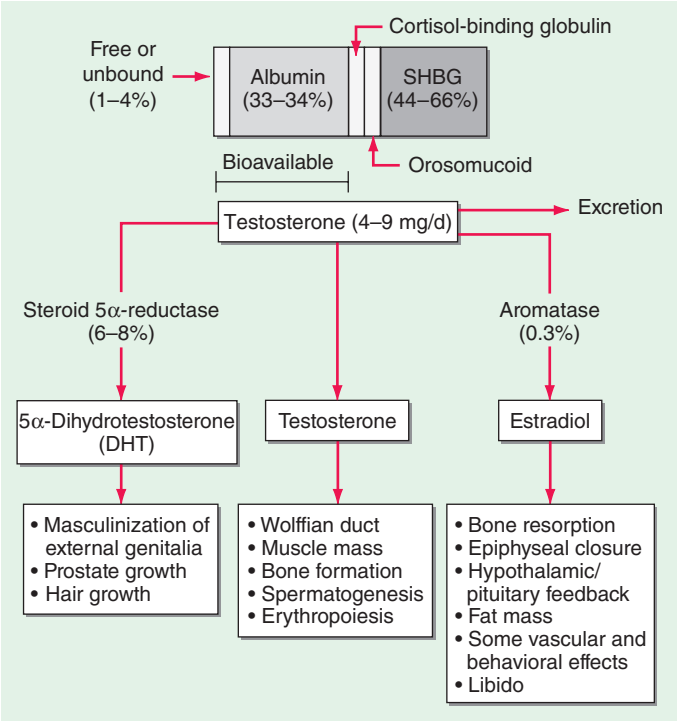

FIGURE 391-4 Androgen metabolism and actions. SHBG, sex hormone–binding globulin.

These compounds undergo glucuronidation or sulfation before being excreted by the kidneys.

Mechanism of Androgen Action Testosterone exerts some of its biologic effects by binding to androgen receptor (AR), either directly or after its conversion to DHT by the steroid 5α reductase. The actions of testosterone on the Wolffian structures, skeletal muscle, erythropoiesis, and bone in men do not require its obligatory conversion to DHT. However, the conversion of testosterone to DHT is necessary for the masculinization of the urogenital sinus and genital tubercle. Aromatization of testosterone to estradiol mediates additional effects of testosterone on bone resorption, epiphyseal closure, sexual desire, vascular endothelium, and fat. DHT can also be converted in some tissues by the combined actions of the 3α-hydroxysteroid dehydrogenase and 3β-hydroxysteroid dehydrogenase to 5α-androstane-3β,17β-diol, which is a high-affinity ligand and agonist of estrogen receptor β. 5α-DHT is further converted in some cell types to 5α-androstane-3α,17β-diol, a modulator of $GABA_A$ receptors.

The AR is structurally related to the nuclear receptors for estrogen, glucocorticoids, and progesterone **(Chap. 377)**. The AR, a 919–amino acid protein with a molecular mass of ~110 kDa, is encoded by a gene on the long arm of the X chromosome. A polymorphic region in the amino terminus of the receptor, which contains a variable number of glutamine and glycine repeats, modifies the transcriptional activity of the receptor. The AR protein is distributed in both the cytoplasm and the nucleus. The ligand binding to the AR induces conformational changes that allow the recruitment and assembly of tissue-specific cofactors and causes it to translocate into the nucleus, where it binds to specific androgen response elements in the DNA or other transcription factors already bound to DNA. Thus, the AR is a ligand-regulated transcription factor that regulates the expression of androgen-dependent genes in a tissue-specific manner. Testosterone binds to AR with half the affinity of DHT. The DHT-AR complex also has greater thermostability and a slower dissociation rate than the testosterone-AR complex. However, the molecular basis for selective testosterone versus DHT actions remains incompletely explained. Some androgen effects, such as those on the smooth muscle, may be mediated by nongenomic AR signal transduction pathways. The nongenomic actions of testosterone involve direct activation of kinase signaling cascades such as mitogen-activated protein kinase and the cyclic AMP response element binding protein transcription factor. Some effects of testosterone on cell proliferation and autophagy require the mediation of GPRC6A.

THE SEMINIFEROUS TUBULES: SPERMATOGENESIS

The seminiferous tubules are convoluted, closed loops with both ends emptying into the rete testis, a network of progressively larger efferent ducts that ultimately form the epididymis (Fig. 391-2). The seminiferous tubules total ~600 m in length and compose about two-thirds of testis volume. The walls of the tubules are formed by polarized Sertoli cells that are apposed to peritubular myoid cells. Tight junctions between Sertoli cells create the blood-testis barrier. Germ cells compose the majority of the seminiferous epithelium (~60%) and are intimately embedded within the cytoplasmic extensions of the Sertoli cells, which function as "nurse cells." Germ cells progress through characteristic stages of mitotic and meiotic divisions. A pool of type A spermatogonia serve as stem cells capable of self-renewal. Primary spermatocytes are derived from type B spermatogonia and undergo meiosis before progressing to spermatids that undergo spermiogenesis (a differentiation process involving chromatin condensation, acquisition of an acrosome, elongation of cytoplasm, and formation of a tail) and are released from Sertoli cells as mature spermatozoa. The complete differentiation process into mature sperm requires 74 days. Peristaltic-type action by peritubular myoid cells transports sperm into the efferent ducts. The spermatozoa spend an additional 21 days in the epididymis, where they undergo further maturation and capacitation. The normal adult testes produce >100 million sperm per day.

Naturally occurring mutations in FSHβ or in the FSH receptor confirm an important, but not essential, role for this pathway in spermatogenesis. Females with mutations in FSHβ or the FSH receptor are hypogonadal and infertile because ovarian follicles do not mature; males with these mutations exhibit variable degrees of reduced spermatogenesis, presumably because of impaired Sertoli cell function. Because Sertoli cells produce inhibin B, an inhibitor of FSH, seminiferous tubule damage (e.g., by radiation) causes a selective increase of FSH. Testosterone reaches very high concentrations locally in the testis and is essential for spermatogenesis. The cooperative actions of FSH and testosterone are important in the progression of meiosis and spermiation. In the prepubertal testis, testosterone alone is insufficient for completion of spermatogenesis; however, in men with postpubertal onset of gonadotropin deficiency, human chorionic gonadotropin (hCG) or recombinant LH can reinitiate spermatogenesis without FSH. FSH and testosterone regulate germ cell survival via the intrinsic and extrinsic apoptotic mechanisms. FSH may also play an important role in supporting spermatogonia. Gonadotropin-regulated testicular RNA helicase (GRTH/DDX25), a testis-specific gonadotropin/androgen-regulated RNA helicase, is present in germ cells and Leydig cells and may be an important factor in the paracrine regulation of germ cell development. Several cytokines and growth factors are also involved in the regulation of spermatogenesis by paracrine and autocrine mechanisms. A number of knockout mouse models exhibit impaired germ cell development or spermatogenesis, presaging possible mutations associated with male infertility.

The human Y chromosome contains two pseudoautosomal regions that are located at the two tips of Y chromosome and can recombine with homologous regions of the X chromosome **(Fig. 391-5)**. The genes in the pseudoautosomal regions are involved in cell signaling, transcriptional regulation, and mitochondrial function. Mutations of genes in pseudoautosomal region 1 are associated with mental disorders and short stature. The euchromatic part of the Y chromosome that does not recombine with the X chromosome is referred to as the male-specific region of the Y chromosome (MSY). The MSY contains nine families of Y-specific multicopy genes; many of these Y-specific genes are also testis-specific and necessary for spermatogenesis. Microdeletions in several nonoverlapping subregions of the Y chromosome—AZFa, AZFb, AZFc, and AZFd, which contain many spermatogenic genes (e.g., RNA-binding motif, *RBM*; deleted in azoospermia, *DAZ*)—are associated with oligospermia or azoospermia.

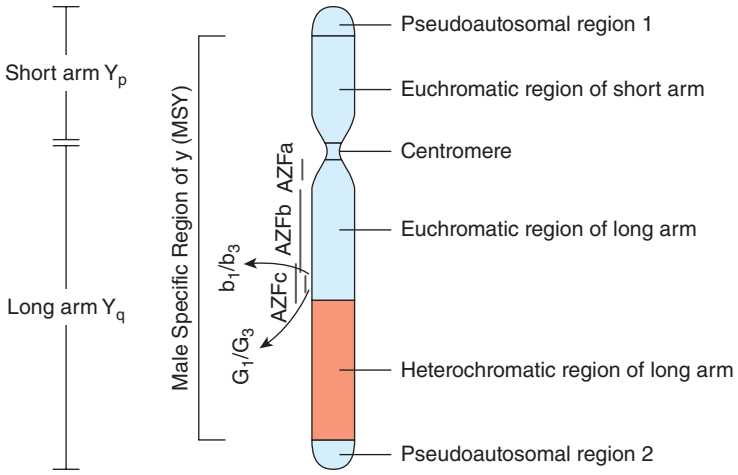

FIGURE 391-5 Structure of the Y chromosome relevant for spermatogenesis.

Approximately 15% of infertile men with azoospermia and ~6% of men with severe oligozoospermia harbor a Y microdeletion. Complete deletions of the AZFa and AZFb subregions are typically associated with Sertoli cells only and azoospermia and a poor prognosis for sperm retrieval. In contrast, AZFc subregion microdeletions are typically associated with oligozoospermia and higher success rates for sperm retrieval. Microdeletion involving the *DAZ* genes in the AZFc region is one of the most common Y chromosome microdeletions in infertile men. Several partial deletions of the AZFc region have been described including the gr/gr deletion, which is associated with infertility among Caucasian men in Europe and the Western Pacific region, whereas the b2/b3 deletion is associated with male infertility in African and Dravidian men.

TREATMENT

Male Factor Infertility

Treatment options for male factor infertility have expanded greatly in recent years. Secondary hypogonadism is highly amenable to treatment with pulsatile GnRH or gonadotropins (see below). Assisted reproductive technologies, such as in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI), have provided new opportunities for patients with primary testicular failure and disorders of sperm transport. Choice of initial treatment options depends on sperm concentration and motility. Expectant management should be attempted initially in men with mild male factor infertility (sperm count of 15–20 × 10^6/mL and normal motility). Treatment of moderate male factor infertility (10–15 × 10^6/mL and 20–40% motility) should begin with intrauterine insemination alone or in combination with treatment of the female partner with clomiphene or gonadotropins, but it may require IVF with or without ICSI. For men with a severe defect (sperm count of <10 × 10^6/mL, 10% motility), IVF with ICSI or donor sperm has become the treatment of choice. Yq microdeletions will be transmitted through ICSI from the affected father to his male offspring if sperm carrying the Yq microdeletion is used.

CLINICAL AND LABORATORY EVALUATION OF MALE REPRODUCTIVE FUNCTION

HISTORY AND PHYSICAL EXAMINATION

The history should focus on developmental stages such as puberty and growth spurts, as well as androgen-dependent events such as early morning erections, frequency and intensity of sexual thoughts, and frequency of masturbation or intercourse. Although libido and the overall frequency of sexual acts are decreased in androgen-deficient men, young hypogonadal men can achieve erections in response to visual erotic stimuli. Men with acquired androgen deficiency often report decreased energy and low mood.

The physical examination should focus on secondary sex characteristics such as hair growth, gynecomastia, testicular volume, prostate, and height and body proportions. *Eunuchoid proportions* are defined as an arm span >2 cm greater than height and suggest that androgen deficiency occurred before epiphyseal fusion. Hair growth in the face, axilla, chest, and pubic regions is androgen-dependent; however, changes may not be noticeable unless androgen deficiency is severe and prolonged. Ethnicity also influences the intensity of hair growth **(Chap. 394)**. Testicular volume is best assessed by using a Prader orchidometer. Testes range from 3.5 to 5.5 cm in length, which corresponds to a volume of 12–25 mL. Advanced age does not influence testicular size, although the consistency becomes less firm. Asian men generally have smaller testes than western Europeans, independent of differences in body size. Because of its possible role in infertility, the presence of varicocele should be sought by palpation while the patient is standing; it is more common on the left side. Patients with Klinefelter syndrome have markedly reduced testicular volumes (1–2 mL). In congenital hypogonadotropic hypogonadism, testicular volumes provide a good index for the degree of gonadotropin deficiency and the likelihood of response to therapy.

GONADOTROPIN AND INHIBIN MEASUREMENTS

LH and FSH are measured using two-site immunoradiometric, immunofluorometric, or chemiluminescent assays, which have very low cross-reactivity with other pituitary glycoprotein hormones and hCG and have sufficient sensitivity to measure the low levels present in patients with hypogonadotropic hypogonadism. In men with a low testosterone level, an LH level can distinguish primary (high LH) versus secondary (low or inappropriately normal LH) hypogonadism. An elevated LH level indicates a primary defect at the testicular level, whereas a low or inappropriately normal LH level suggests a defect at the hypothalamic-pituitary level. LH pulses occur about every 1–3 h in normal men. Thus, gonadotropin levels fluctuate, and samples should be pooled or repeated when results are equivocal. FSH is less pulsatile than LH because it has a longer half-life. Selective increase in FSH suggests damage to the seminiferous tubules. Inhibin B, a Sertoli cell product that suppresses FSH, is reduced with seminiferous tubule damage. Inhibin B is a dimer with α-β_B subunits and is measured by two-site immunoassays.

GnRH Stimulation Testing The GnRH test is performed by measuring LH and FSH concentrations at baseline and at 30 and 60 min after intravenous administration of 100 μg of GnRH. A minimally acceptable response is a twofold LH increase and a 50% FSH increase. In the prepubertal period or with severe GnRH deficiency, the gonadotrope may not respond to a single bolus of GnRH because it has not been primed by endogenous hypothalamic GnRH; in these patients, GnRH responsiveness may be restored by chronic, pulsatile GnRH administration. With the availability of sensitive and specific LH assays, GnRH stimulation testing is used rarely.

TESTOSTERONE ASSAYS

Total Testosterone Total testosterone includes both unbound and protein-bound testosterone and is measured by radioimmunoassays, immunometric assays, or liquid chromatography tandem mass spectrometry (LC-MS/MS). LC-MS/MS involves extraction of serum by organic solvents, separation of testosterone from other steroids by high-performance liquid chromatography and mass spectrometry, and quantitation of unique testosterone fragments by mass spectrometry. LC-MS/MS provides accurate and sensitive measurements of testosterone levels even in the low range and has emerged as the method of choice for testosterone measurement. The use of LC-MS/MS for the measurement of testosterone in laboratories that have been certified by the Centers for Disease Control and Prevention's (CDC) Hormone Standardization Program for Testosterone (HoST) can ensure that testosterone measurements are accurate and calibrated to an international standard. A single fasting morning sample provides a good approximation of the average testosterone concentration with the realization

that testosterone levels fluctuate because of its pulsatile, diurnal, and circannual secretory rhythms. Testosterone is generally lower in the late afternoon and is reduced by acute illness. The harmonized normal range for total testosterone, measured using LC-MS/MS in nonobese populations of European and American men aged 19–39 years, is 264–916 ng/dL. This harmonized reference range can be applied to values from laboratories that are certified by the CDC's HoST program.

Alterations in SHBG levels due to aging, obesity, diabetes mellitus, hyperthyroidism, some types of medications, or chronic illness, or on a congenital basis, can affect total testosterone levels. Heritable factors contribute substantially to the population-level variation in testosterone levels, and genome-wide association studies have revealed polymorphisms in the SHBG gene as important contributors to variation in testosterone levels.

Measurement of Unbound Testosterone Levels Most circulating testosterone is bound to SHBG and to albumin; only 2.0–4% of circulating testosterone is unbound, or "free." Free testosterone should ideally be measured by equilibrium dialysis under standardized conditions using an accurate and reliable assay for total testosterone. The unbound testosterone concentration also can be calculated from total testosterone, SHBG, and albumin concentrations. Recent research has shown that testosterone binding to SHBG is a multistep process that involves complex allosteric interactions between the two binding sites within the SHBG dimer; a novel ensemble allosteric model of testosterone's binding to SHBG dimers provides good estimates of free testosterone concentrations. The previous law-of-mass-action equations based on linear models of testosterone binding to SHBG used assumptions that have been shown to be erroneous. Tracer analogue methods are relatively inexpensive and convenient, but they are inaccurate. The term *bioavailable testosterone* refers to unbound testosterone plus testosterone bound loosely to albumin and reflects the concept that albumin-bound testosterone can dissociate at the capillary level, especially in tissues with long transit time, such as the liver and the brain. *Bioavailable testosterone* can be determined by the ammonium sulfate precipitation method. However, the measurements of bioavailable testosterone using the ammonium sulfate precipitation are technically challenging, susceptible to imprecision, and not recommended.

hCG Stimulation Test The hCG stimulation test is performed by administering a single injection of 1500–4000 IU of hCG intramuscularly and measuring testosterone levels at baseline and 24, 48, 72, and 120 h after hCG injection. An alternative regimen involves three injections of 1500 units of hCG on successive days and measuring testosterone levels 24 h after the last dose. An acceptable response to hCG is a doubling of the testosterone concentration in adult men. In prepubertal boys, an increase in testosterone to >150 ng/dL indicates the presence of testicular tissue. No response may indicate an absence of testicular tissue or marked impairment of Leydig cell function. Measurement of MIS, a Sertoli cell product, is also used to detect the presence of testes in prepubertal boys with cryptorchidism.

SEMEN ANALYSIS

Semen analysis is the most important step in the evaluation of male infertility. Samples are collected by masturbation following a period of abstinence for 2–3 days. Semen volumes and sperm concentrations vary considerably among fertile men, and several samples may be needed before concluding that the results are abnormal. Analysis should be performed within an hour of collection. Using semen samples from >4500 men in 14 countries, whose partners had a time to pregnancy of <12 months, the World Health Organization (WHO) has generated the following one-sided reference limits for semen parameters: semen volume, 1.5 mL; total sperm number, 39 million per ejaculate; sperm concentration, 15 million per mL; vitality, 58% live; progressive motility, 32%; total (progressive + nonprogressive) motility, 40%; and morphologically normal forms, 4.0%. Some men with low sperm counts are nevertheless fertile. Some studies suggest that sperm counts have declined in recent decades. A variety of tests for sperm function can be performed in specialized laboratories, but these add relatively little to the treatment options.

TESTICULAR BIOPSY

Testicular biopsy is useful in some patients with oligospermia or azoospermia as an aid in diagnosis and indication for the feasibility of treatment. Using fine-needle aspiration biopsy is performed under local anesthesia to aspirate tissue for histology. Alternatively, open biopsies can be performed under local or general anesthesia when more tissue is required. A normal biopsy in an azoospermic man with a normal FSH level suggests obstruction of the vas deferens, which may be correctable surgically. Biopsies are also used to harvest sperm for ICSI and to classify disorders such as hypospermatogenesis (all stages present but in reduced numbers), germ cell arrest (usually at primary spermatocyte stage), and Sertoli cell–only syndrome (absent germ cells) or hyalinization (sclerosis with absent cellular elements).

Testing for Y Chromosome Microdeletions Y chromosome microdeletions are detected by extracting DNA from peripheral blood leukocytes and using polymerase chain reaction (PCR) amplification using primers for ~300 sequence-tagged sites on the Y chromosome, followed by gel electrophoresis to determine whether the DNA sequences corresponding to the selected Y chromosome markers are present. However, because these ~300 Y chromosome markers account for only a small fraction of the 23 million base pairs on the Y chromosome, a negative test does not exclude microdeletions in other subregions of the Y chromosome.

DISORDERS OF SEXUAL DIFFERENTIATION

See Chap. 390.

DISORDERS OF PUBERTY

The onset and tempo of puberty vary greatly in the general population and are affected by genetic, nutritional, and environmental factors. Although a substantial fraction of the variance in the timing of puberty is explained by heritable factors, the genes involved remain unknown.

PRECOCIOUS PUBERTY

Puberty in boys aged <9 years is considered precocious. Earlier onset of puberty is associated with increased risk for several cancers, cardiovascular disease, hypertension, type 2 diabetes, hair pigmentation, and shorter life span. Genome-wide association studies for age of menarche in girls and age of voice deepening in boys have identified 389 independent loci in girls and 76 independent loci for the timing of puberty in boys.

Isosexual precocity refers to premature sexual development consistent with phenotypic sex and includes features such as the development of facial hair and phallic growth. Isosexual precocity is divided into gonadotropin-dependent and gonadotropin-independent causes of androgen excess (Table 391-1). *Heterosexual precocity* refers to the premature development of estrogenic features in boys, such as breast development.

Gonadotropin-Dependent Precocious Puberty This disorder, called *central precocious puberty* (CPP), is less common in boys than in girls. It is caused by premature activation of the GnRH pulse generator, sometimes because of central nervous system (CNS) lesions such as hypothalamic hamartomas, but it is often idiopathic. CPP is characterized by gonadotropin levels that are inappropriately elevated for age. Because pituitary priming has occurred, GnRH elicits LH and FSH responses typical of those seen in puberty or in adults. MRI should be performed to exclude a mass, structural defect, infection, or inflammatory process. Mutations in kisspeptin, kisspeptin receptor, and *MKRN3*, an imprinted gene encoding makorin ring finger protein 3, which is expressed only from the paternally inherited allele, have been associated with CPP. Loss-of-function mutations in *MKRN3* remove the brake that restrains pulsatile GnRH, resulting in precocious puberty.

Gonadotropin-Independent Precocious Puberty Androgens from the testis or the adrenal are increased but gonadotropins are low. This group of disorders includes hCG-secreting tumors; CAH; sex steroid–producing tumors of the testis, adrenal, and ovary; accidental or

TABLE 391-1 Causes of Precocious or Delayed Puberty in Boys

I. Precocious puberty
- A. Gonadotropin-dependent
  1. Idiopathic
  2. Hypothalamic hamartoma or other lesions
  3. CNS tumor or inflammatory state
  4. Mutations in genes that regulate GnRH secretion, such as kisspeptin (*KISS1*), kisspeptin receptor (*KISS1R*), and makorin ring finger protein 3 (*MKRN3*)
- B. Gonadotropin-independent
  1. Congenital adrenal hyperplasia
  2. hCG-secreting tumor
  3. McCune-Albright syndrome
  4. Activating LH receptor mutation
  5. Exogenous androgens
  6. Androgen producing tumors of the adrenal or the testis

II. Delayed puberty

Abbreviations: CNS, central nervous system; GnRH, gonadotropin-releasing hormone; hCG, human chronic gonadotropin; LH, luteinizing hormone.

deliberate exogenous sex steroid administration; hypothyroidism; and activating mutations of the LH receptor or $G_s\alpha$ subunit.

Familial Male-Limited Precocious Puberty Also called *testotoxicosis*, familial male-limited precocious puberty is an autosomal dominant disorder caused by activating mutations in the LH receptor, leading to constitutive stimulation of the cyclic AMP pathway and testosterone production. Clinical features include premature androgenization in boys, growth acceleration in early childhood, and advanced bone age followed by premature epiphyseal fusion. Testosterone is elevated, and LH is suppressed. Treatment options include inhibitors of testosterone synthesis (e.g., ketoconazole, medroxyprogesterone acetate), AR antagonists (e.g., flutamide and bicalutamide), and aromatase inhibitors (e.g., anastrozole).

MCCUNE-ALBRIGHT SYNDROME This is a sporadic disorder caused by somatic (postzygotic) activating mutations in the $G_s\alpha$ subunit that links G protein–coupled receptors to intracellular signaling pathways (Chap. 412). The mutations impair the guanosine triphosphatase activity of the $G_s\alpha$ protein, leading to ligand-independent signaling of the G_s-coupled receptor and constitutive activation of adenylyl cyclase. Like activating LH receptor mutations, this stimulates testosterone production and causes gonadotropin-independent precocious puberty. In addition to sexual precocity, affected individuals may have autonomy in the adrenals, pituitary, and thyroid glands. *Café au lait* spots are characteristic skin lesions that reflect the onset of the somatic mutations in melanocytes during embryonic development. Constitutive $G_s\alpha$ activation in the postnatal multipotent skeletal stem cells leads to the formation of immature woven bone and replacement of the bone marrow with fibrotic stroma (polyostotic fibrous dysplasia). Treatment is similar to that in patients with activating LH receptor mutations. Bisphosphonates have been used to treat bone lesions.

CONGENITAL ADRENAL HYPERPLASIA Boys with CAH who are not well controlled with glucocorticoid suppression of adrenocorticotropic hormone (ACTH) can develop premature virilization because of excessive androgen production by the adrenal gland (Chaps. 386 and 390). LH is low, and the testes are small. Adrenal rests may develop within the testis of poorly controlled patients with CAH because of chronic ACTH stimulation; adrenal rests do not require surgical removal and regress with effective glucocorticoid therapy. Some children with CAH may develop gonadotropin-dependent precocious puberty with early maturation of the hypothalamic-pituitary-gonadal axis, elevated gonadotropins, and testicular growth.

Heterosexual Sexual Precocity Breast enlargement in prepubertal boys can result from familial aromatase excess, estrogen-producing tumors in the adrenal gland, Sertoli cell tumors in the testis, marijuana smoking, or exogenous estrogens or androgens. Occasionally, germ cell tumors that secrete hCG can be associated with breast enlargement due to excessive stimulation of estrogen production (see "Gynecomastia," below).

APPROACH TO THE PATIENT

Precocious Puberty

After verification of precocious development, serum testosterone, LH, and FSH levels should be measured to determine whether gonadotropins are increased in relation to chronologic age (gonadotropin-dependent) or whether sex steroid secretion is occurring independent of LH and FSH (gonadotropin-independent). In children with gonadotropin-dependent precocious puberty, CNS lesions should be excluded by history, neurologic examination, and MRI scan of the head. If organic causes are not found, one is left with the diagnosis of idiopathic central precocity. Patients with high testosterone but suppressed LH concentrations have gonadotropin-independent sexual precocity; in these patients, DHEA sulfate (DHEAS) and 17α-hydroxyprogesterone should be measured. High levels of testosterone and 17α-hydroxyprogesterone suggest the possibility of CAH due to 21α-hydroxylase or 11β-hydroxylase deficiency. If testosterone and DHEAS are elevated, adrenal tumors should be excluded by obtaining a CT scan of the adrenal glands. Patients with elevated testosterone but without increased 17α-hydroxyprogesterone or DHEAS should undergo careful evaluation of the testis by palpation and ultrasound to exclude a Leydig cell neoplasm. Activating mutations of the LH receptor should be considered in children with gonadotropin-independent precocious puberty in whom CAH, androgen abuse, and adrenal and testicular neoplasms have been excluded.

TREATMENT

Precocious Puberty

In patients with a known cause (e.g., a CNS lesion or a testicular tumor), therapy should be directed toward the underlying disorder. In patients with idiopathic CPP, treatment with long-acting GnRH analogues is indicated in boys showing rapid pubertal progression, who are more advanced in pubertal development (e.g., Tanner stage 3 or greater genital development) and experiencing rapid linear growth apparent at their first visit. GnRH analogues suppress gonadotropins and testosterone, halt early pubertal development, delay accelerated bone maturation, prevent early epiphyseal closure, promote final height gain, and mitigate the psychosocial consequences of early pubertal development without causing osteoporosis. The treatment is most effective for increasing final adult height

if it is initiated before age 6. Puberty resumes after discontinuation of the GnRH analogue. Counseling is an important aspect of the overall treatment strategy.

In children with gonadotropin-independent precocious puberty, inhibitors of steroidogenesis, such as ketoconazole, AR antagonists, and aromatase inhibitors have been used empirically. Long-term treatment with spironolactone (a weak androgen antagonist) and ketoconazole has been reported to normalize growth rate and bone maturation and to improve predicted height in small, nonrandomized trials in boys with familial male-limited precocious puberty. Aromatase inhibitors, such as testolactone and letrozole, have been used as adjuncts to antiandrogen therapy for children with familial male-limited precocious puberty, CAH, and McCune-Albright syndrome. More potent novel inhibitors of testosterone synthesis, such as abiraterone, have not been evaluated in boys with gonadotropin-independent precocious puberty.

DELAYED PUBERTY

Puberty is considered delayed in boys if it has not ensued by age 14, an age that is 2–2.5 standard deviations above the mean for healthy children. Pubertal delay is not necessarily pathologic and may be a variant of normal pubertal development in some children. Delayed puberty has been associated with lower peak bone mass, higher risk for metabolic and cardiovascular disorders, and lower risk for breast and endometrial cancer in women.

Delayed puberty is more common in boys than in girls. There are four main categories of delayed puberty: (1) constitutional delay of growth and puberty (~60% of cases); (2) functional hypogonadotropic hypogonadism caused by systemic illness or malnutrition (~20% of cases); (3) hypogonadotropic hypogonadism caused by genetic or acquired defects in the hypothalamic-pituitary region (~10% of cases); and (4) hypergonadotropic hypogonadism secondary to primary gonadal failure (~15% of cases) (Table 391-1). The constitutional delay of growth and puberty is the most common cause that accounts for nearly two-thirds of boys and one-third of girls with delayed puberty. The constitutional delay of growth and puberty clusters in families and displays a complex inheritance pattern, having an autosomal dominant pattern of inheritance in some families, but autosomal recessive, X-linked, or bilineal pattern in other families. Only rarely have mutations in genes known to disrupt the hypothalamic-pituitary-gonadal axis been identified in cases of pubertal delay; most of these mutations have been reported in relatives of patients with idiopathic hypogonadotropic hypogonadism. Functional hypogonadotropic hypogonadism is more common in girls than in boys. Permanent causes of hypogonadotropic or hypergonadotropic hypogonadism are identified in <25% of boys with delayed puberty.

APPROACH TO THE PATIENT

Delayed Puberty

History of systemic illness, eating disorders, excessive exercise, social and psychological problems, and abnormal patterns of linear growth during childhood should be verified. Boys with pubertal delay may have accompanying emotional and physical immaturity relative to their peers, which can be a source of anxiety. Physical examination should focus on height; arm span; weight; visual fields; and secondary sex characteristics, including hair growth, testicular volume, phallic size, and scrotal reddening and thinning. Testicular size >2.5 cm generally indicates that the child has entered puberty.

The main diagnostic challenge is to distinguish those with constitutional delay, who will progress through puberty at a later age, from those with an underlying pathologic process. Constitutional delay should be suspected when there is a family history and when there are delayed bone age and short stature. Pituitary priming by pulsatile GnRH is required before LH and FSH are synthesized and secreted normally. Thus, blunted responses to exogenous GnRH can be seen in patients with constitutional delay, GnRH deficiency, or pituitary disorders. On the other hand, low-normal basal gonadotropin levels or a normal response to exogenous GnRH is consistent with an early stage of puberty, which is often heralded by nocturnal GnRH secretion. Thus, constitutional delay is a diagnosis of exclusion that requires ongoing evaluation until the onset of puberty and the growth spurt.

TREATMENT

Delayed Puberty

If therapy is considered appropriate, it can begin with 25–50 mg of testosterone enanthate or testosterone cypionate every 2 weeks or by using a 2.5-mg testosterone patch or 25-mg testosterone gel. Because aromatization of testosterone to estrogen is obligatory for mediating androgen effects on epiphyseal fusion, concomitant treatment with aromatase inhibitors may allow attainment of greater final adult height. Testosterone treatment should be interrupted after 6 months to determine if endogenous LH and FSH secretion have ensued. Other causes of delayed puberty should be considered when there are associated clinical features or when boys do not enter puberty spontaneously after a year of observation or treatment.

Reassurance without hormonal treatment is appropriate for many individuals with presumed constitutional delay of puberty. However, the impact of delayed growth and pubertal progression on a child's social relationships and school performance should be weighed. Boys with constitutional delay of puberty are less likely to achieve their full genetic height potential and have reduced total body bone mass as adults, mainly due to narrow limb bones and vertebrae as a result of impaired periosteal expansion during puberty. Furthermore, the time of onset of puberty is negatively associated with bone mineral content and density in boys at skeletal maturity. Judicious use of androgen therapy in carefully selected boys with constitutional delay can induce pubertal induction and progression and promote short-term growth without compromising final height, and when administered with an aromatase inhibitor, it may improve final height.

DISORDERS OF THE MALE REPRODUCTIVE AXIS DURING ADULTHOOD

HYPOGONADOTROPIC HYPOGONADISM

Because LH and FSH are trophic hormones for the testes, impaired secretion of these pituitary gonadotropins results in secondary hypogonadism, which is characterized by low testosterone in the setting of low or inappropriately normal LH and FSH. Those with the most severe gonadotropin deficiency have complete absence of pubertal development, sexual infantilism, and, in some cases, hypospadias and undescended testes. Patients with partial gonadotropin deficiency have delayed or arrested sex development. The 24-h LH secretory profiles are heterogeneous in patients with hypogonadotropic hypogonadism, reflecting variable abnormalities of LH pulse frequency or amplitude. In severe cases, basal LH is low, and there are no LH pulses. A smaller subset of patients has low-amplitude LH pulses or markedly reduced pulse frequency. Occasionally, only sleep-entrained LH pulses occur, reminiscent of the pattern seen in the early stages of puberty. Hypogonadotropic hypogonadism can be classified into congenital and acquired disorders. Congenital disorders most commonly involve GnRH deficiency, which leads to gonadotropin deficiency. Acquired disorders are much more common than congenital disorders and may result from a variety of sellar mass lesions or infiltrative diseases of the hypothalamus or pituitary or be due to the effects of drugs, nutritional or psychiatric disorders, or systemic diseases.

Congenital Disorders Associated with Gonadotropin Deficiency (See Chap. 379) Congenital hypogonadotropic hypogonadism is a heterogeneous group of disorders characterized by decreased gonadotropin secretion and testicular dysfunction either due to impaired function of the GnRH pulse generator or the gonadotrope.

The disorders characterized by GnRH deficiency represent a family of oligogenic disorders whose phenotype spans a wide spectrum. Some individuals with GnRH deficiency may suffer from complete absence of pubertal development, while others may manifest varying degrees of gonadotropin deficiency and pubertal delay, and a subset that carries the same mutations as their affected family members may even have normal reproductive function. In ~10% of men with idiopathic hypogonadotropic hypogonadism (IHH), reversal of gonadotropin deficiency may occur in adult life after sex steroid therapy. Also, a small fraction of men with IHH may present with androgen deficiency and infertility in adult life after having gone through apparently normal pubertal development. Nutritional, emotional, or metabolic stress may unmask gonadotropin deficiency and reproductive dysfunction (e.g., hypothalamic amenorrhea) in some patients who harbor mutations in the candidate genes but who previously had normal reproductive function. The clinical phenotype may include isolated anosmia or hyposmia. Oligogenicity and gene-gene and gene-environment interactions may contribute to variations in clinical phenotype.

Mutations in a number of genes involved in the development and migration of GnRH neurons or in the regulation of GnRH secretion have been linked to GnRH deficiency, although the genetic defect remains elusive in nearly two-thirds of cases. Familial hypogonadotropic hypogonadism can be transmitted as an X-linked (20%), autosomal recessive (30%), or autosomal dominant (50%) trait. Some individuals with IHH have sporadic mutations in the same genes that cause inherited forms of the disorder. The genetic defects associated with GnRH deficiency can ben conveniently classified as anosmic (Kallmann syndrome) or normosmic **(Table 391-2)**, although the occurrence of both anosmic and normosmic forms of GnRH deficiency in the same families suggests commonality of pathophysiologic mechanisms. *Kallmann syndrome*, the anosmic form of GnRH deficiency, can result from mutations in one or more neurodevelopmental genes associated with olfactory bulb morphogenesis or the migration of GnRH neurons from their origin in the region of the olfactory placode, along the scaffold established by the olfactory nerves, through the cribriform plate into their final location into the preoptic region of the hypothalamus. Thus, mutations in *KAL1*, NMDA receptor synaptonuclear signaling and neuronal migration factor (*NSMF*), genes involved in fibroblast growth factor (FGF) signaling (*FGF8*, *FGFR1*, *FGF17, IL17RD, DUSP6, SPRY4,* and *FLRT3*), *NELF*, genes involved in *PROK* signaling (*PROK2* and *PROK2R*), *WDR11, SOX10, TUBB3 SEMA3, HS6ST1, CHD7,* and *FEZF1* have been described in patients with Kallmann syndrome. An X-linked form of IHH is caused by mutations in the *KAL1* gene, which encodes anosmin, a protein that mediates the migration of neural progenitors of the olfactory bulb and GnRH-producing neurons. These individuals have GnRH deficiency and variable combinations of anosmia or hyposmia, renal defects, and neurologic abnormalities including mirror movements. Proteins such as those involved in FGF and prokineticin signaling and *KAL1*, which account for the great majority of Kallmann syndrome cases, interact with heparin sulfate glycosaminoglycan compounds within the extracellular matrix in supporting GnRH neuronal migration. Mutations in the *FGFR1* gene cause an autosomal dominant form of hypogonadotropic hypogonadism that clinically resembles Kallmann syndrome; mutations in its putative ligand, the *FGF8* gene product, have also been associated with IHH. Craniofacial tissues and olfactory ensheathing cells also play important roles in neurogenesis and migration of the GnRH neurons, and additional proteins that regulate these cell types may also be involved in the pathogenesis of Kallmann syndrome. The co-occurrence of tooth anomalies, cleft palate, craniofacial anomalies, pigmentation, and neurologic defects in patients with Kallmann syndrome suggests that the syndrome may be a part of the spectrum of neurocristopathies. Other dysmorphic features associated with some forms of IHH include renal agenesis, hearing loss, synkinesia, short metacarpals, eye movement abnormalities, cerebellar ataxia, and dental agenesis. The presence of these dysmorphic features can offer clues to the underlying genetic abnormality and guide genetic testing.

Normosmic GnRH deficiency results from defects in pulsatile GnRH secretion, its regulation, or its action on the gonadotrope and has been associated with mutations in *GnRHR, GNRH1, KISS1R, TAC3, TACR3, NROB1* (*DAX1*), leptin, or leptin receptor. Some mutations, such as those in *PROK2, PROKR2, NSMF, FGFR1, FGF8, SEMA3A, WDR11*, and *CHD7*, have been associated with both anosmic and normosmic forms of IHH; it is possible that these genes are involved in GnRH neuronal migration as well in regulation of GnRH secretion. *GnRHR* mutations, the most frequent identifiable cause of normosmic IHH, account for ~40% of autosomal recessive and 10% of sporadic cases of hypogonadotropic hypogonadism. These patients have decreased LH response to exogenous GnRH. Some receptor mutations alter GnRH binding affinity, allowing apparently normal responses to pharmacologic doses of exogenous GnRH, whereas other mutations may alter signal transduction downstream of hormone binding. Mutations of the *GnRH1* gene have also been reported in patients with hypogonadotropic hypogonadism, although they are rare. The G protein–coupled receptor *KISS1R* (*GPR54*) and its cognate ligand, kisspeptin (*KISS1*), are important regulators of sexual maturation in primates. Recessive mutations in *GPR54* cause gonadotropin deficiency without anosmia. Patients retain responsiveness to exogenous GnRH, suggesting an abnormality in the neural pathways controlling GnRH release. The genes encoding NKB (*TAC3*), which is involved in preferential activation of GnRH release in early development, and its receptor (*TAC3R*) have been implicated in some families with normosmic IHH. The neurokinin pathway plays an important role in GnRH activation during "mini-puberty" as well as in puberty. Prokineticin 2 (PROK2) and its receptor (PROK2R) are highly expressed in the olfactory ventricle and subventricular zone of the lateral ventricle and are associated with neurogenesis of the olfactory bulbs and the migration of the olfactory neuronal cells. Mutations in the *CHD7* gene that encodes for the chromodomain helicase DNA binding protein 7 causes CHARGE syndrome characterized by eye coloboma, heart anomalies, choanal atresia, growth and developmental retardation, genitourinary anomalies, hypogonadism, and ear abnormalities. X-linked hypogonadotropic hypogonadism also occurs in *adrenal hypoplasia congenita*, a disorder caused by mutations in the *DAX1* gene, which encodes a nuclear receptor in the adrenal gland and reproductive axis. Adrenal hypoplasia congenita is characterized by absent development of the adult zone of the adrenal cortex, leading to neonatal adrenal insufficiency. Puberty usually does not occur or is arrested, reflecting variable degrees of gonadotropin deficiency. Although sexual differentiation is normal, some patients have testicular dysgenesis and impaired spermatogenesis despite gonadotropin replacement. Less commonly, adrenal hypoplasia congenita, sex reversal, and hypogonadotropic hypogonadism can be caused by mutations of steroidogenic factor 1 (SF1). Rarely, recessive mutations in the *LHβ* or *FSHβ* genes have been described in patients with selective deficiencies of these gonadotropins.

A number of homeodomain transcription factors are involved in the development and differentiation of the specialized hormone-producing cells within the pituitary gland (Table 391-2). Patients with mutations of *PROP1* have combined pituitary hormone deficiency that includes GH, prolactin (PRL), thyroid-stimulating hormone (TSH), LH, and FSH, but not ACTH. *LHX3* mutations cause combined pituitary hormone deficiency in association with cervical spine rigidity. *HESX1* mutations cause septo-optic dysplasia and combined pituitary hormone deficiency. Mutations of *ARNT1*, inherited as an autosomal recessive disorder, are associated with diabetes insipidus; ACTH, GH, LH, and FSH deficiency; anterior pituitary hypoplasia; hypoplastic frontal and temporal lobes; thin corpus callosum; prominent forehead; and retrognathia. Patients with *SOX2* mutations can have gonadotropin deficiency, variable deficiencies of TSH and ACTH, pituitary hypoplasia, microphthalmia, and intellectual disability.

Prader-Willi syndrome (PWS) is characterized by obesity, hypotonic musculature, intellectual disability, hypogonadism, short stature, and small hands and feet. Prader-Willi syndrome is a genomic imprinting disorder caused by deletions of the proximal portion of the paternally derived chromosome 15q11-15q13 region, which contains a bipartite imprinting center; uniparental disomy of the maternal alleles; or mutations of the genes/loci involved in imprinting **(Chap. 466)**. Recent studies suggest that at least some of the major

Abbreviations: ACTH, adrenocorticotropic hormone; AD, autosomal dominant; AR, autosomal recessive; CHARGE syndrome, eye coloboma, heart defects, choanal atresia, growth and developmental retardation, genitourinary anomalies, ear anomalies; CPHD, combined pituitary hormone deficiency; *DAX1*, dosage-sensitive sex-reversal, adrenal hypoplasia congenita, X chromosome; *DMXL2*, DMX like 2; *DUSP6*, dual specificity phosphatase 6; *FGFR1*, fibroblast growth factor receptor 1; *FGF17*, fibroblast growth factor 17; *FSHβ*, follicle-stimulating hormone β-subunit; *FLRT3*, fibronectin like domain containing leucine rich transmembrane protein 3; GH, growth hormone; *GLCE*, glucuronic acid epimerase; *GNRHR*, gonadotropin-releasing hormone receptor; *GPR54*, G protein–coupled receptor 54; *HESX1*, homeobox gene expressed in embryonic stem cells 1; *KAL1*, Kallmann syndrome interval gene 1, also known as anosmin 1; *LEP*, leptin; *LEPR*, leptin receptor; *LHX3*, LIM homeobox gene 3; *LHβ*, luteinizing hormone β-subunit; *NELF*, nasal embryonic luteinizing hormone–releasing hormone factor; *NSMF*, NMDA receptor synaptonuclear signaling and neuronal migration factor; *NR0B1*, nuclear receptor subfamily 0, group B, member 1; *OTUD4*, OUT domain containing protein 4; *PNPLA6*, patatin-like phospholipase domain-containing protein 6; *PC1*, prohormone convertase 1; *PROK2*, prokineticin 2; *PROP1*, prophet of pit 1; *RNF216*, ring finger protein 216; *POLR3B*, polymerase III RNA subunit B; *SF1*, steroidogenic factor 1; *SPRY4*, sprouty RTK signaling antagonist 4; *STUB1*, srip 1 homologous and U box containing protein 1; *TUBB3*, tubulin beta 3; *IL17RD*, interleukin 17 receptor D.

manifestations of PWS may be due to reduced expression of prohormone convertase 1.

Laurence-Moon syndrome is an autosomal recessive disorder characterized by obesity, hypogonadism, mental retardation, polydactyly, and retinitis pigmentosa. Recessive mutations of leptin, or its receptor, cause severe obesity and pubertal arrest, apparently because of hypothalamic GnRH deficiency **(Chap. 401)**.

Acquired Hypogonadotropic Disorders • **SEVERE ILLNESS, STRESS, MALNUTRITION, AND EXERCISE** These may cause reversible gonadotropin deficiency. Although gonadotropin deficiency and reproductive dysfunction are well documented in these conditions in women, men exhibit similar but less pronounced responses. Unlike women, most male runners and other endurance athletes have normal gonadotropin and sex steroid levels, despite low body fat and frequent intensive exercise. Testosterone levels fall at the onset of illness and recover during recuperation. The magnitude of gonadotropin suppression generally correlates with the severity of illness. Although hypogonadotropic hypogonadism is the most common cause of androgen deficiency in patients with acute illness, some have elevated levels of LH and FSH, which suggest primary gonadal dysfunction. The pathophysiology of reproductive dysfunction during acute illness is unknown but likely involves a combination of cytokine and/or glucocorticoid effects. There is a high frequency of low testosterone levels in patients with chronic illnesses such as HIV infection, end-stage renal disease, chronic obstructive lung disease, and many types of cancer and in patients receiving glucocorticoids. About 20% of HIV-infected men with low testosterone levels have elevated LH and FSH levels; these patients presumably have primary testicular dysfunction. The remaining 80% have either normal or low LH and FSH levels; these men have a central hypothalamic-pituitary defect or a dual defect involving both the testis and the hypothalamic-pituitary centers. Muscle wasting is common in chronic diseases associated with hypogonadism, which also leads to debility, poor quality of life, and adverse outcome of disease. There is great interest in exploring strategies that can reverse androgen deficiency or attenuate the sarcopenia associated with chronic illness.

Men using opioids for relief of cancer or noncancerous pain or because of addiction often have suppressed testosterone and LH levels and high prevalence of sexual dysfunction and osteoporosis; the degree of suppression is dose-related and particularly severe with long-acting opioids such as methadone. Opioids suppress GnRH secretion and alter the sensitivity to feedback inhibition by gonadal steroids. Men who are heavy users of marijuana have decreased testosterone secretion and sperm production. The mechanism of marijuana-induced hypogonadism is decreased GnRH secretion. Gynecomastia observed in marijuana users can also be caused by plant estrogens in crude preparations. Androgen deprivation therapy in men with prostate cancer has been associated with increased risk of bone fractures, diabetes mellitus, cardiovascular events, fatigue, sexual dysfunction, tender gynecomastia, and poor quality of life.

OBESITY In men with mild to moderate obesity, SHBG levels decrease in proportion to the degree of obesity, resulting in lower total testosterone levels. However, free testosterone levels usually remain within the normal range. SHBG production in the liver is inhibited by hepatic lipids and by tumor necrosis factor α and interleukin 1, but it is not affected by insulin. Thus, the low SHBG levels seen in obesity and diabetes are likely the result of low-grade inflammation and the increased amount of hepatic lipids rather than high insulin levels. Estradiol levels are higher in obese men compared to healthy, nonobese controls, because of aromatization of testosterone to estradiol in adipose tissue. Weight loss is associated with reversal of these abnormalities including an increase in total and free testosterone levels and a decrease in estradiol levels. A subset of obese men with moderate to severe obesity may have a defect in the hypothalamic-pituitary axis as suggested by low free testosterone in the absence of elevated gonadotropins. Weight gain in adult men can accelerate the rate of age-related decline in testosterone levels.

HYPERPROLACTINEMIA **(See also Chap. 380)** Elevated PRL levels are associated with hypogonadotropic hypogonadism. PRL inhibits hypothalamic GnRH secretion either directly or through modulation of tuberoinfundibular dopaminergic pathways. A PRL-secreting tumor may also destroy the surrounding gonadotropes by invasion or compression of the pituitary stalk. Treatment with dopamine agonists reverses gonadotropin deficiency, although there may be a delay relative to PRL suppression.

SELLAR MASS LESIONS Neoplastic and nonneoplastic lesions in the hypothalamus or pituitary can directly or indirectly affect gonadotrope function. In adults, pituitary adenomas constitute the largest category of space-occupying lesions affecting gonadotropin and other pituitary hormone production. Pituitary adenomas that extend into the suprasellar region can impair GnRH secretion and mildly increase PRL secretion (usually <50 μg/L) because of impaired tonic inhibition by dopaminergic pathways. These tumors that cause hyperprolactinemia by stalk compression should be distinguished from prolactinomas, which typically are associated with higher PRL levels. The presence of diabetes insipidus suggests the possibility of a craniopharyngioma, infiltrative disorder, or other hypothalamic lesions **(Chap. 381)**.

HEMOCHROMATOSIS **(See also Chap. 414)** Both the pituitary and testis can be affected by excessive iron deposition. However, the pituitary defect is the predominant lesion in most patients with hemochromatosis and hypogonadism. The diagnosis of hemochromatosis is suggested by the association of characteristic skin discoloration, hepatic enlargement or dysfunction, diabetes mellitus, arthritis, cardiac conduction defects, and hypogonadism.

PRIMARY TESTICULAR CAUSES OF HYPOGONADISM

Common causes of primary testicular dysfunction include Klinefelter syndrome, uncorrected cryptorchidism, cancer chemotherapy, radiation to the testes, trauma, torsion, infectious orchitis, HIV infection, anorchia syndrome, and myotonic dystrophy. Primary testicular disorders may be associated with impaired spermatogenesis, decreased androgen production, or both. **See Chap. 390 for disorders of testis development, androgen synthesis, and androgen action.**

Klinefelter Syndrome **(See also Chap. 390)** Klinefelter syndrome is the most common chromosomal disorder associated with testicular dysfunction and male infertility. It occurs in about 1 in 600 live-born males. Azoospermia is the rule in men with Klinefelter syndrome who have the 47,XXY karyotype due to the progressive loss of 47,XXY spermatogonial stem cells; however, men with mosaicism may have germ cells, especially at a younger age. The clinical phenotype of Klinefelter syndrome can be variable, possibly because of mosaicism, polymorphisms in AR gene, the parental origin of the X chromosome, X-linked copy number variations, gene-dosage effects in conjunction with X chromosome inactivation, variable testosterone levels, or other genetic factors. Testicular histology shows hyalinization of seminiferous tubules and germ cell aplasia. However, spermatogenesis can be observed in a small number of tubules from which sperm can be harvested during testicular sperm extraction for IVF. Although their function is impaired, the number of Leydig cells appears to increase. Testosterone is decreased and estradiol is increased, leading to clinical features of undervirilization and gynecomastia. Men with Klinefelter syndrome are at increased risk of systemic lupus erythematosus, Sjögren's syndrome, breast cancer, diabetes mellitus, osteoporosis, non-Hodgkin's lymphoma, and some types of lung cancer and at reduced risk of prostate cancer. Periodic mammography for breast cancer surveillance is recommended for men with Klinefelter syndrome. Fertility can be achieved by intracytoplasmic injection of sperm retrieved surgically from the testes of men with Klinefelter syndrome, including some men with nonmosaic form of Klinefelter syndrome. Although sperm retrieval for fertility preservation offers no benefit over harvesting in adulthood, fertility counseling, including the potential for sperm retrieval, should be offered prior to starting testosterone replacement therapy. The karyotypes 48,XXXY and 49,XXXXY are associated with

a more severe phenotype, increased risk of congenital malformations, and lower intelligence than 47,XXY individuals.

Cryptorchidism Cryptorchidism occurs when there is incomplete descent of the testis from the abdominal cavity into the scrotum. About 1–4% of full-term and 30% of premature male infants have at least one undescended testis at birth, but descent is usually complete by the first few weeks of life. Fifty percent of undescended testes at birth will descend spontaneously within the first 6–18 months of life; consequently, the incidence of cryptorchidism is <1% by 9 months of age. Cryptorchidism should be distinguished from retractile testes that can be pulled down into the scrotum during physical examination and require no treatment.

Androgens regulate predominantly the inguinoscrotal descent of the testes through degeneration of the cranio-suspensory ligament and a shortening of the gubernaculums, respectively. Mutations in *INSL3* and leucine-rich repeat family of G-protein-coupled receptor 8 (*LGR8*), which regulate the transabdominal portion of testicular descent, have been found in some patients with cryptorchidism.

Cryptorchidism is associated with increased risk of malignancy, infertility, inguinal hernia, and torsion. Unilateral cryptorchidism, even when corrected before puberty, is associated with decreased sperm count, possibly reflecting unrecognized damage to the fully descended testis or other genetic factors. Therefore, surgical correction is usually performed between 6 and 18 months of age depending on the location of the testes, the child's body size, and parental preference. Epidemiologic, clinical, and molecular evidence supports the idea that cryptorchidism, hypospadias, impaired spermatogenesis, and testicular cancer may be causally related to common genetic and environment perturbations and are components of the testicular dysgenesis syndrome.

Acquired Testicular Defects *Viral orchitis* may be caused by the mumps virus, echovirus, lymphocytic choriomeningitis virus, and group B arboviruses. Orchitis occurs in as many as one-fourth of adult men with mumps; the orchitis is unilateral in about two-thirds and bilateral in the remainder. Orchitis usually develops a few days after the onset of parotitis but may precede it. The testis may return to normal size and function or undergo atrophy. Semen analysis returns to normal for three-fourths of men with unilateral involvement but for only one-third of men with bilateral orchitis. *Trauma*, including testicular torsion, can also cause secondary atrophy of the testes. The exposed position of the testes in the scrotum renders them susceptible to both thermal and physical trauma, particularly in men with hazardous occupations.

The late-term adverse effects of cancer treatment on reproductive health have emerged as an important concern among cancer survivors. Many professional cancer societies have published guidelines on the fertility preservation in patients with cancer and endorsed formal consideration of fertility preservation measures prior to initiation of cancer treatment. The testes are sensitive to *radiation damage* due to the direct effects of ionized radioactive particles as well as indirect effects of free radicals generated from water. Although radiation doses as low as 0.75 Gy can transiently raise LH, only doses >20 Gy are associated with Leydig cell dysfunction and increased FSH and LH levels. Radiation doses <1.0 Gy are associated with only a transient decline in sperm density; doses between 1.0 and 2.0 Gy are associated with temporary azoospermia, and doses >2.0 Gy are generally associated with permanent azoospermia. Permanent androgen deficiency in adult men is uncommon after therapeutic radiation; however, most boys given direct testicular radiation therapy for acute lymphoblastic leukemia have permanently low testosterone levels. Direct testicular radiation and whole-body radiation before bone marrow transplantation pose the greatest risk of permanent testicular damage.

Combination chemotherapy for acute leukemia, Hodgkin's disease, and testicular and other cancers may impair Leydig cell function and cause infertility. The degree of gonadal dysfunction depends on the type of chemotherapeutic agent and the dose and duration of therapy. Because of the high response rates and the young age of these men, infertility and androgen deficiency have emerged as important long-term complications of cancer chemotherapy. Cyclophosphamide and combination regimens containing alkylating agents such as procarbazine are particularly toxic to germ cells. Thus, 90% of men with Hodgkin's lymphoma receiving MOPP (mechlorethamine, oncovin, procarbazine, prednisone) therapy develop azoospermia or extreme oligozoospermia; newer regimens that do not include procarbazine, such as ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine), are less toxic to germ cells. Azoospermia is uncommon with cyclophosphamide equivalent doses of <4000 mg/m^2, and higher doses of alkylating agents are generally associated with varying degree of damage to germ cells. The outcomes of assisted reproductive technologies in cancer survivors using cryopreserved sperm collected prior to cancer treatment are similar to those in infertile men who do not have cancer. A smaller subset of cancer survivors treated with large doses of alkylating agents may also suffer from testosterone deficiency and sexual dysfunction.

Drugs interfere with testicular function by several mechanisms, including inhibition of testosterone synthesis (e.g., ketoconazole), blockade of androgen action (e.g., spironolactone), increased estrogen (e.g., marijuana), and toxic effects on spermatogenesis (e.g., chemotherapy).

Alcohol, when consumed in excess for prolonged periods, decreases testosterone, independent of liver disease or malnutrition. Elevated estradiol and decreased testosterone levels may occur in men taking digitalis.

The occupational and recreational history should be carefully evaluated in all men with infertility because of the toxic effects of many *chemical agents* on spermatogenesis. Known environmental hazards include pesticides (e.g., vinclozolin, dicofol, atrazine), sewage contaminants (e.g., ethinyl estradiol in birth control pills, surfactants such as octylphenol, nonylphenol), plasticizers (e.g., phthalates), flame retardants (e.g., polychlorinated biphenyls, polybrominated diphenol ethers), industrial pollutants (e.g., heavy metals such as cadmium and lead, dioxins, polycyclic aromatic hydrocarbons), microwaves, and ultrasound. In some populations, sperm density is said to have declined by as much as 40% in the past 50 years. Environmental estrogens or antiandrogens may be partly responsible.

Testicular failure also occurs as a part of *polyglandular autoimmune insufficiency* **(Chap. 388)**. Sperm antibodies can cause isolated male infertility. In some instances, these antibodies are secondary phenomena resulting from duct obstruction or vasectomy. Granulomatous diseases can affect the testes, and testicular atrophy occurs in 10–20% of men with lepromatous leprosy because of direct tissue invasion by the mycobacteria. The tubules are involved initially, followed by endarteritis and destruction of Leydig cells.

Systemic disease can cause primary testis dysfunction in addition to suppressing gonadotropin production. In cirrhosis, a combined testicular and pituitary abnormality leads to decreased testosterone production independent of the direct toxic effects of ethanol. Impaired hepatic extraction of adrenal androstenedione leads to extraglandular conversion to estrone and estradiol, which partially suppresses LH. Testicular atrophy and gynecomastia are present in approximately one-half of men with cirrhosis. In chronic renal failure, androgen synthesis and sperm production decrease despite elevated gonadotropins. The elevated LH level is due to reduced clearance, but it does not restore normal testosterone production. About one-fourth of men with renal failure have hyperprolactinemia. Improvement in testosterone production with hemodialysis is incomplete, but successful renal transplantation may return testicular function to normal. Testicular atrophy is present in one-third of men with sickle cell anemia. The defect may be at either the testicular or the hypothalamic-pituitary level. Sperm density can decrease temporarily after acute febrile illness in the absence of a change in testosterone production. Infertility in men with celiac disease is associated with a hormonal pattern typical of androgen resistance, namely elevated testosterone and LH levels.

Neurologic diseases associated with altered testicular function include myotonic dystrophy, spinobulbar muscular atrophy, and paraplegia. In myotonic dystrophy, small testes may be associated with

impairment of both spermatogenesis and Leydig cell function. Spinobulbar muscular atrophy is caused by an expansion of the glutamine repeat sequences in the amino-terminal region of the AR; this expansion impairs function of the AR, but it is unclear how the alteration is related to the neurologic manifestations. Men with spinobulbar muscular atrophy often have undervirilization and infertility as a late manifestation. Spinal cord injury that causes paraplegia is often associated with low testosterone levels and may cause persistent defects in spermatogenesis; some patients retain the capacity for penile erection and ejaculation.

ANDROGEN INSENSITIVITY SYNDROMES

Mutations in the AR cause resistance to the action of testosterone and DHT. These X-linked mutations are associated with variable degrees of defective male phenotypic development and undervirilization **(Chap. 390)**. Although not technically hormone-insensitivity syndromes, two genetic disorders impair testosterone conversion to active sex steroids. Mutations in the *SRD5A2* gene, which encodes 5α-reductase type 2, prevent the conversion of testosterone to DHT, which is necessary for the normal development of the male external genitalia. Mutations in the *CYP19* gene, which encodes aromatase, prevent testosterone conversion to estradiol. Males with *CYP19* mutations have delayed epiphyseal fusion, tall stature, eunuchoid proportions, visceral adiposity, and osteoporosis, consistent with evidence from an estrogen receptor–deficient individual that these testosterone actions are mediated via estrogen.

GYNECOMASTIA

Gynecomastia refers to enlargement of the male breast. It is caused by excess estrogen action and is usually the result of an increased estrogen/androgen ratio. True gynecomastia is associated with glandular breast tissue that is >4 cm in diameter and often tender. Glandular tissue enlargement should be distinguished from excess adipose tissue: glandular tissue is firmer and contains fibrous-like cords. Gynecomastia occurs as a normal physiologic phenomenon in the newborn (due to transplacental transfer of maternal and placental estrogens), during puberty (high estrogen-to-androgen ratio in early stages of puberty), and with aging (increased fat tissue and increased aromatase activity along with the age-related decline in testosterone levels), but it can also result from pathologic conditions associated with androgen deficiency or estrogen excess. The prevalence of gynecomastia increases with age and body mass index (BMI), likely because of increased aromatase activity in adipose tissue. Medications that alter androgen metabolism or action may also cause gynecomastia. The relative risk of breast cancer is increased in men with gynecomastia, although the absolute risk is relatively small.

PATHOLOGIC GYNECOMASTIA

Any cause of *androgen deficiency* can lead to gynecomastia, reflecting an increased estrogen/androgen ratio, as estrogen synthesis still occurs by aromatization of residual adrenal and gonadal androgens. Gynecomastia is a characteristic feature of Klinefelter syndrome **(Chap. 390)**. *Androgen insensitivity* disorders also cause gynecomastia. *Excess estrogen production* may be caused by tumors, including Sertoli cell tumors in isolation or in association with Peutz-Jeghers syndrome or Carney complex. Tumors that produce hCG, including some testicular tumors, stimulate Leydig cell estrogen synthesis. *Increased conversion of androgens to estrogens* can be a result of increased availability of substrate (androstenedione) for extraglandular estrogen formation (CAH, hyperthyroidism, and most feminizing adrenal tumors) or of diminished catabolism of androstenedione (liver disease) so that estrogen precursors are shunted to aromatase in peripheral sites. Obesity is associated with increased aromatization of androgen precursors to estrogens. Extraglandular aromatase activity can also be increased in tumors of the liver or adrenal gland or rarely as an inherited disorder. Several families with *increased peripheral aromatase activity* inherited as an autosomal dominant or as an X-linked disorder have been described. In some families with this disorder, an inversion in chromosome 15q21.2-3 causes the *CYP19* gene to be activated by the regulatory elements of contiguous genes, resulting in excessive estrogen production in the fat and other extragonadal tissues. The familial aromatase excess syndrome due to *CYP19* mutation or chromosomal rearrangement is characterized by pre- or peripubertal onset of gynecomastia, advanced bone age, short adult height due to premature epiphyseal closure, and hypogonadotropic hypogonadism. Peutz-Jeghers syndrome is characterized by intestinal hamartomas, mucocutaneous pigmentation, calcifying Sertoli cell tumors, and prepubertal gynecomastia due to increased aromatization and premature epiphyseal closure. *Drugs* can cause gynecomastia by acting directly as estrogenic substances (e.g., oral contraceptives, phytoestrogens, digitalis) or inhibiting androgen synthesis (e.g., ketoconazole) or action (e.g., spironolactone, AR blockers such as enzalutamide); for many drugs, such as cimetidine, imatinib, or some antiretroviral drugs for HIV, the precise mechanism is unknown. Unintentional exposure to estrogenic agents in skin care products has been reported as a cause of gynecomastia in prepubertal children.

Because up to two-thirds of pubertal boys and about half of hospitalized men have palpable glandular tissue that is benign, detailed investigation or intervention is not indicated in all men presenting with gynecomastia **(Fig. 391-6)**. In addition to the extent of gynecomastia, recent onset, rapid growth, tender tissue, and occurrence in a lean subject should prompt more extensive evaluation. This should include a careful drug history, measurement and examination of the testes, assessment of virilization, evaluation of liver function, and hormonal measurements including testosterone, estradiol, androstenedione, LH, and hCG. Markedly elevated estradiol concentrations along with suppressed LH should prompt a search for a testicular or adrenal estrogen-secreting tumor. A karyotype should be obtained in men with very small testes to exclude Klinefelter syndrome. Despite

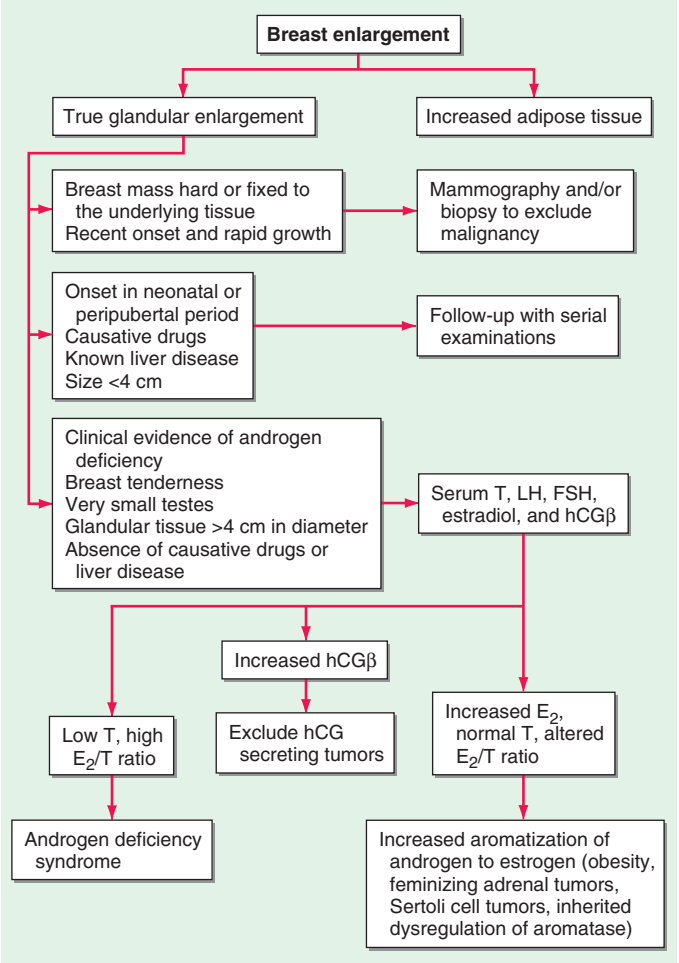

FIGURE 391-6 Evaluation of gynecomastia. E_2, 17β-estradiol; FSH, follicle-stimulating hormones; hCGβ, human chorionic gonadotropin β; LH, luteinizing hormone; T, testosterone.

extensive evaluation, the etiology is established in fewer than one-half of patients.

TREATMENT

Gynecomastia

When the primary cause can be identified and corrected shortly after the onset of gynecomastia, breast enlargement usually subsides over several months. However, if gynecomastia is of long duration, surgery is the most effective therapy. Indications for surgery include severe psychological and/or cosmetic problems, continued growth or tenderness, or suspected malignancy. In patients who have painful gynecomastia and in whom surgery cannot be performed, treatment with antiestrogens such as tamoxifen (20 mg/d) can reduce pain and breast tissue size in over half the patients. The estrogen receptor antagonists tamoxifen and raloxifene have been reported in small trials to reduce breast size in men with pubertal gynecomastia, although complete regression of breast enlargement is unusual with the use of estrogen receptor antagonists. Aromatase inhibitors can be effective in the early proliferative phase of the disorder. However, in a randomized trial in men with established gynecomastia, anastrozole proved no more effective than placebo in reducing breast size. Tamoxifen is effective in prevention and treatment of breast enlargement and breast pain in men with prostate cancer who are receiving antiandrogen therapy.

AGING-RELATED CHANGES IN MALE REPRODUCTIVE FUNCTION

A number of cross-sectional and longitudinal studies (e.g., the Baltimore Longitudinal Study of Aging, the Framingham Heart Study, the Massachusetts Male Aging Study, and the European Male Aging Study [EMAS]) have established that testosterone concentrations decrease with advancing age. This age-related decline starts in the third decade of life and progresses slowly; the rate of decline in testosterone concentrations is greater in obese men, in men with chronic illness, and in those taking medications. Because SHBG concentrations are higher in older men than in younger men, free or bioavailable testosterone concentrations decline with aging to a greater extent than total testosterone concentrations. The age-related decline in testosterone is due to defects at all levels of the hypothalamic-pituitary-testicular axis: pulsatile GnRH secretion is attenuated, LH response to GnRH is reduced, and testicular response to LH is impaired. However, the gradual rise of LH with aging suggests that testis dysfunction is the main cause of declining androgen levels. The term *andropause* has been used to denote age-related decline in testosterone concentrations; this term is a misnomer because there is no discrete time when testosterone concentrations decline abruptly.

Several epidemiologic studies, such as the Framingham Heart Study, the EMAS, and the Study of Osteoporotic Fractures in Men (MrOS), that used mass spectrometry for measuring testosterone levels have reported ~10% prevalence of low testosterone levels in middle-aged and older men; the prevalence of unequivocally low testosterone and sexual symptoms in men aged 40–70 years in the EMAS was 2.1% and increased with age from 0.1% for men aged 40–49 years of age to 5.1% for those aged 70–79 years. The age-related decline in testosterone should be distinguished from classical hypogonadism due to diseases of the testes, the pituitary, and the hypothalamus. Low total and bioavailable testosterone concentrations have been associated with decreased appendicular skeletal muscle mass and strength, decreased self-reported physical function, higher visceral fat mass, insulin resistance, and increased risk of coronary artery disease and mortality. An analysis of signs and symptoms in older men in the EMAS revealed a syndromic association of sexual symptoms with total testosterone levels <320 ng/dL and free testosterone levels <64 pg/mL in community-dwelling older men.

A series of placebo-controlled testosterone trials have provided important information about the efficacy of testosterone in improving outcomes in older men. Testosterone replacement in older men, aged ≥65, with sexual symptoms improved sexual activity, sexual desire, and erectile function more than placebo. Testosterone replacement did not improve fatigue or cognitive function and had only a small effect on mood and mobility. Among older men with low testosterone and age-associated memory impairment, testosterone replacement did not improve memory or other measures of cognition relative to placebo. Testosterone replacement was associated with significantly greater increase in vertebral as well as femoral volumetric bone mineral density and estimated bone strength relative to placebo. Testosterone replacement was associated with a greater increase in hemoglobin levels and corrected anemia in a greater proportion of men who had unexplained anemia of aging. Testosterone administration was associated with a significantly greater increase in coronary artery noncalcified plaque volume, as measured by coronary artery computed tomography angiography. Neither the testosterone trials nor a randomized trial of the effects of testosterone on atherosclerosis progression in aging men (TEAAM trial) with low or low normal testosterone levels found significant differences between testosterone and placebo arms in the rates of change in either the coronary artery calcium scores or the common carotid artery intima-media thickness. Neither of the trials was long enough or large enough to determine the effects of testosterone replacement therapy on prostate or major adverse cardiovascular events. In systematic reviews of randomized controlled trials, testosterone therapy of healthy older men with low or low-normal testosterone levels was associated with greater increments in lean body mass, grip strength, and self-reported physical function than that associated with placebo. Testosterone therapy has not been shown to improve clinical depression, fracture risk, progression to dementia, progression from prediabetes to diabetes, or response to phosphodiesterase inhibitors in older men.

The long-term risks of testosterone therapy remain largely unknown. While there is no evidence that testosterone causes prostate cancer, there is concern that testosterone therapy might cause subclinical prostate cancers to grow. Testosterone therapy is associated with increased risk of detection of prostate events.

The data relating cardiovascular disease (CVD) and venous thromboembolic (VTE) risk with the use of testosterone supplementation in men with low testosterone levels and hypogonadal symptoms are few and inconclusive. The relationship between testosterone and cardiovascular events in cross-sectional and prospective cohort studies has been inconsistent. A small number of epidemiologic studies have reported an inverse relationship between testosterone concentrations and common carotid artery intima-media thickness. Low testosterone level has been associated with increased risk of all-cause mortality, especially cardiovascular mortality. It is possible that testosterone is a marker of health; older men with multiple comorbid conditions who are at increased risk of death may have low testosterone levels as a result of comorbid conditions.

Most meta-analyses have not shown a statistically significant association between testosterone and cardiovascular events, major adverse cardiovascular events, or deaths. No adequately powered randomized trials have been conducted to determine the effects of testosterone replacement on major adverse cardiovascular events. Thus, there are insufficient data to establish a causal link between testosterone therapy and cardiovascular events.

Population screening of all older men for low testosterone levels is not recommended, and testing should be restricted to men who have symptoms or signs attributable to androgen deficiency. Testosterone therapy is not recommended for all older men with low testosterone levels. In older men with significant symptoms of androgen deficiency who have unequivocally low testosterone levels, testosterone therapy may be considered on an individualized basis and should be instituted after careful discussion of the risks and benefits (see "Testosterone Replacement," below).

Testicular morphology, semen production, and fertility are maintained up to a very old age in men. Although concern has been expressed about age-related increases in germ cell mutations and impairment of DNA repair mechanisms, there is no clear evidence that the frequency of chromosomal aneuploidy is increased in the

sperm of older men. However, the incidence of autosomal dominant diseases, such as achondroplasia, polyposis coli, Marfan syndrome, and Apert syndrome, increases in the offspring of men who are advanced in age, consistent with transmission of sporadic missense mutations. Advanced paternal age may be associated with increased rates of de novo mutations, which may contribute to an increased risk of neurodevelopmental diseases such as schizophrenia and autism. The somatic mutations in male germ cells that enhance the proliferation of germ cells could lead to within-testis expansion of mutant clonal lines, thus favoring the propagation of germ cells carrying these pathogenic mutations and increasing the risk of mutations in the offspring of older fathers (the "selfish spermatogonial selection" hypothesis).

APPROACH TO THE PATIENT

Androgen Deficiency

Hypogonadism is often characterized by decreased sex drive, reduced frequency of sexual activity, inability to maintain erections, reduced beard growth, loss of muscle mass, decreased testicular size, and gynecomastia. Erectile dysfunction and androgen deficiency are two distinct clinical disorders that can coexist in middle-aged and older men. Some, but not all, patients with erectile dysfunction have testosterone deficiency. Thus, it is useful to evaluate men presenting with erectile dysfunction for androgen deficiency. Except when extreme, these clinical features of androgen deficiency may be difficult to distinguish from changes that occur with normal aging. Moreover, androgen deficiency may develop gradually. When symptoms or clinical features suggest possible androgen deficiency, the laboratory evaluation is initiated by the measurement of total testosterone in a fasting specimen, preferably in the morning using a reliable assay, such as LC-MS/MS that has been calibrated to an international testosterone standard **(Fig. 391-7)**. A consistently low total testosterone level below the lower limit of the normal male range, measured by an LC-MS/MS assay in a CDC-certified laboratory, in association with symptoms, is evidence of testosterone deficiency. An early-morning testosterone level >400 ng/dL makes the diagnosis of androgen deficiency unlikely. In men with testosterone levels between 200 and 400 ng/dL, the total testosterone level should be repeated, and a free testosterone level should be measured. In older men and in patients with other clinical states that are associated with alterations in SHBG levels, a direct measurement of free testosterone level by equilibrium dialysis can be useful in unmasking testosterone deficiency.

When androgen deficiency has been confirmed by the consistently low testosterone concentrations, LH should be measured to classify the patient as having primary (high LH) or secondary (low or inappropriately normal LH) hypogonadism. An elevated LH level indicates that the defect is at the testicular level. Common causes of primary testicular failure include Klinefelter syndrome, HIV infection, uncorrected cryptorchidism, cancer chemotherapeutic agents, radiation, surgical orchiectomy, or prior infectious orchitis. Unless causes of primary testicular failure are known, a karyotype should be performed in men with low testosterone and elevated LH to diagnose Klinefelter syndrome. Men who have a low testosterone but "inappropriately normal" or low LH levels have secondary hypogonadism; their defect resides at the hypothalamic-pituitary level. Common causes of acquired secondary hypogonadism include space-occupying lesions of the sella, hyperprolactinemia, chronic illness, hemochromatosis, excessive exercise, and the use of anabolic-androgenic steroids, opiates, marijuana, glucocorticoids, and alcohol. Measurement of PRL and MRI scan of the hypothalamic-pituitary region can help exclude the presence of a space-occupying lesion. Patients in whom known causes of hypogonadotropic hypogonadism have been excluded are classified as having IHH. It is not unusual for congenital causes of hypogonadotropic hypogonadism, such as Kallmann syndrome, to be diagnosed in young adults.

TREATMENT

Androgen Deficiency

GONADOTROPINS

Gonadotropin therapy is used to establish or restore fertility in patients with gonadotropin deficiency of any cause. Several gonadotropin preparations are available. Human menopausal gonadotropin (hMG; purified from the urine of postmenopausal women) contains 75 IU FSH and 75 IU LH per vial. hCG (purified from the urine of pregnant women) has little FSH activity and resembles LH in its ability to stimulate testosterone production by Leydig cells. Recombinant LH is also available. Treatment is usually begun with hCG alone, and hMG is added later to promote the FSH-dependent stages of spermatid development. Recombinant human FSH (hFSH) is available and is indistinguishable from purified urinary hFSH in its biologic activity and pharmacokinetics in vitro and in vivo, although the mature β subunit of recombinant hFSH has seven fewer amino acids. Recombinant hFSH is available in ampoules containing 75 IU (~7.5 μg FSH), which accounts for >99% of protein content. Once spermatogenesis is restored using combined FSH and LH therapy, hCG alone is often sufficient to maintain spermatogenesis.

Although a variety of treatment regimens are used, 1000 IU of hCG or recombinant human LH (rhLH) administered intramuscularly three times weekly is a reasonable starting dose. Testosterone levels should be measured 6–8 weeks later and 48–72 h after the hCG or rhLH injection; the hCG/rhLH dose should be adjusted to achieve testosterone levels in the mid-normal range. Sperm counts should be monitored on a monthly basis. It may take several months for spermatogenesis to be restored; therefore, it is important to forewarn patients about the potential length and expense of the treatment and to provide conservative estimates of success rates. If testosterone levels are in the mid-normal range but the sperm concentrations are low after 6 months of therapy with hCG alone, FSH should be added. This can be done by using hMG, highly purified urinary hFSH, or recombinant hFSH. The selection of FSH dose is empirical. A common practice is to start with the addition of 75 IU FSH three times each week in conjunction with the hCG/rhLH injections. If sperm densities are still low after 3 months of combined treatment, the FSH dose should be increased to 150 IU. Occasionally, it may take ≥18–24 months for spermatogenesis to be restored.

The two best predictors of the success of gonadotropin therapy in hypogonadotropic men are testicular volume at presentation and time of onset of gonadotropin deficiency. In general, men with testicular volumes >8 mL have better response rates than those who have testicular volumes <4 mL. Patients who become hypogonadotropic after puberty experience higher success rates than those who have never undergone pubertal changes. Spermatogenesis can usually be reinitiated by hCG alone, with high rates of success for men with postpubertal onset of hypogonadotropism. The presence of a primary testicular abnormality, such as cryptorchidism, will attenuate testicular response to gonadotropin therapy. Prior androgen therapy does not preclude subsequent response to gonadotropin therapy, although some studies suggest that it may attenuate response to subsequent gonadotropin therapy.

TESTOSTERONE REPLACEMENT

Androgen therapy is indicated to restore testosterone levels to normal to correct features of androgen deficiency in men with organic hypogonadism due to known diseases of the testes, pituitary, and the hypothalamus. Testosterone replacement induces secondary sex characteristics; improves libido and overall sexual activity; increases lean muscle mass, hemoglobin, hematocrit, and bone mineral density; and decreases fat mass. The benefits of testosterone replacement therapy have only been proven in men who have documented symptomatic androgen deficiency, as demonstrated by testosterone levels that are well below the lower limit of normal.

Testosterone is available in a variety of formulations with distinct pharmacokinetics **(Table 391-3)**. Testosterone serves as a prohormone and is converted to 17β-estradiol by aromatase and to 5α-DHT by steroid 5α-reductase. Therefore, when evaluating testosterone formulations, it is important to consider whether the formulation being used can achieve physiologic estradiol and DHT concentrations, in addition to normal testosterone concentrations. The current recommendation is to restore testosterone levels to the mid-normal range.

Oral Derivatives of Testosterone Testosterone is well absorbed after oral administration but is quickly degraded during the first pass through the liver. Therefore, it is difficult to achieve sustained blood levels of testosterone after oral administration of crystalline testosterone. 17α-Alkylated derivatives of testosterone (e.g., 17α-methyl testosterone, oxandrolone, fluoxymesterone) are relatively resistant to hepatic degradation and can be administered orally; however, because of the potential for hepatotoxicity, including cholestatic jaundice, peliosis, and hepatoma, these formulations should not be used for testosterone replacement. Hereditary angioedema due to C1 esterase deficiency is the only exception to this general recommendation; in this condition, oral 17α-alkylated androgens are useful because they stimulate hepatic synthesis of the C1 esterase inhibitor.

Injectable Forms of Testosterone The esterification of testosterone at the 17β-hydroxy position makes the molecule hydrophobic and extends its duration of action. The slow release of testosterone ester from an oily depot in the muscle accounts for its extended duration of action. The longer the side chain, the greater is the hydrophobicity of the ester and longer the duration of action. Thus, testosterone enanthate, cypionate, and undecanoate with longer side chains have longer durations of action than testosterone propionate. Within 24 h after intramuscular administration of 200 mg testosterone enanthate or cypionate, testosterone levels rise into the high-normal or supraphysiologic range and then gradually decline into the hypogonadal range over the next 2 weeks. A bimonthly regimen of testosterone enanthate or cypionate therefore results in peaks and troughs in testosterone levels that may be accompanied by changes in a patient's mood, sexual desire, and energy level; weekly administration of testosterone enanthate or cypionate can reduce these variations in testosterone levels during the dosing interval. The kinetics of testosterone enanthate and cypionate are similar. Estradiol and DHT levels are normal if testosterone replacement is physiologic.

A long-acting testosterone undecanoate in oil, administered at an initial priming dose of 750 mg intramuscularly followed by a second dose of 750 mg 4 weeks later, and then at a maintenance dose of 750 mg every 10 weeks, maintains serum testosterone, estradiol, and DHT in the normal male range and corrects symptoms of androgen deficiency in a majority of treated men. However, its relative drawbacks are the large injection volume and the risk of pulmonary oil microembolism (POME) reaction in a very small proportion of patients.

Transdermal Testosterone Patch The nongenital testosterone patch, when applied in an appropriate dose, can normalize testosterone, DHT, and estradiol levels 4–12 h after application. Sexual function and well-being are restored in androgen-deficient men treated with the nongenital patch. One 4-mg patch may not be sufficient to increase testosterone into the mid-normal male range in all hypogonadal men; many patients may need two 4-mg patches daily to achieve the targeted testosterone concentrations. The use of testosterone patches may be associated with skin irritation in some individuals.

Testosterone Gel Several transdermal testosterone gels, Androgel, Testim, Fortesta, and Axiron, and some generic versions, when applied topically to the skin in appropriate doses (Table 391-3), can maintain total and free testosterone concentrations in the normal range in hypogonadal men. The current recommendations are to begin with an initial U.S. Food and Drug Administration–recommended dose and adjust the dose based on testosterone levels.

TABLE 391-3 Clinical Pharmacology of Some Testosterone Formulations

FORMULATION	REGIMEN	PHARMACOKINETIC PROFILE	DHT AND E2	ADVANTAGES	DISADVANTAGES
T enanthate or cypionate	150–200 mg IM q2wk or 70–100 mg/wk	After a single IM injection, serum T levels rise into the supraphysiologic range, then decline gradually into the low-normal or the hypogonadal range by the end of the dosing interval	DHT and E2 levels rise in proportion to the increase in T levels; T:DHT and T:E2 ratios do not change	Corrects symptoms of androgen deficiency; relatively inexpensive if self-administered; flexibility of dosing	Requires IM injection; peaks and valleys in serum T levels that are associated with fluctuations in patient's mood, energy level, and sex drive
Topical T gels and axillary T solution	Available in sachets, tubes, and pumps	When used in appropriate doses, these topical formulations restore serum T and E2 levels to the physiologic male range	Serum DHT levels and DHT:T ratio are higher in hypogonadal men treated with the transdermal gels than in healthy eugonadal men	Corrects symptoms of androgen deficiency, ease of application, good skin tolerability	Potential of transfer to a female partner or child by direct skin-to-skin contact; skin irritation in a small proportion of treated men; moderately high DHT levels; considerable interindividual and intraindividual variation in on-treatment testosterone levels
Transdermal T patch	1 or 2 patches, designed to nominally deliver 4–8 mg T over 24 h applied daily on nonpressure areas	Restores serum T, DHT, and E2 levels to the physiologic male range	T:DHT and T:E2 levels are in the physiologic male range	Ease of application, corrects symptoms of androgen deficiency	Serum T levels in some androgen-deficient men may be in the low-normal range; these men may need application of 2 patches daily; skin irritation at the application site occurs frequently in many patients
Buccal, bioadhesive, T tablets	30-mg, controlled-release, bioadhesive tablets bid	Absorbed from the buccal mucosa	Normalizes serum T and DHT levels in hypogonadal men	Corrects symptoms of androgen deficiency	Gum-related adverse events in 16% of treated men
T pellets	Several pellets implanted SC; dose and regimen vary with formulation	Serum T peaks at 1 month and then is sustained in normal range for 3–4 months, depending on formulation	T:DHT and T:E2 ratios do not change	Corrects symptoms of androgen deficiency	Requires surgical incision for insertions; pellets may extrude spontaneously
17α-Methyl T	This 17α-alkylated compound should *not* be used because of potential for liver toxicity	Orally active			Clinical responses are variable; potential for liver toxicity; should *not* be used for treatment of androgen deficiency
Oral T undecanoate (TU)	237 mg PO bid with food	TU formulated in a self-emulsifying drug delivery system that includes hydrophilic and lipophilic excipients to enable the solubilization of TU and its absorption through the lymphatics after oral ingestion with a typical meal. After each administration, serum T levels rise and return to baseline by 12 h. When administered at the recommended dose, average serum T levels are maintained in the normal range in a majority of treated men	High DHT:T ratio	Convenience of oral administration	High DHT:T ratio
Injectable long-acting TU in oil	U.S. regimen 750 mg IM, followed by 750 mg at 4 weeks, and 750 mg every 10 weeks	When administered at the recommended dose, serum T levels are maintained in the normal range in a majority of treated men	DHT and E2 levels rise in proportion to the increase in T levels; T:DHT and T:E2 ratios do not change	Corrects symptoms of androgen deficiency; requires infrequent administration	Requires IM injection of a large volume; serious pulmonary oil microembolism (POME) reactions, characterized by cough, dyspnea, throat tightening, chest pain, dizziness, and syncope, and episodes of anaphylaxis have been reported to occur during or immediately after the injection in a very small number of patients; patients should be watched for POME reaction for 30 min after each injection
T-in-adhesive matrix patch[a]	2 × 60 cm^2 patches delivering ~4.8 mg of T/d	Restores serum T, DHT, and E2 to the physiologic range	T:DHT and T:E2 are in the physiologic range	Lasts 2 d	Some skin irritation
Intranasal T	2 actuations of the metered-dose pump (11 mg) applied into the nostrils 3 times daily	Restores T into the normal male range	T:DHT and T:E2 ratio in the physiologic range		Requires 3 times daily application; nasal irritation, epistaxis, nasopharyngitis

[a]These formulations are not approved for clinical use in the United States but are available outside the United States in many countries. Physicians in those countries where these formulations are available should follow the approved drug regimens.

Abbreviations: DHT, dihydrotestosterone; E2, estradiol; T, testosterone.

The advantages of the testosterone gel include the ease of application. A major concern is the potential for inadvertent transfer of the gel to a sexual partner or to children who may come in close contact with the patient. The ratio of DHT to testosterone concentrations is higher in men treated with the testosterone gel than in healthy men. Also, there is considerable intra- and interindividual variation in serum testosterone levels in men treated with the transdermal gel due to variations in transdermal absorption and plasma clearance of testosterone. Therefore, monitoring of serum testosterone levels and multiple dose adjustments may be required to achieve and maintain testosterone levels in the target range.

Buccal Adhesive Testosterone A buccal testosterone tablet, which adheres to the buccal mucosa and releases testosterone as it is slowly dissolved, has been approved. After twice-daily application of 30-mg tablets, serum testosterone levels are maintained within the normal male range in a majority of treated hypogonadal men. The adverse effects include buccal ulceration and gum problems in a few subjects. The effects of food and brushing on absorption have not been studied in detail.

Pellets of crystalline testosterone can be inserted in the subcutaneous tissue through a small skin incision. Testosterone is released by surface erosion of the implant and absorbed into the systemic circulation, and testosterone levels can be maintained in the normal range for 3–4 months. Potential drawbacks include incising the skin for insertion and removal and spontaneous extrusions and fibrosis at the site of the implant.

Testosterone undecanoate, formulated in a self-emulsifying drug delivery system that includes hydrophilic and lipophilic excipients to enable its solubilization in the gut, is absorbed through the lymphatics after oral ingestion with a typical meal and is spared the first-pass degradation in the liver. After each administration, serum testosterone levels rise and return to baseline by 12 h. When administered at the recommended dose, average serum testosterone levels are maintained in the normal range in a majority of treated men, but DHT-to-testosterone ratios are higher in hypogonadal men treated with oral testosterone undecanoate, as compared to eugonadal men.

An intranasal testosterone gel is now available as a metered-dose pump and is administered typically at a starting dose of 11 mg testosterone in the form of two pump actuations, one in each nostril three times daily. Formulation-specific adverse effects include rhinorrhea, nasal discomfort, epistaxis, nasopharyngitis, and nasal scab.

Novel Androgen Formulations A number of androgen formulations with better pharmacokinetics or more selective activity profiles are under development. Long-acting biodegradable microsphere formulations have also been investigated. 7α-Methyl-19-nortestosterone is an androgen that cannot be 5α-reduced; therefore, compared to testosterone, it has relatively greater agonist activity in muscle and gonadotropin suppression but lesser activity on the prostate.

Selective AR modulators (SARMs) are a class of AR ligands that bind the AR and display tissue-selective actions. A number of nonsteroidal SARMs that act as agonists on the muscle and bone and that spare the prostate to varying degrees have advanced to phase 3 human trials. Nonsteroidal SARMs do not serve as substrates for either the steroid 5α-reductase or the CYP19 (aromatase). SARM binding to AR induces specific conformational changes in the AR protein, which then modulates protein–protein interactions between AR and its coregulators, resulting in tissue-specific regulation of gene expression. SARMs that are strong agonists for the muscle, bone, and sexual function and antagonists for the prostate may be valuable in treating men with prostate cancer who are receiving androgen deprivation therapy.

Pharmacologic Uses of Androgens Androgens and SARMs are being evaluated as anabolic therapies for functional limitations associated with aging and chronic illness. Testosterone supplementation increases skeletal muscle mass, maximal voluntary strength, and muscle power in healthy men, hypogonadal men, older men with low testosterone levels, HIV-infected men with weight loss, and men receiving glucocorticoids. These anabolic effects of testosterone are related to testosterone dose and circulating concentrations. Systematic reviews have confirmed that testosterone therapy of HIV-infected men with weight loss promotes improvements in body weight, lean body mass, muscle strength, and depression indices, leading to the recommendation that testosterone be considered as an adjunctive therapy in HIV-infected men who are experiencing unexplained weight loss and who have low testosterone levels. It is unknown whether testosterone therapy of older men with functional limitations is safe and effective in improving physical function, vitality, and health-related quality of life, and reducing disability. Concerns about potential adverse effects of testosterone on the prostate and cardiovascular event rates have encouraged the development of SARMs that are preferentially anabolic and spare the prostate.

Testosterone administration induces hypertrophy of both type 1 and 2 fibers and increases satellite cell (muscle progenitor cells) and myonuclear number. Androgens promote the differentiation of mesenchymal, multipotent progenitor cells into the myogenic lineage and inhibit their differentiation into the adipogenic lineage. Testosterone binding to AR promotes the association of liganded AR with β-catenin and its translocation into the nucleus where it binds TCF-4 and activates Wnt-target genes, including follistatin, which blocks signaling through the transforming growth factor β pathway, thereby promoting myogenic differentiation of muscle progenitor cells. Testosterone may have additional effects on satellite cell replication and polyamine pathway, which may contribute to an increase in skeletal muscle mass.

Other indications for androgen therapy are in selected patients with anemia due to bone marrow failure (an indication largely supplanted by erythropoietin) or for hereditary angioedema.

Male Hormonal Contraception Based on Combined Administration of Testosterone and Gonadotropin Inhibitors Supraphysiologic doses of testosterone (200 mg testosterone enanthate weekly) suppress LH and FSH secretion and induce azoospermia in 50% of Caucasian men and >95% of Chinese men. The WHO-supported multicenter efficacy trials have demonstrated that suppression of spermatogenesis to azoospermia or severe oligozoospermia (<3 million/mL) by administration of supraphysiologic doses of testosterone enanthate to men results in highly effective contraception. Because of concern about long-term adverse effects of supraphysiologic testosterone doses, regimens that combine other gonadotropin inhibitors, such as GnRH antagonists and progestins, with replacement doses of testosterone have been investigated. Regimens containing an androgen plus a progestin such as depo-medroxyprogesterone acetate, etonogestrel, or norethisterone enanthate have been highly effective in inducing azoospermia or severe oligozoospermia (sperm density <1 million/mL) in nearly 99% of treated men over a 1-year period. The combined regimens of testosterone plus a progestin have been associated with weight gain, acne, mood changes including depressed mood, libido changes, and decreased plasma high-density lipoprotein (HDL) cholesterol, and their long-term safety has not been demonstrated. One such trial of a combined regimen of testosterone undecanoate plus norethisterone enanthate was stopped early due to adverse events. SARMs, which are more potent inhibitors of gonadotropins than testosterone and spare the prostate, hold promise for their contraceptive potential.

Recommended Regimens for Androgen Replacement Testosterone esters are administered typically at doses of 70–100 mg intramuscularly every week or 140–200 mg every 2 weeks. Testosterone undecanoate is administered at an initial dose of 750 mg followed 4 weeks later by a second injection of 750 mg and then 750 mg every 10 weeks. Testosterone gels are typically applied over a covered area of skin at initial doses that vary with the formulation. Patients should wash their hands after gel application and keep the area of gel application covered with clothing to minimize the risk of gel transfer to another person. One or two 4-mg nongenital

testosterone patches are applied daily over the skin of the back, thigh, or upper arm away from pressure areas. Bioadhesive buccal testosterone tablets at a dose of 30 mg are applied twice daily on the buccal mucosa. Oral testosterone undecanoate is taken twice daily with meals at a starting dose of 237 mg. Intranasal testosterone is administered as a spray in each nostril three times a day (33 mg/d).

Evaluating Efficacy of Testosterone Replacement Therapy Because a clinically useful marker of androgen action is not available, correction of symptoms, induction and maintenance of secondary sex characteristics, and restoration of testosterone levels into the mid-normal range remain the goals of therapy. Measurements of LH and FSH are not useful in assessing the adequacy of testosterone replacement. Testosterone should be measured 3 months after initiating therapy to assess adequacy of therapy. There is substantial interindividual variability in serum testosterone levels, especially with transdermal gels, presumably due to genetic differences in testosterone clearance and substantial variation in transdermal absorption. In patients who are treated with testosterone enanthate or cypionate, testosterone levels should be 350–600 ng/dL 1 week after the injection. If testosterone levels are outside this range, adjustments should be made either in the dose or in the interval between injections. In men on transdermal patch, gel, or buccal testosterone therapy, testosterone levels should be in the mid-normal range (400–750 ng/dL) 4–12 h after application. If testosterone levels are outside this range, the dose should be adjusted. Multiple dose adjustments are often necessary to achieve testosterone levels in the desired therapeutic range.

Restoration of sexual function, induction and maintenance of secondary sex characteristics, well-being, and maintenance of muscle and bone health are important objectives of testosterone replacement therapy. The patient should be asked about sexual desire and activity, the presence of early morning erections, and the ability to achieve and maintain erections adequate for sexual intercourse. The hair growth in response to androgen replacement is variable and depends on ethnicity. Hypogonadal men with prepubertal onset of androgen deficiency who begin testosterone therapy in their late twenties or thirties may find it difficult to adjust to their newly found sexuality and may benefit from counseling. If the patient has a sexual partner, the partner should be included in counseling because of the dramatic physical and sexual changes that occur with androgen treatment.

Contraindications for Androgen Administration Testosterone administration is contraindicated in men with prostate or breast cancer **(Table 391-4)**. Testosterone therapy should not be administered without further urologic evaluation to men with a palpable prostate nodule or induration, a prostate-specific antigen >3 ng/mL, or severe lower urinary tract symptoms (American Urological Association lower urinary tract symptom score >19). Testosterone replacement should not be administered to men with baseline hematocrit ≥50%, severe untreated obstructive sleep apnea, or uncontrolled or poorly controlled congestive heart failure, or with myocardial infarction, stroke, or acute coronary syndrome in the preceding 3 months.

TABLE 391-4 Conditions in Which Testosterone Administration Is Associated with an Increased Risk of Adverse Outcomes

Conditions in which testosterone administration is associated with very high risk of serious adverse outcomes:
Metastatic prostate cancer
Breast cancer
Conditions in which testosterone administration is associated with moderate to high risk of adverse outcomes:
Undiagnosed prostate nodule or induration
PSA >3
Erythrocytosis (hematocrit >50%)
Severe lower urinary tract symptoms associated with benign prostatic hypertrophy as indicated by American Urological Association/International prostate symptom score >19
Uncontrolled or poorly controlled congestive heart failure
Myocardial infarction, stroke, or acute coronary syndrome in the preceding 3 months

Abbreviation: PSA, prostate-specific antigen.

Monitoring Potential Adverse Experiences The clinical effectiveness and safety of testosterone replacement therapy should be assessed 3–6 months after initiating testosterone therapy and annually thereafter **(Table 391-5)**. Potential adverse effects include acne, oiliness of skin, erythrocytosis, breast tenderness and enlargement, leg edema, and increased risk of detection of prostate events. In addition, there may be formulation-specific adverse effects such as skin irritation with transdermal patch; risk of gel transfer to a sexual partner with testosterone gels; buccal ulceration and gum problems with buccal testosterone; pain and mood fluctuation with injectable testosterone esters; cough and injection site pain with long-acting testosterone undecanoate; and nasal irritation, epistaxis, and nasal scab with intranasal formulation.

Hemoglobin Levels Administration of testosterone to androgen-deficient men is typically associated with only a small (~3%) increase in hemoglobin levels, due to direct effects of testosterone on hematopoietic progenitors in the bone marrow, stimulation of erythropoietin, suppression of hepcidin, and increased iron availability for erythropoiesis. The magnitude of hemoglobin increase during testosterone therapy is greater in older men than younger men and in men who have sleep apnea, a significant smoking history, or chronic obstructive lung disease or who live at high altitude. The frequency of erythrocytosis is higher in hypogonadal men treated with injectable testosterone esters than in those treated with transdermal formulations, presumably due to the higher testosterone dose delivered by the typical regimens of testosterone esters. Erythrocytosis is the most frequent adverse event reported in testosterone trials in middle-aged and older men and is also the most frequent cause of treatment discontinuation in these trials. If hematocrit rises above 54%, testosterone therapy should be stopped until hematocrit has fallen to <50%. After evaluation of the patient for hypoxia and sleep apnea, testosterone therapy may be reinitiated at a lower dose.

Prostate and Serum Prostate-Specific Antigen (PSA) Levels Testosterone replacement therapy increases prostate volume to the size seen in age-matched controls but does not increase prostate volume beyond that expected for age. There is no evidence that testosterone therapy causes prostate cancer. However, androgen administration can exacerbate preexisting metastatic prostate cancer. Many older men harbor microscopic foci of cancer in their prostates. It is not known whether long-term testosterone administration will induce these microscopic foci to grow into clinically significant cancers.

PSA levels are lower in testosterone-deficient men and are restored to normal after testosterone replacement. There is considerable test-retest variability in PSA measurements. Increments in PSA levels after testosterone supplementation in androgen-deficient men are generally <0.5 ng/mL, and increments >1.0 ng/mL over a 3–6-month period are unusual. The 90% confidence interval for the change in PSA values in men with benign prostatic hypertrophy, measured 3–6 months apart, is 1.4 ng/mL. Therefore, the Endocrine Society expert panel suggested that an increase in PSA >1.4 ng/mL in any 1 year after starting testosterone therapy, if confirmed, should lead to urologic evaluation. PSA velocity criterion can be used for patients who have sequential PSA measurements for >2 years; a change of >0.40 ng/mL per year merits closer urologic follow-up. PSA level >4 ng/mL during treatment, if confirmed by repeat testing, requires further urologic evaluation.

Cardiovascular Risk As discussed above, there is insufficient evidence to determine whether testosterone replacement therapy increases the risk of major adverse cardiovascular events in hypogonadal men. In two randomized, placebo-controlled trials, the

TABLE 391-5 Monitoring Men Receiving Testosterone Therapy

1. Evaluate the patient 3–6 months after treatment initiation and then annually to assess whether symptoms have responded to treatment and whether the patient is suffering from any adverse effects.
2. Monitor testosterone level 3–6 months after initiation of testosterone therapy:
   - Therapy should aim to raise serum testosterone level into the mid-normal range.
     - Injectable testosterone enanthate or cypionate: Measure serum testosterone level midway between injections. If testosterone is >600 ng/dL (20.9 nmol/L) or <350 ng/dL (12.2 nmol/L), adjust dose or frequency.
     - Transdermal patches: Assess testosterone level 3–12 h after application of the patch; adjust dose to achieve testosterone level in the mid-normal range.
     - Buccal testosterone bioadhesive tablet: Assess level immediately before application of fresh system.
     - Transdermal gels and solution: Assess testosterone level 2–12 h after patient has been on treatment for at least 2 weeks; adjust dose to achieve serum testosterone level in the mid-normal range.
     - Testosterone pellets: Measure testosterone levels at the end of the dosing interval. Adjust the number of pellets and/or the dosing interval to achieve serum testosterone levels in the normal range
     - Oral testosterone undecanoate: Measure testosterone levels 4–6 h after an oral dose.
     - Injectable testosterone undecanoate: Measure serum testosterone level just prior to each subsequent injection and adjust the dosing interval to maintain serum testosterone in mid-normal range.
3. Check hematocrit at baseline, at 3–6 months, and then annually. If hematocrit is >54%, stop therapy until hematocrit decreases to a safe level; evaluate the patient for hypoxia and sleep apnea; reinitiate therapy with a reduced dose.
4. Measure bone mineral density of lumbar spine and/or femoral neck after 1–2 years of testosterone therapy in hypogonadal men with osteoporosis or low trauma fracture, consistent with regional standard of care.
5. In men aged ≥40 years with baseline PSA >0.6 ng/mL, perform digital rectal examination and check PSA level before initiating treatment, at 3–6 months, and then in accordance with guidelines for prostate cancer screening depending on the age and race of the patient.
6. Obtain urologic consultation if there is:
   - An increase in serum PSA concentration >1.4 ng/mL within any 12-month period of testosterone treatment, confirmed by repeating the test.
   - A PSA level >4 ng/mL any time during treatment, confirmed by repeating the test.
   - Detection of a prostatic abnormality on digital rectal examination.
   - An AUA/IPSS prostate symptom score of >19 along with an increase in IPSS score of ≥5 points above baseline.
7. Evaluate formulation-specific adverse effects at each visit:
   - Buccal testosterone tablets[a]: Inquire about alterations in taste and examine the gums and oral mucosa for irritation.
   - Injectable testosterone esters (enanthate, cypionate, and undecanoate): Ask about fluctuations in mood or libido, and rarely cough after injections.
   - Testosterone patches: Look for skin reaction at the application site.
   - Testosterone gels: Advise patients to cover the application sites with a shirt and to wash the skin with soap and water before having skin-to-skin contact because testosterone gels leave a testosterone residue on the skin that can be transferred to a woman or child who might come in close contact. Serum testosterone levels are maintained when the application site is washed 4–6 h after application of the testosterone gel.
   - Testosterone undecanoate injection: Observe patients for POME reaction for 30 min after each injection.
   - Testosterone pellets: Look for signs of infection, fibrosis, or pellet extrusion.
   - Intranasal testosterone: Look for signs of nasal irritation or scab.

[a]Not approved for clinical use in the United States.

Abbreviations: AUA/IPSS, American Urological Association International Prostate Symptom Score; POME, pulmonary oil microembolism; PSA, prostate-specific antigen.

rate of progression of coronary artery atherosclerosis did not differ between the testosterone- and placebo-treated men. In another randomized trial, compared to placebo, testosterone treatment was associated with greater increase in noncalcified plaque volume in the coronary arteries, assessed using CT coronary angiography. An ongoing large prospective randomized trial (TRAVERSE trial) will determine the effects of testosterone replacement therapy on major adverse cardiovascular events in middle-aged and older hypogonadal men at increased risk of CVD.

Androgen Abuse by Athletes and Recreational Bodybuilders The illicit use of androgenic-anabolic steroids (AAS) to enhance athletic performance first surfaced in the 1950s among powerlifters and spread rapidly to other sports, professional as well as high school athletes, and recreational bodybuilders. In the early 1980s, the use of AAS spread beyond the athletic community into the general population, and now, as many as 3–4 million Americans—most of them men—have likely used these compounds. Most AAS users are not athletes, but rather recreational weightlifters, almost all men, who use these drugs to look lean and more muscular. A subset of AAS users suffers from muscle dysmorphia, a form of body image disorder characterized by excessive preoccupation with leanness and muscularity and poor functioning in social and occupational life. A secular transformation in idealized body image toward greater muscularity and leanness has contributed to increasing prevalence of body image disorders and the use of muscle-building anabolic drugs in young men.

The most commonly used AAS include testosterone esters, nandrolone, stanozolol, methandienone, and methenolol. AAS users generally use large doses of multiple steroids in cycles, a practice known as stacking. AAS users may also typically use other drugs that are perceived to be muscle building or performance enhancing, such as human GH; erythropoiesis-stimulating agents; insulin; stimulants such as amphetamine, clenbuterol, cocaine, ephedrine, and thyroxine; and drugs perceived to reduce adverse effects such as hCG, aromatase inhibitors, or estrogen antagonists. Recent years have witnessed increasing use of unapproved nonsteroidal SARMs and GH secretagogues purchased from internet sites.

Most of the information about the adverse effects of AAS has emerged from case reports, uncontrolled studies, or clinical trials that used replacement doses of testosterone. The adverse event data from clinical trials using physiologic replacement doses of testosterone have been extrapolated unjustifiably to AAS users, who may administer 10–100 times the replacement doses of testosterone over many years, to support the claim that AAS use is safe and manageable. The adverse events associated with AAS use may be due to AAS themselves, concomitant use of other drugs, high-risk behaviors, and host characteristics that may render these individuals more susceptible to AAS use or to other high-risk behaviors.

The high rates of premature mortality and morbidities observed in AAS users are alarming. One Finnish study reported 4.6 times the risk of death among elite powerlifters compared with age-matched men from the general population. The causes of death among powerlifters included suicides, myocardial infarction, and liver failure. A retrospective review of patient records in Sweden also reported higher standardized mortality ratios for AAS users than for nonusers and increased death rates due to suicide, homicide, and accidents.

Four categories of adverse events associated with AAS abuse are of particular concern: cardiovascular events, psychiatric, prolonged suppression of the hypothalamic-pituitary-testicular axis, and potential neurotoxicity. Numerous reports of premature cardiac death among young AAS users raise concerns about the adverse cardiovascular effects of AAS. High doses of AAS may induce proatherogenic dyslipidemia, accelerate atherogenesis, increase thrombosis risk via effects on clotting factors and platelets, and induce vasospasm through their effects on vascular nitric oxide. Long-term AAS use may be associated with myocardial hypertrophy and fibrosis. Myocardial tissue of powerlifters using AAS has been shown to be infiltrated with fibrous tissue and fat droplets. Current AAS users display significantly reduced left ventricular systolic and diastolic function compared to previous users and nonusers. Additionally, studies using CT angiography have reported higher coronary artery plaque volume in AAS users than

in nonusers. Lifetime AAS dose is strongly associated with coronary atherosclerotic burden. Power athletes using AAS often have short QT intervals but increased QT dispersion, which may predispose them to ventricular arrhythmias.

Unlike replacement doses of testosterone, which are associated with only a small decrease in HDL cholesterol and little or no effect on total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels, supraphysiologic doses of testosterone and orally administered 17α-alkylated, nonaromatizable AAS are associated with marked reductions in HDL cholesterol and increases in LDL cholesterol.

Some AAS users develop hypomanic and manic symptoms (irritability, aggressiveness, reckless behavior, and occasional psychotic symptoms, sometimes associated with violence) during AAS exposure, and depression, sometimes associated with suicidality, during AAS withdrawal. Users may also be susceptible to other forms of illicit drug use.

Long-term AAS use suppresses LH, FSH, and testosterone production and spermatogenesis. Men who have used AAS for more than a few months experience marked suppression of the hypothalamic-pituitary-testicular (HPT) axis after stopping AAS that may be associated with sexual dysfunction, fatigue, infertility, depressed mood, and even suicidality. In some long-term AAS users, recovery of the HPT axis may take a long time, may be incomplete, or may never occur. The symptoms of androgen deficiency caused by androgen withdrawal may cause some men to revert back to using AAS, leading to continued use and AAS dependence. As many as 30% of AAS users develop a syndrome of AAS dependence, characterized by long-term AAS use despite adverse medical and psychiatric effects. AAS withdrawal hypogonadism has emerged as an important cause of androgen deficiency, accounting for a substantial fraction of testosterone prescriptions in many men's health clinics; therefore, AAS use should be considered in the differential diagnosis of hypogonadism in young men.

Supraphysiologic doses of testosterone may also impair insulin sensitivity. Orally administered androgens also have been associated with insulin resistance and diabetes.

AAS users are more likely to engage in high-risk behaviors such as unsafe injection practices and have increased rates of incarceration that may render them at increased risk of HIV and hepatitis B and C. AAS users are more likely to report high-risk unprotected anal sex than nonusers.

Elevated liver enzymes, cholestatic jaundice, hepatic neoplasms, and peliosis hepatis have been reported with oral, 17α-alkylated AAS. AAS use may cause muscle hypertrophy without compensatory adaptations in tendons, ligaments, and joints, thus increasing the risk of tendon and joint injuries. Upper extremity tendon ruptures are observed almost exclusively among weightlifters who use AAS. AAS use is associated with acne, baldness, and increased body hair.

APPROACH TO THE PATIENT

Androgenic-Anabolic Steroids Use

The suspicion of AAS use should be raised by increased hemoglobin and hematocrit levels, suppressed LH and FSH and testosterone levels, low HDL cholesterol, and low testicular volume and sperm density in a person who looks highly muscular. In AAS users seeking medical attention, evaluation using the Appearance and Performance Enhancing Drug Use Schedule (APEDUS), a validated semi-structured interview, is sufficient to assess the associated body image or eating disorder, psychiatric symptoms, and the use of AAS and other substances; formal testing for AAS usually is not needed. History of AAS use should be obtained in all young men being evaluated for hypogonadism. As AAS use is often associated with the use of other substances, a urine dug screen for other substances is helpful in guiding treatment. If needed, accredited laboratories use gas chromatography–mass spectrometry or liquid chromatography–mass spectrometry to detect anabolic steroid abuse. High-resolution mass spectrometry and tandem mass spectrometry have further improved the sensitivity of detecting AAS use. Illicit testosterone use is detected generally by the measurement of urinary testosterone-to-epitestosterone ratio and further confirmed by the ^{13}C:^{12}C ratio in testosterone using isotope ratio combustion mass spectrometry. Exogenous testosterone administration increases urinary testosterone glucuronide excretion and consequently the testosterone-to-epitestosterone ratio. Ratios >4 suggest exogenous testosterone use but can also reflect genetic variation. Genetic variations in the uridine diphospho-glucuronyltransferase 2B17 (*UGT2B17*), the major enzyme for testosterone glucuronidation, affect the testosterone-to-epitestosterone ratio. Synthetic testosterone has a lower ^{13}C:^{12}C ratio than endogenously produced testosterone, and these differences in ^{13}C:^{12}C ratio can be detected by isotope ratio combustion mass spectrometry, which is used to confirm exogenous testosterone use in individuals with a high testosterone-to-epitestosterone ratio.

The treatment of AAS use disorder requires a multidisciplinary team that includes an endocrinologist or an internist to treat the AAS withdrawal hypogonadism and other medical problems; a mental health expert to treat the substance use disorder and depressive symptoms and to address suicide risk and body image disorder; and sometimes a social worker for care coordination. In patients who are willing to stop or who have already stopped AAS use, the initial step is to restore the hypothalamic-pituitary-gonadal axis by administering either clomiphene (or its enantiomer trans enclomiphene), a partial estrogen agonist, at an initial dose of 50 mg daily or hCG at a dose of 750–1000 IU three times weekly. Some men may not respond to clomiphene and may require switching to hCG. AAS users also need evaluation and treatment of the underlying body image disorder. Mirror exposure therapy in which the patient stands in front of a mirror and describes his body appearance to the mental health provider has been moderately efficacious in small, randomized trials. Body dysmorphia may require cognitive-behavioral therapy or pharmacotherapy using selective serotonin uptake inhibitors or tricyclic antidepressants.

392 Disorders of the Female Reproductive System

Janet E. Hall, Anuja Dokras

The female reproductive system regulates the hormonal changes responsible for puberty and adult reproductive function. Normal reproductive function in women requires the dynamic integration of hormonal signals from the hypothalamus, pituitary, and ovary, resulting in repetitive cycles of follicle development, ovulation, and preparation of the endometrial lining of the uterus for implantation should conception occur.

For further discussion of related topics, see the following chapters: amenorrhea and pelvic pain **(Chap. 393)**, infertility and contraception **(Chap. 396)**, menopause **(Chap. 395)**, disorders of sex development **(Chap. 390)**, and disorders of the male reproductive system **(Chap. 391)**.

DEVELOPMENT OF THE OVARY AND EARLY FOLLICULAR GROWTH

The ovary orchestrates the development and release of a mature oocyte and secretes hormones (e.g., estrogen, progesterone, inhibins A and B, relaxin) that play critical roles in a variety of target tissues, including breast, bone, and uterus, in addition to the hypothalamus and pituitary. To achieve these functions in repeated monthly cycles, the ovary undergoes some of the most dynamic changes of any organ in the body. Primordial germ cells can be identified by the third week of gestation, and their migration to the genital ridge is complete by 6 weeks of gestation. Germ cells persist within the genital ridge, are then referred to as *oogonia*, and are essential for induction of ovarian development. In patients with 45,X Turner syndrome, primordial germ cells proliferate and migrate to the genital ridge but do not persist because their survival requires pregranulosa cells that are dependent on the presence of both X chromosomes **(Chap. 390)**.

The germ cell population expands, and starting at ~8 weeks of gestation, oogonia begin to enter prophase of the first meiotic division and become primary oocytes. This allows the oocyte to be surrounded by a single layer of flattened granulosa cells to form a primordial follicle **(Fig. 392-1)**. Granulosa cells are derived from mesonephric cells that migrate into the ovary early in its development, pushing the germ cells to the periphery. Although there is evidence that both oocyte-like cells and follicle-like structures can form from embryonic stem cells in culture, there is, as yet, no clear evidence that this occurs in vivo, and thus, the ovary appears to contain a nonrenewable pool of germ cells. Through the combined processes of mitosis, meiosis, and atresia, the population of oogonia reaches its maximum of 6–7 million by 20 weeks in the fetus, after which there is a progressive loss of both oogonia and primordial follicles through the process of atresia. It appears that entry into meiosis provides some degree of protection from programmed cell death. At birth, oogonia are no longer present in the ovary, and only 1–2 million germ cells remain in the form of primordial follicles **(Fig. 392-2)**. The oocyte persists in prophase of the first meiotic division until just before ovulation, when meiosis resumes.

The quiescent primordial follicles are recruited to further growth and differentiation through a highly regulated process that limits the size of the developing cohort to ensure that folliculogenesis can continue throughout the reproductive life span. This initial recruitment of primordial follicles to form primary follicles (Fig. 392-1) is characterized by growth of the oocyte and the transition from squamous to cuboidal granulosa cells. The theca interna cells that surround the developing follicle begin to form as the primary follicle grows. Acquisition of a zona pellucida by the oocyte and the presence of several layers of surrounding cuboidal granulosa cells mark the development of secondary follicles. It is at this stage that granulosa cells develop follicle-stimulating hormone (FSH), estradiol, and androgen receptors and communicate with one another through the development of gap junctions.

Bidirectional signaling between the germ cells and the somatic cells in the ovary is a necessary component underlying the maturation of the oocyte and the capacity for hormone secretion. For example, oocyte-derived growth differentiation factor 9 (GDF-9) and bone morphogenic protein-15 (BMP-15), also known as GDF-9b, are required for migration of pregranulosa and pretheca cells to the outer surface of the developing follicle and, hence, initial follicle formation. GDF-9 is also required for formation of secondary follicles, as are granulosa cell–derived KIT ligand (KITL) and the forkhead transcription factor (FOXL2). A significant number of genes have been identified that are required for development of the normal complement of oogonia in the ovary, initial follicle development, and resistance to follicle loss; all are candidates for premature ovarian insufficiency (POI), and mutations in >50 genes have been identified in patients with POI, with even more that have been associated with an earlier age at natural menopause.

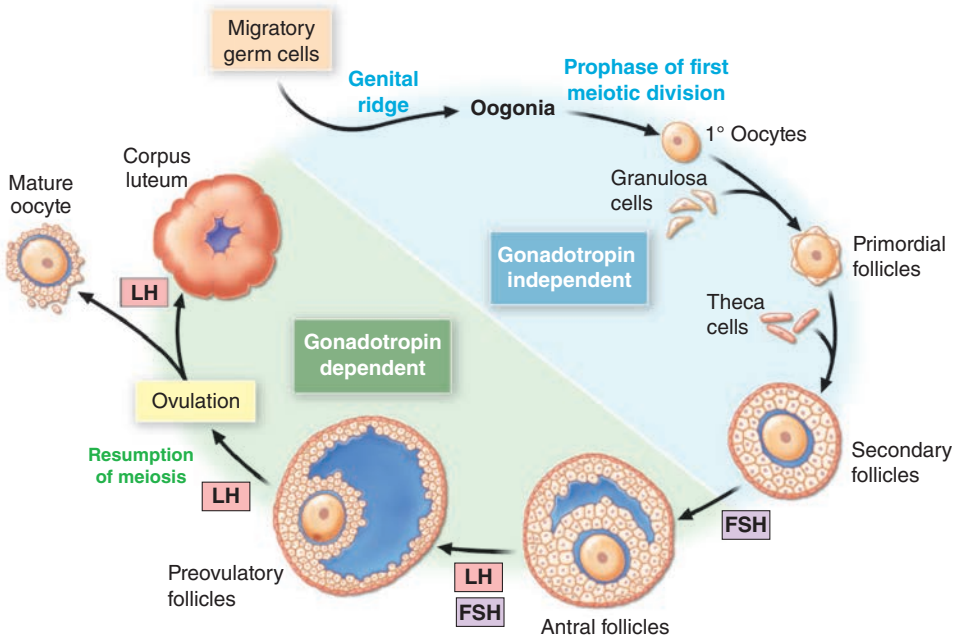

FIGURE 392-1 Stages of ovarian development from the arrival of the migratory germ cells at the genital ridge through gonadotropin-independent and gonadotropin-dependent phases that ultimately result in ovulation of a mature oocyte. FSH, follicle-stimulating hormone; LH, luteinizing hormone.

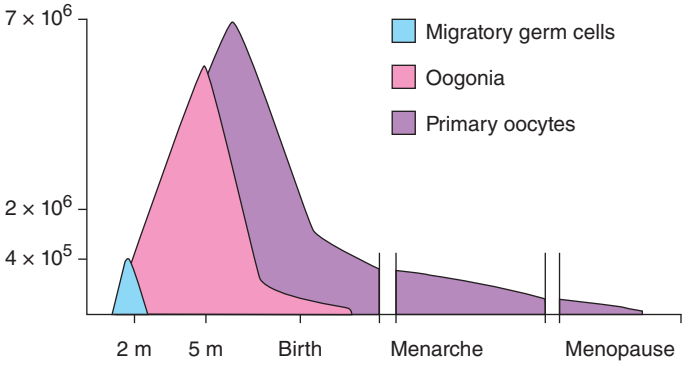

FIGURE 392-2 Ovarian germ cell number is maximal at mid-gestation and decreases precipitously thereafter.

DEVELOPMENT OF A MATURE FOLLICLE

The early stages of follicle growth are primarily driven by intraovarian factors. Further maturation to the preovulatory stage, including the resumption of meiosis in the oocyte, requires the combined stimulus of FSH and luteinizing hormone (LH) (Fig. 392-1). Recruitment of secondary follicles from the resting follicle pool requires the direct action of FSH, whereas anti-müllerian hormone (AMH) produced from small growing follicles (preantral) restrains this effect of FSH, controlling the number of follicles entering the actively growing pool. Accumulation of follicular fluid between the layers of granulosa cells creates an antrum that divides the granulosa cells into two functionally distinct groups: mural cells that line the follicle wall and cumulus cells that surround the oocyte **(Fig. 392-3)**. In addition to its role in normal development of the müllerian system, the WNT signaling pathway is required for normal antral follicle development and may also play a role in ovarian steroidogenesis. Recruitment to the small antral stage generally occurs over several cycles with further growth to follicle sizes of >4–7 mm in waves during a single cycle. A single dominant follicle emerges from the growing follicle pool within the first 5–7 days after the onset of menses while the majority of follicles fall off their growth trajectory and become atretic. Autocrine actions of activin and BMP-6, derived from the granulosa cells, and paracrine actions of GDF-9, BMP-15, BMP-6, and Gpr149, derived from the oocyte, are involved in granulosa cell proliferation and modulation of FSH responsiveness. Differential exposure to these factors, and to vascular endothelial growth factor (VEGF), can alter vascular density and permeability, likely explaining the mechanism whereby a given follicle is selected for continued growth to the preovulatory stage. The dominant follicle can be distinguished by its size, evidence of granulosa cell proliferation, large number of FSH receptors, high aromatase activity, and elevated concentrations of estradiol and inhibin A in follicular fluid. In addition, secretion of estradiol and inhibin from the dominant follicle inhibits FSH and the growth of other follicles.

The dominant follicle undergoes rapid expansion during the 5–6 days prior to ovulation, reflecting granulosa cell proliferation and accumulation of follicular fluid. FSH induces LH receptors on the granulosa cells, and the preovulatory, or Graafian, follicle moves to the outer ovarian surface in preparation for ovulation. The LH surge triggers the resumption of meiosis, the suppression of granulosa cell proliferation, and the induction of cyclooxygenase 2 (COX-2), prostaglandins, the progesterone receptor (PR), and the epidermal growth factor (EGF)-like growth factors amphiregulin, epiregulin, betacellulin, and neuroregulin 1, all of which are required for ovulation. Ovulation requires production of extracellular matrix, leading to expansion of the cumulus cell population that surrounds the oocyte and the controlled expulsion of the egg and follicular fluid. Both progesterone and prostaglandins (induced by the ovulatory stimulus) are essential for this process, as are members of the matrix metalloproteinase family. After ovulation, luteinization of theca and granulosa cells is induced by LH in conjunction with the acquisition of a rich vascular network in response to VEGF and basic fibroblast growth factor (FGF). Traditional regulators of central reproductive control, gonadotropin-releasing hormone (GnRH) and its receptor (GnRHR), as well as kisspeptin, are also produced in the ovary and may be involved in corpus luteum function.

REGULATION OF OVARIAN FUNCTION

HYPOTHALAMIC AND PITUITARY SECRETION

GnRH neurons derive from cells in the olfactory placode and, to a lesser extent, the neural crest. They migrate along the scaffold of the olfactory neurons across the cribriform plate to the hypothalamus where they separate from the olfactory neurons. Studies in GnRH-deficient patients who fail to undergo puberty have provided insights into genes that control the ontogeny and function of GnRH neurons **(Fig. 392-4)**. *KAL1*, *FGF8/FGFR1*, *PROK2/PROKR2*, *NSMF*, *HS6SD1*, and *CDH7*, among others **(Chap. 391)**, have been implicated in the migration of GnRH neurons to the hypothalamus while *KISS*, *TAC3*, *Dyn* and their receptors are involved in the upstream regulation of GnRH secretion. Approximately 7000 GnRH neurons, scattered throughout the medial basal hypothalamus, establish contacts with capillaries of the pituitary portal system in the median eminence. GnRH is secreted into the pituitary portal system in discrete pulses to stimulate synthesis and secretion of LH and FSH from pituitary gonadotropes, which comprise ~10% of cells in the pituitary **(Chap. 378)**. Functional connections of GnRH neurons with the portal system are established by the end of the first trimester, coinciding with the production of pituitary gonadotropins. Thus, like the ovary, the hypothalamic and pituitary components of the reproductive system are present before birth. However, the high levels of estradiol and progesterone produced by the placenta suppress hypothalamic-pituitary stimulation of ovarian hormonal secretion in the fetus.

After birth and the loss of placenta-derived steroids, gonadotropin levels rise. FSH levels are much higher in girls than in boys. This rise in FSH results in circulating estradiol and increased inhibin B, but without terminal follicle maturation or ovulation. Studies that have identified mutations in *TAC3*, which encodes neurokinin B, and its receptor, *TAC3R*, in patients with GnRH deficiency indicate that both are involved in control of GnRH secretion and may be particularly important at this early stage of development. By 12–20 months of age, the reproductive axis is again suppressed, and a period of relative quiescence persists until puberty **(Fig. 392-5)**. At the onset of puberty, pulsatile GnRH secretion induces pituitary gonadotropin production. In the early stages of puberty, LH and FSH secretion are apparent only during sleep, but as puberty develops, pulsatile LH secretion occurs throughout the day and night.

The mechanisms responsible for the childhood quiescence and pubertal reactivation of the reproductive axis remain incompletely understood. GnRH neurons in the hypothalamus respond to both excitatory and inhibitory factors. Increased sensitivity to the inhibitory

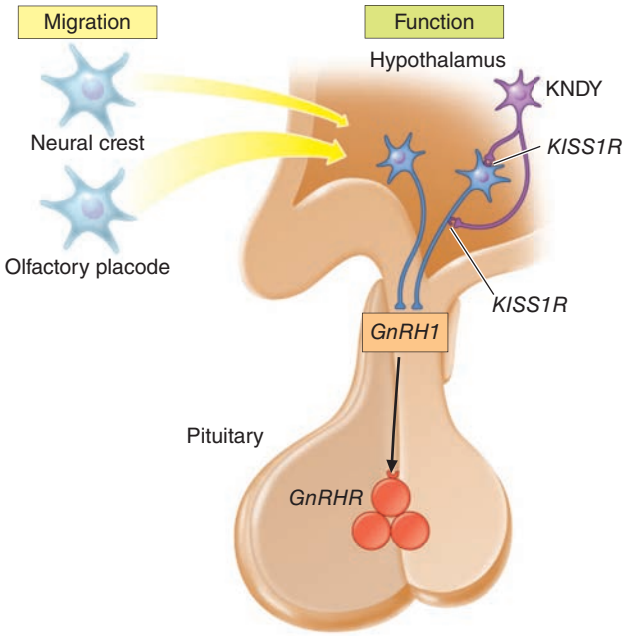

FIGURE 392-4 Genetic studies in patients with congenital forms of hypogonadotropic hypogonadism have expanded our understanding of the development and migration of gonadotropin-releasing hormone (GnRH) neurons from the olfactory placode and neural crest to the hypothalamus as well as the upstream regulation of GnRH secretion by kisspeptin (*KISS1*), neurokinin B (*TAC3*) and dynorphin (*Dyn*) which are co-expressed in the KNDY neurons.

influence of gonadal steroids has long been implicated in the inhibition of GnRH secretion during childhood but has not been definitively established in the human. Metabolic signals, including adipocyte-derived leptin, play a permissive role in reproductive function **(Chap. 401)**. Studies of patients with isolated GnRH deficiency reveal that mutations in the G protein–coupled receptor 54 (*GPR54*) gene (now known as *KISS1R*) preclude the onset of puberty. The ligand for this receptor is derived from the parent peptide, kisspeptin-1 (*KISS1*), and is a powerful stimulant for GnRH release. A potential role for kisspeptin in the onset of puberty has been suggested by upregulation of *KISS1* and *KISS1R* transcripts in the hypothalamus at the time of puberty. *TAC3,* which stimulates GnRH secretion through kisspeptin signaling, and dynorphin (*Dyn*), which plays an inhibitory role in GnRH control, are frequently co-expressed with *KISS1* in KNDY neurons of the median eminence that project to GnRH neurons. This system is intimately involved in both estrogen and progesterone negative feedback regulation of GnRH secretion.

RFamide-related peptides (RFRPs) are the mammalian orthologues of gonadotropin inhibitory hormone (GnIH), which was initially discovered in the quail. While RFRP-1 and RFRP-3 neurons send axonal projections to GnRH neurons in humans and RFRPs are secreted into the pituitary portal system, further studies are required to determine their potential physiologic role in the human.

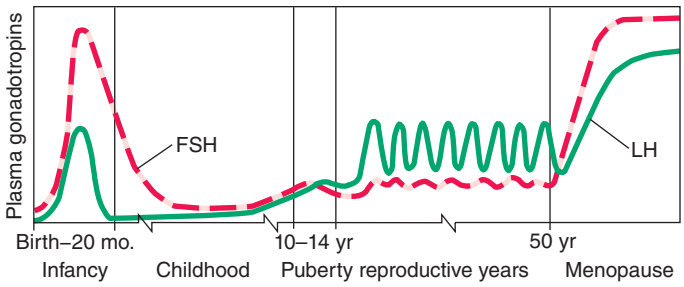

FIGURE 392-5 Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are increased during the neonatal years but go through a period of childhood quiescence before increasing again during puberty. Gonadotropin levels are cyclic during the reproductive years and increase dramatically with the loss of negative feedback that accompanies menopause.

OVARIAN STEROIDS

Ovarian steroid-producing cells do not store hormones but produce them in response to FSH and LH during the normal menstrual cycle. The sequence of steps and the enzymes involved in the synthesis of steroid hormones are similar in the ovary, adrenal, and testis. However, the enzymes required to catalyze specific steps are compartmentalized and may not be abundant or even present in all cell types. Within the developing ovarian follicle, estrogen synthesis from cholesterol requires close integration between theca and granulosa cells—sometimes called the *two-cell model for steroidogenesis* **(Fig. 392-6)**. FSH receptors are confined to the granulosa cells, whereas LH receptors are restricted to the theca cells until the late stages of follicular development, when they are also found on granulosa cells. The theca cells surrounding the follicle are highly vascularized and use cholesterol, derived primarily from circulating lipoproteins, as the starting point for the synthesis of androstenedione and testosterone under the control of LH. These steroid precursors cross the basal lamina to the granulosa cells, which receive no direct blood supply. The mural granulosa cells are particularly rich in aromatase and, under the control of FSH, produce estradiol, the primary steroid secreted from the follicular phase ovary and the most potent estrogen. Theca cell–produced androstenedione and, to a lesser extent, testosterone are also secreted into peripheral blood, where they can be converted to dihydrotestosterone in skin and to estrogens in adipose tissue. The hilar interstitial cells of the ovary are functionally similar to Leydig cells and are also capable of secreting androgens. Stromal cells proliferate in response to androgens (as in polycystic ovary syndrome [PCOS]) but do not secrete androgens. However, high levels of androgens may be produced by luteinized theca cells in women with hyperthecosis.

Development of the rich capillary network following rupture of the follicle at the time of ovulation makes it possible for large molecules such as low-density lipoprotein (LDL) to reach the luteinized granulosa and theca lutein cells. As in the follicle, both cell types are required for steroidogenesis in the corpus luteum. The luteinized granulosa cells are the main source of progesterone production, whereas the smaller theca lutein cells produce 17-hydroxyprogesterone and androgenic substrates for aromatization to estradiol by the luteinized granulosa cells. Production of estrogen metabolites by the corpus luteum plays a significant role in maintenance of the vascularization required for its function. LH is critical for formation and maintenance of corpus luteum structure and function. LH and human chorionic gonadotropin (hCG) bind to a common receptor; thus, in conception cycles, hCG produced upon fertilization rescues the declining function of the

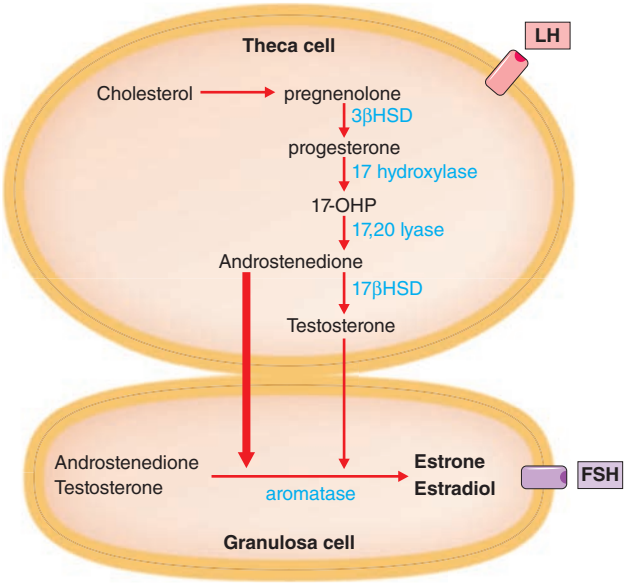

FIGURE 392-6 Estrogen production in the ovary requires the cooperative function of the theca and granulosa cells under the control of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). HSD, hydroxysteroid dehydrogenase; OHP, hydroxyprogesterone.

corpus luteum, maintaining steroid and peptide secretion for the first 10 weeks of pregnancy. hCG is commonly used for luteal phase support in the treatment of infertility.

Steroid Hormone Actions Both estrogen and progesterone play critical roles in the expression of secondary sexual characteristics in women (Chap. 377). Estrogen promotes development of the ductule system in the breast, whereas progesterone is responsible for glandular development. In the reproductive tract, estrogens create a receptive environment for fertilization and support pregnancy and parturition through carefully coordinated changes in the endometrium, thickening of the vaginal mucosa, thinning of the cervical mucus, and uterine growth and contractions. Progesterone induces secretory activity in the estrogen-primed endometrium, increases the viscosity of cervical mucus, and inhibits uterine contractions. Both gonadal steroids play critical roles in negative and positive feedback of gonadotropin secretion. Progesterone also increases basal body temperature, which is used clinically as a marker of ovulation.

The vast majority of circulating estrogens and androgens are carried in the blood bound to carrier proteins, which restrain their free diffusion into cells and prolong their clearance, serving as a reservoir. High-affinity binding proteins include sex hormone–binding globulin (SHBG), which binds androgens with somewhat greater affinity than estrogens, and corticosteroid-binding globulin (CBG), which also binds progesterone. Modulations in binding protein levels by insulin, androgens, and estrogens contribute to high bioavailable testosterone levels in PCOS and to high circulating total estrogen and progesterone levels during pregnancy.

Estrogens act primarily through binding to the nuclear receptors, estrogen receptor (ER) α and β. Transcriptional coactivators and co-repressors modulate ER action (Chap. 377). Both ER subtypes are present in the hypothalamus, pituitary, ovary, and reproductive tract. Although ERα and β exhibit some functional redundancy, there is also a high degree of specificity, particularly in expression within cell types. For example, ERα functions in ovarian theca cells, whereas ERβ is critical for granulosa cell function. There is also evidence for membrane-initiated signaling by estrogen. Similar signaling mechanisms pertain for progesterone with evidence of transcriptional regulation through PR A and B protein isoforms, as well as rapid membrane signaling.

OVARIAN PEPTIDES

Inhibin was initially isolated from gonadal fluids based on its ability to selectively inhibit FSH secretion from pituitary cells. Inhibin is a heterodimer composed of an α subunit and a βA or βB subunit to form inhibin A or inhibin B, both of which are secreted from the ovary. Activin is a homodimer of inhibin β subunits with the capacity to stimulate the synthesis and secretion of FSH. Inhibins and activins are members of the transforming growth factor β (TGF-β) superfamily of growth and differentiation factors. During the purification of inhibin, follistatin, an unrelated monomeric protein that inhibits FSH secretion, was discovered. Within the pituitary, follistatin inhibits FSH secretion indirectly by binding and neutralizing activin.

Inhibin B is constitutively secreted from the granulosa cells of small antral follicles, and its serum levels increase in conjunction with granulosa cell proliferation during recruitment of secondary follicles under the control of FSH. Inhibin B is an important inhibitor of FSH, independent of estradiol, during the menstrual cycle. Inhibin A is present in both granulosa and theca cells and is secreted by the dominant follicle. Inhibin A is also present in luteinized granulosa cells and is a major secretory product of the corpus luteum. Synthesis and secretion of inhibin A are directly controlled by FSH and LH. Although activin is also secreted from the ovary, the excess of follistatin in serum, combined with its nearly irreversible binding of activin, make it unlikely that ovarian activin plays an endocrine role in FSH regulation. However, there is evidence that activin plays an autocrine/paracrine role in the ovary, in addition to its intrapituitary role in modulation of FSH production.

AMH (also known as müllerian-inhibiting substance) is important in ovarian biology in addition to the function from which it derived its name (i.e., promotion of the degeneration of the müllerian system during embryogenesis in the male). AMH is produced by granulosa cells from small preantral and early antral follicles and is a marker of ovarian reserve with advantages over inhibin B because of its relative stability across the menstrual cycle. AMH inhibits the recruitment of primordial follicles into the follicle pool and counters FSH stimulation of aromatase expression. AMH levels are highest in the early twenties and decrease markedly by menopause. AMH is increased in PCOS in conjunction with the abundance of small follicles in this disorder.

Gonadotropin surge attenuating factor (GnSAF) is an ovarian factor that attenuates GnRH-induced gonadotropin secretion. Its role is not yet fully understood, but there is an inverse relationship between GnSAF and follicle size, suggesting that its primary role involves the early stages of follicle development rather than curtailing the gonadotropin surge as its name implies.

Relaxin is produced primarily by the theca lutein cells of the corpus luteum. Both relaxin and its receptor, RXFP1, are highly expressed in the uterus during the peri-implantation period in the marmoset, and its primary role appears to be in promoting decidualization and vascularization of the endometrium prior to implantation. Relaxin was named for its ability to suppress myometrial contractility in pigs and rodents, but it does not appear to exert this activity in women.

HORMONAL INTEGRATION OF THE NORMAL MENSTRUAL CYCLE

The sequence of changes responsible for mature reproductive function is coordinated through a series of negative and positive feedback loops that alter pulsatile GnRH secretion, the pituitary response to GnRH, and the relative secretion of LH and FSH from the gonadotrope. The frequency and amplitude of pulsatile GnRH secretion differentially modulate the synthesis and secretion of LH and FSH. Slow GnRH pulse frequencies favor FSH synthesis, whereas increased GnRH pulse frequency and amplitude favor LH synthesis. Activin is produced in both pituitary gonadotropes and folliculostellate cells and stimulates the synthesis and secretion of FSH through autocrine-paracrine mechanisms that are modulated by follistatin. Inhibins function as potent antagonists of activins through sequestration of the activin receptors. Although inhibin is expressed in the pituitary, gonadal inhibin is the principal source of feedback inhibition of FSH.

For the majority of the cycle, the reproductive system functions in a classic endocrine negative feedback mode. Estradiol and progesterone inhibit GnRH secretion, acting through kisspeptin and dynorphin in the KNDy neurons, while the inhibins act at the pituitary to selectively inhibit FSH synthesis and secretion (Fig. 392-7). Estradiol also contributes to negative feedback at the pituitary with an effect that is greater for FSH than LH. This tightly regulated negative feedback control of FSH is critical for development of the single mature oocyte that characterizes normal reproductive function in women. In addition to these negative feedback controls, the menstrual cycle is uniquely dependent on estrogen-induced positive feedback to produce an LH surge that is essential for ovulation of a mature follicle. Estrogen negative feedback in women occurs primarily at the hypothalamus with a small pituitary contribution, whereas estrogen positive feedback occurs at the pituitary in women with upregulation of GnRH signaling and responsiveness. In women, hypothalamic GnRH secretion plays a permissive role in generating the preovulatory gonadotropin surge, a mechanism that differs significantly from that in rodents and other species that rely on seasonal and circadian cues, in which a surge of GnRH also occurs.

THE FOLLICULAR PHASE

The follicular phase is characterized by recruitment of a cohort of secondary follicles and the ultimate selection of a dominant preovulatory follicle (Fig. 392-8). The follicular phase begins, by convention, on the first day of menses. However, follicle recruitment is initiated by the rise in FSH that begins in the late luteal phase of the previous cycle in conjunction with the loss of negative feedback of gonadal steroids and likely inhibin A. The fact that a 20–30% increase in FSH is adequate for follicular recruitment speaks to the marked sensitivity of the resting follicle pool to FSH. The resultant granulosa cell proliferation is responsible for increasing early follicular phase levels of inhibin B. Inhibin B, in conjunction with rising

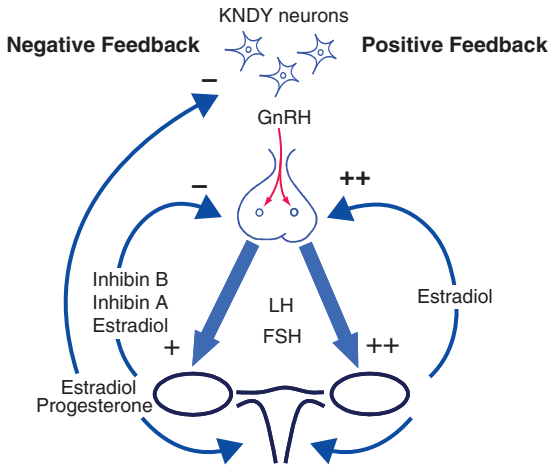

FIGURE 392-7 The reproductive system in women is critically dependent on both negative feedback of gonadal steroids and inhibin to modulate follicle-stimulating hormone (FSH) secretion and on estrogen positive feedback to generate the preovulatory luteinizing hormone (LH) surge. GnRH, gonadotropin-releasing hormone.

levels of estradiol and inhibin A, restrains FSH secretion during this critical period such that only a single follicle matures in the vast majority of cycles. The increased risk of multiple gestation associated with the increased levels of FSH characteristic of advanced maternal age or with exogenous gonadotropin administration in the treatment of infertility attests to the importance of negative feedback regulation of FSH. With further growth of the dominant follicle, estradiol and inhibin A increase and the follicle acquires LH receptors. Increasing levels of estradiol are responsible for proliferative changes in the endometrium. The exponential rise in estradiol results in positive feedback on the pituitary, leading to the generation of an LH surge (and a smaller FSH surge), thereby triggering ovulation and luteinization of granulosa and theca cells.

THE LUTEAL PHASE

The luteal phase begins with the formation of the corpus luteum from the ruptured follicle (Fig. 392-8). Progesterone and inhibin A are produced from the luteinized granulosa cells, which continue to aromatize theca-derived androgen precursors, producing estradiol. The combined actions of estrogen and progesterone are responsible for the secretory changes in the endometrium that are necessary for implantation. The corpus luteum is supported by LH but has a finite life span because of diminished sensitivity to LH. The demise of the corpus luteum results in a progressive decline in hormonal support of the endometrium. Inflammation or local hypoxia and ischemia result in vascular changes in the endometrium, leading to the release of cytokines, cell death, and shedding of the endometrium.

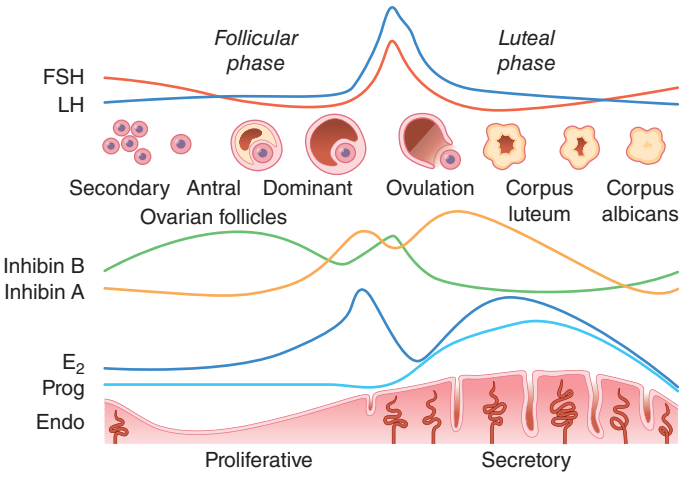

FIGURE 392-8 Relationship between gonadotropins, follicle development, gonadal secretion, and endometrial changes during the normal menstrual cycle. E_2, estradiol; Endo, endometrium; FSH, follicle-stimulating hormone; LH, luteinizing hormone; Prog, progesterone.

If conception occurs, hCG produced by the trophoblast binds to LH receptors on the corpus luteum, maintaining steroid hormone production and preventing involution of the corpus luteum until its hormonal function is taken over by the placenta 6–10 weeks after conception.

CLINICAL ASSESSMENT OF OVARIAN FUNCTION

Menstrual bleeding should become regular within 2–4 years of menarche, although anovulatory and irregular cycles are common before that. For the remainder of adult reproductive life, the cycle length counted from the first day of menses to the day preceding subsequent menses is ~28 days, with a range of 25–35 days. However, cycle-to-cycle variability for an individual woman is ±2 days. Luteal phase length is relatively constant between 12 and 14 days in normal cycles; thus, the major variability in cycle length is due to variations in follicular phase length. The duration of menstrual bleeding in ovulatory cycles varies between 4 and 6 days. There is a gradual shortening of cycle length with age such that women aged >35 years have cycles that are shorter than during their younger reproductive years. Anovulatory cycles increase as women approach menopause, and bleeding patterns may be erratic.

Women who report regular monthly bleeding generally have ovulatory cycles, but several other clinical signs can be used to assess the likelihood of ovulation. Some women experience *mittelschmerz*, described as midcycle pelvic discomfort that is thought to be caused by the rapid expansion of the dominant follicle at the time of ovulation. A constellation of premenstrual moliminal symptoms such as bloating, breast tenderness, mood changes, and food cravings often occur several days before menses in ovulatory cycles, but their absence cannot be used as evidence of anovulation. Methods that can be used to determine whether ovulation occurred include a serum progesterone level >3 ng/mL ~7 days after ovulation, an increase in basal body temperature of 0.24°C (>0.5°F) in the second half of the cycle due to the thermoregulatory effect of progesterone, or detection of the urinary LH surge using ovulation predictor kits. Because ovulation occurs ~36 h after the LH surge, urinary LH can be helpful in timing intercourse to coincide with ovulation.

Ultrasound can be used to detect the growth of the fluid-filled antrum of the developing follicle and to assess endometrial thickness in response to increasing estradiol levels in the follicular phase. It can also be used to provide evidence of ovulation by documenting collapse of the dominant follicle and/or the presence of a corpus luteum as well as the characteristic echogenicity of the secretory endometrium of the luteal phase.

PUBERTY

NORMAL PUBERTAL DEVELOPMENT IN GIRLS

The first menstrual period (*menarche*) occurs relatively late in the series of developmental milestones that characterize normal pubertal development (Table 392-1). Menarche is preceded by the appearance of pubic and then axillary hair (*adrenarche*) as a result of maturation of the zona reticularis in the adrenal gland and increased adrenal androgen secretion, particularly dehydroepiandrosterone (DHEA). The triggers for adrenarche remain unknown but may involve increases in body mass index, as well as in utero and neonatal factors. Menarche is also preceded by breast development (*thelarche*). The breast is exquisitely sensitive to the very low levels of estrogen that result from peripheral conversion of adrenal androgens and the low levels of estrogen secreted

TABLE 392-1 Mean Age (Years) of Pubertal Milestones in Girls

	ONSET OF BREAST/ PUBIC HAIR DEVELOPMENT	AGE OF PEAK HEIGHT VELOCITY	MENARCHE	FINAL BREAST/ PUBIC HAIR DEVELOPMENT	ADULT HEIGHT
White	10.2	11.9	12.6	14.3	17.1
Black	9.6	11.5	12	13.6	16.5

Source: Adapted with permission from FM Biro et al: Pubertal correlates in black and white girls. J Pediatr 148:234, 2006.

from the ovary early in pubertal maturation. This estrogen sensitivity also explains why infants occasionally develop breast tissue in response to exogenous or environmental estrogens. Breast development precedes the appearance of pubic and axillary hair in ~60% of girls. The interval between the onset of breast development and menarche is ~2 years. There has been a gradual decline in the age of menarche over the past century, attributed in large part to improvement in nutrition, and there is a relationship between adiposity and earlier sexual maturation in girls. In the United States, menarche occurs at an average age of 12.5 years (Table 392-1).

Much of the variation in the timing of puberty is due to genetic factors. Heritability estimates from twin studies range between 50 and 80%. Adrenarche and thelarche occur ~1 year earlier in black girls compared with white girls, although the difference in the timing of menarche is less pronounced. Genome-wide association studies have identified over a hundred genes associated with pubertal timing in boys and girls attesting to the high degree of coordination of this reproductive and growth milestone. These findings include genes involved in GnRH secretion (e.g., *TACR3,* and the maternally imprinted gene, *MKRN3*, that has been associated with familial precocious puberty), pituitary development and function (e.g., *POU1F1*), hormone synthesis and bioactivity (e.g., *STARD4, ESR1, RXRG*), gonadal feedback (e.g., *INHBA, ESR1*), and energy homeostasis and growth, including *LIN28B*, a sentinel puberty gene, which is a potent regulator of microRNA processing.

Other important hormonal changes also occur in conjunction with puberty. Growth hormone (GH) levels increase early in puberty, stimulated in part by the pubertal increase in estrogen secretion. GH increases insulin-like growth factor-1 (IGF-1), which enhances linear growth. The growth spurt is generally less pronounced in girls than in boys, with a peak growth velocity of ~7 cm/year. Linear growth is ultimately limited by closure of epiphyses in the long bones as a result of prolonged exposure to estrogen. Puberty is also associated with mild insulin resistance.

DISORDERS OF PUBERTY

The differential diagnosis of precocious and delayed puberty is similar in boys **(Chap. 391)** and girls. However, there are differences in the timing of normal puberty and differences in the relative frequency of specific disorders in girls compared with boys.

Precocious Puberty Traditionally, precocious puberty has been defined as the development of secondary sexual characteristics before the age of 8 in girls based on data from Marshall and Tanner in British girls studied in the 1960s. More recent studies led to recommendations that girls be evaluated for precocious puberty if breast development or pubic hair is present at <7 years of age for white girls or <6 years for black girls; however, these guidelines have not been widely accepted in favor of careful follow-up in girls presenting at <8 years.

Precocious puberty in girls is most often centrally mediated **(Table 392-2)**, resulting from early activation of the hypothalamic-pituitary-ovarian axis. It is characterized by pulsatile LH secretion (which is initially associated with deep sleep) and an enhanced LH and FSH response to exogenous GnRH or a GnRH agonist (two- to threefold stimulation) **(Table 392-3)**. True precocity is marked by advancement in bone age of >2 standard deviations, a recent history of growth acceleration, and progression of secondary sexual characteristics. In girls, centrally mediated precocious puberty (CPP) is idiopathic in ~85% of cases; however, neurogenic causes must be considered. Activating mutations in *KISS, KISS1,* and *KISS1R* have been found in a small number of patients with CPP, and loss-of-function mutations in *MKRN3* have been reported in familial CPP. However, the frequency of these mutations is insufficient to justify their use in routine clinical testing. GnRH agonists that induce pituitary desensitization are the mainstay of treatment to prevent premature epiphyseal closure and preserve adult height, as well as to manage psychosocial repercussions of precocious puberty.

Peripherally mediated precocious puberty does not involve activation of the hypothalamic-pituitary-ovarian axis and is characterized by suppressed gonadotropins in the presence of elevated estradiol. Management of peripheral precocious puberty involves treating the underlying disorder (Table 392-2) and limiting the effects of gonadal steroids using aromatase inhibitors, inhibitors of steroidogenesis, and ER blockers. It is important to be aware that central precocious puberty can also develop in girls whose precocity was initially peripherally mediated, as in McCune-Albright syndrome and congenital adrenal hyperplasia.

TABLE 392-2 Differential Diagnosis of Precocious Puberty

CENTRAL (GnRH DEPENDENT)	PERIPHERAL (GnRH INDEPENDENT)
Idiopathic	Congenital adrenal hyperplasia
CNS tumors	Estrogen-producing tumors
Hamartomas	Adrenal tumors
Astrocytomas	Ovarian tumors
Adenomyomas	Gonadotropin/hCG-producing tumors
Gliomas	Exogenous exposure to estrogen or androgen or lavender or tea-tree oil
Germinomas	McCune-Albright syndrome
CNS infection	Aromatase excess syndrome
Genetic, i.e., *KISS1, KISS1R, MKRN3, DLK1*	
Head trauma	
Iatrogenic

Abbreviations: ACTH, adrenocorticotropic hormone; DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; IGF-1, insulin-like growth factor 1; IGFBP-3, IGF-binding protein 3; LH, luteinizing hormone; MRI, magnetic resonance imaging; TSH, thyroid-stimulating hormone; T_4, thyroxine.

Incomplete and intermittent forms of precocious puberty may also occur. For example, premature breast development may occur in girls before the age of 2 years, with no further progression and without significant advancement in bone age, estrogen production, or compromised height. Premature adrenarche can also occur in the absence of progressive pubertal development, but it must be distinguished from late-onset congenital adrenal hyperplasia and androgen-secreting tumors, in which case it may be termed *heterosexual precocity*. Premature adrenarche may be associated with obesity, hyperinsulinemia, and the subsequent predisposition to PCOS.

Delayed Puberty Delayed puberty **(Table 392-4)** is defined as the absence of secondary sexual characteristics by age 13 in girls. The diagnostic considerations are very similar to those for primary amenorrhea **(Chap. 393)**. Between 25 and 40% of delayed puberty in girls is of ovarian origin, with Turner syndrome accounting for the majority of such patients. Delayed puberty may occur in the setting of systemic illnesses, including celiac disease and chronic renal disease, and endocrinopathies such as diabetes and hypothyroidism. In addition, girls appear to be particularly susceptible to the adverse effects of decreased energy balance resulting from exercise, dieting, and/or eating disorders, and thus, functional hypothalamic amenorrhea (HA) can present with primary amenorrhea. Together, these reversible conditions account for ~25% of delayed puberty in girls. Congenital hypogonadotropic hypogonadism in girls or boys can be caused by mutations in several different genes or combinations of genes (Fig. 392-4, **Chap. 391**, Table 392-2). Approximately 50% of girls with congenital hypogonadotropic hypogonadism, with or without anosmia, have a history of some degree of breast development, and 10% report one to two episodes of vaginal bleeding. Family studies suggest that genes identified in association with absent puberty may also cause delayed puberty, and recent reports have further suggested that a genetic susceptibility to environmental stresses such as diet and exercise may account for at least some cases of functional HA, including in girls who present with primary amenorrhea. Although neuroanatomic causes of delayed puberty are considerably less common in girls than in boys, it is always important to rule these out in the setting of hypogonadotropic hypogonadism.

393 Menstrual Disorders and Pelvic Pain

Janet E. Hall, Anuja Dokras

Menstrual dysfunction can signal an underlying abnormality that may have long-term health consequences. Although frequent or prolonged bleeding usually prompts a woman to seek medical attention, infrequent or absent bleeding may seem less troubling, and the patient may not bring it to the attention of the physician. Thus, a focused menstrual history is a critical part of every encounter with a female patient. Pelvic pain is a common complaint that may relate to an abnormality of the reproductive organs but also may be of gastrointestinal, urinary

tract, or musculoskeletal origin. Depending on its cause, pelvic pain may require urgent surgical attention. Recent guidelines no longer recommend routine pelvic examination in asymptomatic, average-risk women other than periodic cervical cancer screening. However, pelvic examination is an important part of the evaluation of amenorrhea, abnormal uterine bleeding, and pelvic pain.

MENSTRUAL DISORDERS

DEFINITION AND PREVALENCE

Amenorrhea refers to the absence of menstrual periods. Amenorrhea is classified as *primary* if menstrual bleeding has never occurred in the absence of hormonal treatment or *secondary* if menstrual periods cease for 3–6 months. Primary amenorrhea is a rare disorder that occurs in <1% of the female population. However, between 3 and 5% of women experience at least 3 months of secondary amenorrhea in any specific year. There is no evidence that race or ethnicity influences the prevalence of amenorrhea. However, because of the importance of adequate nutrition for normal reproductive function, both the age at menarche and the prevalence of secondary amenorrhea vary significantly in different parts of the world.

Oligomenorrhea is defined as a cycle length >35 days or <10 menses per year. Both the frequency and the amount of vaginal bleeding are irregular in oligomenorrhea, and moliminal symptoms (premenstrual breast tenderness, food cravings, mood lability), suggestive of ovulation, are variably present. Anovulation can also present with intermenstrual intervals <24 days. Frequent or heavy irregular bleeding is termed *dysfunctional uterine bleeding* if anatomic uterine and outflow tract lesions or a bleeding diathesis have been excluded. Oligo- and anovulation are most frequently associated with polycystic ovarian syndrome (PCOS).

Primary Amenorrhea The absence of menarche (the first menstrual period) by age 16 has been used traditionally to define primary amenorrhea. However, other factors, such as growth, secondary sexual characteristics, and the presence of cyclic pelvic pain, also influence the age at which primary amenorrhea should be investigated. Recent studies suggest that puberty is occurring at an earlier age, particularly in obese girls. However, it is important to note that these data reflect earlier breast development alone with minimal change in the age of menarche. Thus, an evaluation for amenorrhea should be initiated by age 15 or 16 in the presence of normal growth and secondary sexual characteristics; age 13 in the absence of secondary sexual characteristics or if height is less than the third percentile; age 12 or 13 in the presence of breast development and cyclic pelvic pain; or within 2 years of breast development if menarche has not occurred.

Secondary Amenorrhea or Oligomenorrhea Irregular cycles are relatively common for up to 3 years after menarche and for 1–2 years before the final menstrual period. In the intervening years, menstrual cycle length is ~28 days, with an intermenstrual interval normally ranging between 25 and 35 days. Cycle-to-cycle variability in an individual woman who is ovulating consistently is generally +/− 2 days. Pregnancy is the most common cause of amenorrhea and should be excluded early in any evaluation of menstrual irregularity. However, many women occasionally miss a single period. Three months of secondary amenorrhea, or 6 months in women with previously irregular cycles, should prompt an evaluation, as should a history of intermenstrual intervals >35 or <21 days or bleeding that persists for >7 days.

DIAGNOSIS

Pregnancy is the most common cause of amenorrhea and must be excluded in all cases, regardless of patient history. Evaluation of menstrual dysfunction depends on understanding the interrelationships between the four critical components of the reproductive tract: (1) the hypothalamus, (2) the pituitary, (3) the ovaries, and (4) the uterus and outflow tract **(Fig. 393-1; Chap. 392)**. This system is maintained by complex negative and positive feedback loops involving the ovarian steroids (estradiol and progesterone) and peptides (inhibin B and inhibin A) and the hypothalamic (gonadotropin-releasing hormone [GnRH]) and pituitary (follicle-stimulating hormone [FSH] and luteinizing hormone [LH]) components of this system (Fig. 393-1).

Disorders of menstrual function can be thought of in two main categories: disorders of the uterus and outflow tract and disorders of ovulation. Many of the conditions that cause primary amenorrhea are congenital but go unrecognized until the time of normal puberty (e.g., genetic, chromosomal, and anatomic abnormalities). All causes of secondary amenorrhea also can cause primary amenorrhea.

Disorders of the Uterus or Outflow Tract Abnormalities of the uterus and outflow tract typically present as primary amenorrhea. In patients with normal pubertal development and a blind vagina, the differential diagnosis includes *obstruction* by a transverse vaginal septum or imperforate hymen; *müllerian agenesis* (Mayer-Rokitansky-Kuster-Hauser syndrome), which can be caused by mutations in the *WNT4* gene, and *androgen insensitivity syndrome* (AIS), which is an X-linked recessive disorder that accounts for ~10% of all cases of primary amenorrhea **(Chap. 391)**. Patients with AIS have a 46,XY karyotype, but because of the lack of androgen receptor responsiveness, those with complete AIS lack features of androgenization and have female external genitalia. The absence of pubic and axillary hair distinguishes them clinically from patients with müllerian agenesis, as does a testosterone level in the male range. The rare patient with 5α reductase type 2 enzyme deficiency has a similar presentation but undergoes virilization at the time of puberty. *Asherman's syndrome*

	Primary	Secondary
Hypothalamus	28%	36%
Pituitary	2%	15%
PCOS	8%	30%
Ovary	43%	12%
Uterus/outflow tract	19%	7%

FIGURE 393-1 Role of the hypothalamic-pituitary-gonadal axis in the etiology of amenorrhea. Gonadotropin-releasing hormone (GnRH) secretion from the hypothalamus stimulates follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion from the pituitary to induce ovarian folliculogenesis and steroidogenesis. Ovarian secretion of estradiol and progesterone controls the shedding of the endometrium, resulting in menses, and, in combination with the inhibins, provides feedback regulation of the hypothalamus and pituitary to control secretion of FSH and LH. The prevalence of amenorrhea resulting from abnormalities at each level of the reproductive system (hypothalamus, pituitary, ovary, uterus, and outflow tract) varies depending on whether amenorrhea is primary or secondary. PCOS, polycystic ovarian syndrome.

presents as secondary amenorrhea or hypomenorrhea and results from partial or complete obliteration of the uterine cavity by adhesions that prevent normal growth and shedding of the endometrium. Curettage performed for pregnancy complications accounts for >90% of cases; genital tuberculosis is an important cause in regions where it is endemic.

TREATMENT

Disorders of the Uterus or Outflow Tract

Obstruction of the outflow tract usually presents as dysmenorrhea or lower abdominal cyclic pain with no menses. Evaluation of the patient includes a medical history, physical examination including a perineal examination, and ultrasound imaging. In some cases, an MRI can more accurately identify the reproductive tract anomaly prior to surgery. It is important that surgery be performed as soon as the diagnosis is made as the risk of endometriosis is increased with retrograde menstrual flow. *Müllerian agenesis* may require surgical intervention to allow sexual intercourse, although vaginal dilatation is adequate in some patients. Because ovarian function is normal, assisted reproductive techniques can be used with a surrogate carrier. More recently, there have been a few cases of successful uterine transplantation in women with müllerian agenesis. AIS **(Chap. 390)** requires gonadectomy because there is risk of gonadoblastoma in the dysgenetic gonads, although surgery is generally delayed until after breast development and the pubertal growth spurt. Estrogen replacement is indicated after gonadectomy, and vaginal dilatation may be required to allow sexual intercourse.

Disorders of Ovulation Once uterus and outflow tract abnormalities have been excluded, other causes of amenorrhea involve disorders of ovulation. The differential diagnosis is based on the results of initial tests, including a pregnancy test, an FSH level (to determine whether the cause is likely to be ovarian or central), and assessment of hyperandrogenism **(Fig. 393-2)**.

HYPOGONADOTROPIC HYPOGONADISM Low estrogen levels in combination with normal or low levels of LH and FSH are seen with anatomic, genetic, or functional abnormalities that interfere with hypothalamic GnRH secretion or normal pituitary responsiveness to GnRH. Although relatively uncommon, tumors and infiltrative diseases should be considered in the differential diagnosis of hypogonadotropic hypogonadism **(Chap. 380)**. These disorders may present with primary or secondary amenorrhea. They may occur in association with other features suggestive of hypothalamic or pituitary dysfunction, such as short stature, diabetes insipidus, galactorrhea, and headache. Hypogonadotropic hypogonadism also may be seen after cranial irradiation. In the postpartum period, amenorrhea occurs normally in association with breast feeding but may also be caused by pituitary necrosis (Sheehan's syndrome) or lymphocytic hypophysitis. Because reproductive dysfunction is commonly associated with hyperprolactinemia from neuroanatomic lesions or medications, prolactin should be measured in all patients with hypogonadotropic hypogonadism **(Chap. 380)**.

Isolated hypogonadotropic hypogonadism (IHH) occurs in women, although it is three times more common in men. IHH generally presents with primary amenorrhea, although 50% have some degree of breast development, and ~10% report one to two menses. IHH is associated with anosmia in half of women (termed Kallmann's syndrome). Genetic causes of IHH have been identified in ~50% of patients **(Chaps. 391 and 392)**.

Functional hypothalamic amenorrhea (HA) is a diagnosis of exclusion of other causes of hypogonadotropic hypogonadism including chronic diseases (type 1 diabetes, celiac disease, hyperthyroidism, Cushing's syndrome) and use of opioids, glucocorticoids, or psychotropic medications that increase prolactin levels. Functional HA is most commonly associated with conditions causing a mismatch between energy expenditure and energy intake and/or significant stress. Variants in genes associated with IHH may increase susceptibility to these environmental inputs, accounting in part for the clinical variability in this disorder. Metabolic and stress signaling is transduced to the reproductive axis, at least in part, through leptin signaling from the periphery and via hypothalamic kisspeptin control of GnRH. The diagnosis

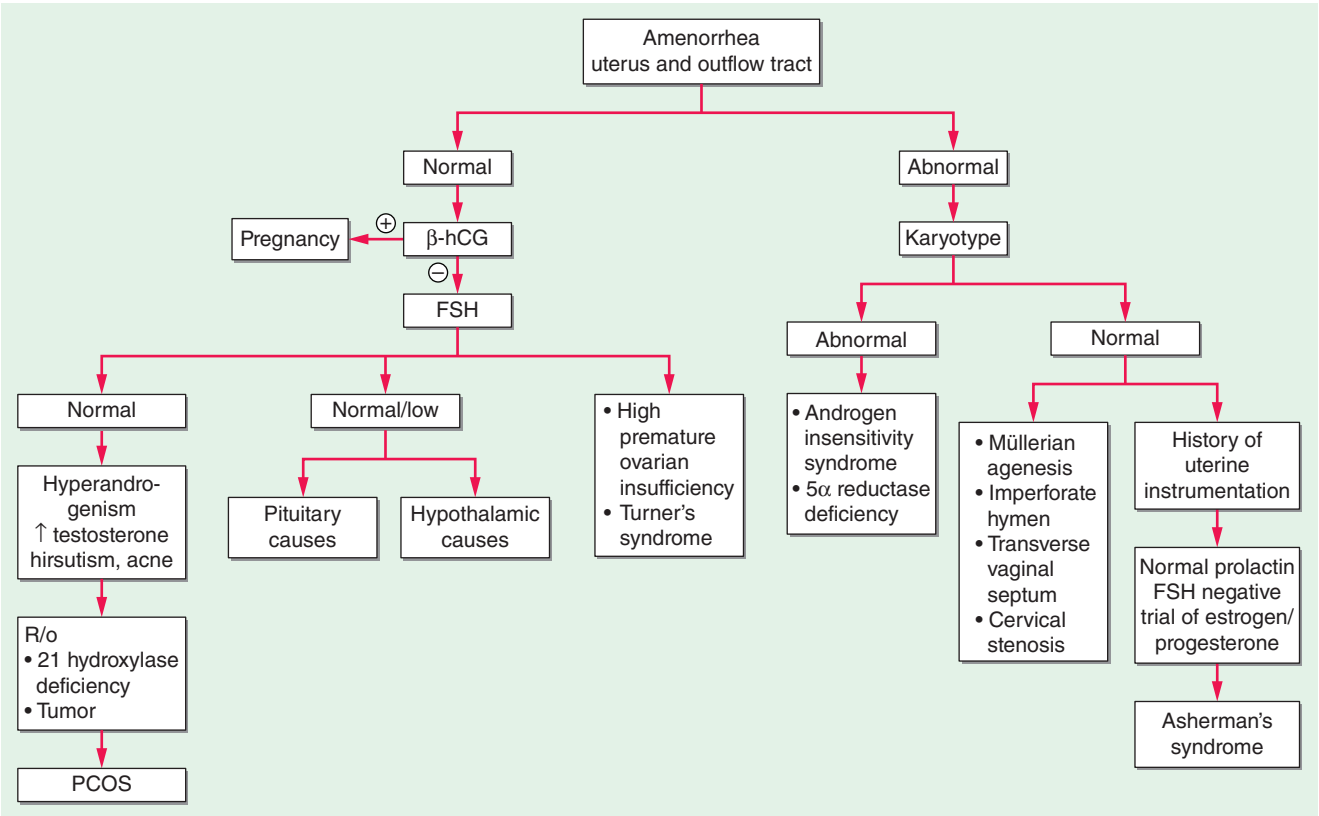

FIGURE 393-2 Algorithm for evaluation of amenorrhea. β-hCG, β-human chorionic gonadotropin; FSH, follicle-stimulating hormone; GYN, gynecologist; MRI, magnetic resonance imaging; PRL, prolactin; R/O, rule out; TSH, thyroid-stimulating hormone.

of HA generally can be made on the basis of a careful history, a physical examination, and the demonstration of low levels of gonadotropins and normal prolactin levels. Eating disorders, excessive exercise, and chronic disease must be specifically excluded. An atypical history, headache, signs of other hypothalamic dysfunction, or hyperprolactinemia, even if mild, necessitates cranial magnetic resonance imaging (MRI) to exclude a neuroanatomic cause. Up to 10% of women with HA may have some features of PCOS (irregular menses, increased ovarian volume with polycystic appearing ovaries, higher anti-müllerian hormone [AMH] levels, and slightly elevated androgen levels).

HYPERGONADOTROPIC HYPOGONADISM Ovarian failure is considered premature when it occurs in women <40 years old and accounts for ~10% of secondary amenorrhea. *Primary ovarian insufficiency* (POI) has replaced the terms *premature menopause* and *premature ovarian failure* in recognition of the continuum of impaired ovarian function encompassed by this disorder. Ovarian insufficiency is associated with the loss of negative feedback restraint on the hypothalamus and pituitary, resulting in increased FSH and LH levels. FSH is a better marker of ovarian failure because of loss of negative feedback effects of both estradiol and the inhibins and because its levels are less variable than those of LH. AMH levels will also be low in patients with POI but are more frequently used in management of infertility. As with natural menopause, POI may wax and wane, and serial measurements may be necessary to establish the diagnosis. The presentation may include irregular menses or complete cessation of menses, hot flashes, and vaginal dryness.

Once the diagnosis of POI has been established, further evaluation is indicated because of other health problems that may be associated with POI. Although POI is most commonly of unknown cause, it also occurs in association with a variety of chromosomal abnormalities (most often Turner's syndrome), autoimmune polyglandular failure syndromes, and other rare disorders. Radiotherapy and chemotherapy may reduce ovarian reserve, with effects on both the oocytes and the supporting granulosa cells. New approaches, including ovarian, oocyte, and embryo cryopreservation, should be offered to women of reproductive age prior to gonadotoxic chemotherapy or pelvic radiation treatment. The recognition that early ovarian insufficiency occurs in premutation carriers of the fragile X syndrome is important because of the increased risk of severe intellectual disability in male children with *FMR1* mutations. Thus, follow-up testing should include a karyotype in all POI patients, serum anti-cortical and 21-hydroxylase antibodies (specific but not sensitive for subsequent adrenal insufficiency), thyroid function and thyroid peroxidase antibodies, *FMR1* premutation screening, and assessment of bone mineral density. Ovarian biopsy is not indicated. Although the number of genetic causes of POI is increasing, routine testing for mutations other than *FMR1* is currently not recommended.

Hypergonadotropic hypogonadism occurs rarely in other disorders, such as mutations in the FSH or LH receptors. Aromatase deficiency and 17α-hydroxylase deficiency are associated with decreased estrogen and elevated gonadotropins and with hyperandrogenism and hypertension, respectively. Gonadotropin-secreting tumors in women of reproductive age generally present with high, rather than low, estrogen levels and cause ovarian hyperstimulation or dysfunctional bleeding.

TREATMENT

Hypo- and Hypergonadotropic Causes of Amenorrhea

Amenorrhea almost always is associated with chronically low levels of estrogen, whether it is caused by hypogonadotropic hypogonadism or ovarian insufficiency. Development of secondary sexual characteristics requires gradual titration of estradiol replacement with eventual addition of progestin. Hormone replacement with either low-dose estrogen/progesterone regimens or oral contraceptive pills is recommended until the usual age of menopause for bone and cardiovascular protection. In women with functional HA or anorexia nervosa, hormone replacement alone may not be sufficient to restore or maintain bone density. Patients with hypogonadotropic hypogonadism who are interested in fertility require treatment with both exogenous FSH and LH. Patients with POI can consider oocyte donation, which has a high rate of success in this population, although its use in women with Turner's syndrome is limited by significant cardiovascular risk in pregnancy.

POLYCYSTIC OVARIAN SYNDROME The diagnosis of PCOS is made in adult women using the Rotterdam criteria: irregular menses (<8 menses per year), clinical or biochemical hyperandrogenism (elevated total or free testosterone, modified Ferriman-Gallwey score >4–6 depending on ethnicity, see **Chap. 394**), and polycystic-appearing ovaries on ultrasound (≥20 antral follicles or ovarian volume ≥10 cm^3 in at least one ovary). The presence of two of the three criteria will confirm the diagnosis, resulting in different phenotypes, namely, hyperandrogenic or non-hyperandrogenic. PCOS is a diagnosis of exclusion, and other etiologies for irregular menses and hyperandrogenism should be excluded (hypothyroidism, hyperprolactinemia, adrenal sources for hyperandrogenism). Diagnosis in adolescents maybe difficult to establish, and it is recommended to wait at least 3 years after menarche before confirming the diagnosis. In adolescents, the diagnosis is based on irregular menses and hyperandrogenism criteria only, as the ultrasound criteria are not established for this age group. The prevalence of obesity is high in PCOS and significantly increases the risk of comorbidities including metabolic syndrome, type 2 diabetes, dyslipidemia, and hypertension. The failure of regular ovulation results in irregular menses and increased risk of endometrial hyperplasia and endometrial cancer (two- to sixfold increased risk). Abnormalities in GnRH pulsatility result in elevated LH and increased production of ovarian androgens. Insulin resistance associated with PCOS may also contribute to increased insulin-stimulated ovarian androgen production. An alternate source of androgens, namely 11-oxygenated androgens, has also been shown to be elevated in women with PCOS. Genome-wide association studies in diverse populations and PCOS phenotypes have identified several loci associated with PCOS. Symptoms generally begin in adolescence and are modified by obesity and age, such that by the fourth decade of life, most women with PCOS will have regular menses and normal serum androgens. Lean oligo-ovulatory patients with PCOS generally have high LH levels in the presence of normal to low levels of FSH and estradiol, although given the pulsatility of LH secretion, a random serum LH/FSH ratio is not included in the diagnostic criteria.

TREATMENT

Polycystic Ovarian Syndrome

The first-line treatment of women with PCOS not attempting pregnancy is combined hormonal contraceptives to regulate menstrual cycles and decrease serum androgens by increasing sex hormone–binding globulin levels. Although serum androgens decrease by 3 months after initiating hormonal therapy, it may take longer to observe the beneficial effects on hirsutism and acne. Patients should be evaluated for metabolic comorbidities and given hormonal contraceptives containing the lowest effective dose of estrogen, either in a cyclic or continuous manner. If there is an inadequate response to hormonal contraceptives for management of hyperandrogenic symptoms, antiandrogens, such as spironolactone and flutamide, can be considered **(Chap. 394)**. Endometrial protection can also be achieved with the use of progestins (medroxyprogesterone acetate, 5–10 mg, or Prometrium [progesterone], 200 mg daily for 10–14 days at least every 3 months, or a levonorgestrel intrauterine device [IUD]). All women with PCOS should be screened for obesity, hypertension, and glycemic control at the time of diagnosis and then at regular intervals. Overweight and obese women should also have a fasting lipid profile at the time of diagnosis. Lifestyle management should be recommended in all women with PCOS, and metformin should be considered for managing cardiometabolic risk factors **(Chap. 408)**. Women with PCOS are at an increased risk of gestational diabetes, gestational hypertension, and preeclampsia.

Lifestyle management is the first-line treatment prior to attempting pregnancy (Chap. 396). Letrozole, an aromatase inhibitor, and clomiphene citrate, a selective estrogen response modulator, are effective first-line treatments for ovulation induction. Exogenous gonadotropins can be used by experienced practitioners; a diagnosis of polycystic ovaries increases the risk of hyperstimulation, even in women with regular, ovulatory menstrual cycles. Metformin is frequently used in patients with PCOS and is appropriate as an adjunct with diet and exercise for obese women with PCOS or for treatment of diabetes or impaired glucose tolerance, as in non-PCOS patients. However, metformin alone is not recommended for endometrial protection or treatment of hyperandrogenic symptoms, infertility, pregnancy loss, or prevention of gestational diabetes.

PELVIC PAIN

The mechanisms that cause pelvic pain are similar to those that cause abdominal pain (Chap. 15) and include inflammation of the parietal peritoneum, obstruction of hollow viscera, vascular disturbances, and pain originating in the abdominal wall. Pelvic pain may reflect pelvic disease per se but also may reflect extrapelvic disorders that refer pain to the pelvis. In up to 60% of cases, pelvic pain can be attributed to gastrointestinal problems, including appendicitis, cholecystitis, infections, intestinal obstruction, diverticulitis, and inflammatory bowel disease. Urinary tract and musculoskeletal disorders are also common causes of pelvic pain.

APPROACH TO THE PATIENT

Pelvic Pain

As with all types of abdominal pain, the first priority is to identify life-threatening conditions (shock, peritoneal signs) that may require emergent surgical management. The possibility of pregnancy should be identified as soon as possible by menstrual history and β-human chorionic gonadotropin (β-hCG) testing. A thorough history that includes the type, location, radiation, and recurrence can help identify the cause of acute pelvic pain. Specific associations with vaginal bleeding, sexual activity, defecation, urination, movement, or eating should be specifically sought. Determination of whether the pain is acute versus chronic and cyclic versus noncyclic will direct further investigation (Table 393-1). However, disorders that cause cyclic pain occasionally may cause noncyclic pain, and the converse is also true.

ACUTE PELVIC PAIN

Pelvic inflammatory disease (PID) refers to infection of the upper genital tract and may present with a spectrum of symptoms. In the acute setting, the most common presentation is bilateral lower abdominal pain of recent onset that may be exacerbated with sexual activity. Risk factors for PID include history of multiple sexual partners, prior sexually transmitted infections (STIs), history of recent uterine procedures, and age <25 years. However, any sexually active woman can be at risk for PID. PID associated with tubo-ovarian abscess or peritonitis may present with severe pain, fever, and peritoneal signs. Abnormal uterine bleeding may occur in about one-third of patients. Cervical motion tenderness, uterine and adnexal pain, and vaginal discharge are common findings on pelvic examination. The presence of right upper quadrant pain is suggestive of perihepatitis (Fitz-Hugh–Curtis syndrome).

The diagnosis of PID is established based on symptoms and clinical examination and can be aided by a wet mount preparation of vaginal discharge and nucleic acid amplification tests for *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. Of note, a presumptive clinical diagnosis is sufficient to prescribe treatment even in the absence of positive test results, as PID can occur due to other vaginal and enteric pathogens. Pelvic imaging can be obtained based on symptoms, findings of the pelvic examination, or if there is lack of response to therapy. With public health efforts to control STIs, the incidence and severity of PID have declined in the United States and Europe; however, this is not the case in the developing world. Subclinical PID with its attendant risks of infertility and ectopic pregnancy remains a significant problem worldwide. Public health and professional organizations recommend annual testing for *C. trachomatis* in all sexually active women <25 years old and both *C. trachomatis* and *N. gonorrhoeae* in all women at increased risk. *Adnexal pathology* can present acutely and may be due to rupture, bleeding, or torsion of ovarian cysts or, much less commonly, the fallopian tubes. Rupture of an ovarian cyst may be diagnosed based on the acute presentation in a reproductive-age woman and pelvic ultrasound findings of a simple, collapsed or hemorrhagic cyst, with or without free fluid in the pelvis. Ovarian torsion typically presents as acute onset of unilateral, intermittent pain and is a diagnosis of exclusion unless absent blood flow to the ovary is demonstrated via Doppler ultrasound imaging. Neoplasms of the ovary or fallopian tube are much less common causes of acute pain. *Ectopic pregnancy* represents 2% of all pregnancies and most commonly occurs in the fallopian tubes. It may present with acute lower abdominal pain, hemodynamic instability, and peritoneal signs. The index of suspicion should be high in any reproductive-age woman presenting with abdominal pain or vaginal bleeding irrespective of current use of contraception. Risk factors for an ectopic pregnancy include history of tubal disease, pelvic infection, tubal surgery, previous ectopic pregnancy, infertility, smoking, and current use of IUD, although a large proportion may have no risk factors. Rupture of the fallopian tube remains a life-threatening emergency; the incidence depends on access to care but is ~18% in developed countries. Diagnosis of an ectopic pregnancy can be established by assessing the patient's menstrual history and symptoms, measuring β-hCG levels, and performing pelvic ultrasound imaging. The discriminatory zone refers to β-hCG values above which the landmarks of a normal intrauterine pregnancy should be seen on ultrasound. Absence of an intrauterine pregnancy and presence of an adnexal mass or free fluid increase the likelihood of an ectopic pregnancy. *Threatened abortion* may also present with amenorrhea, abdominal pain, and vaginal bleeding in the setting of an intrauterine pregnancy with cardiac activity in the first trimester of pregnancy. Although more common than ectopic pregnancy, it is rarely associated with systemic signs. *Uterine pathology* includes endometritis and, less frequently, degenerating leiomyomas (fibroids) present with acute pain. Endometritis often is associated with vaginal bleeding and systemic signs of infection. It occurs in the setting of STIs, uterine instrumentation, or postpartum infection.

TABLE 393-1 Gynecologic Causes of Pelvic Pain

	ACUTE	CHRONIC
Cyclic pelvic pain		Mittelschmerz Dysmenorrhea
Noncyclic pelvic pain	Pelvic inflammatory disease Ruptured or hemorrhagic ovarian cyst, endometrioma, or ovarian torsion Ectopic pregnancy Endometritis Acute growth or degeneration of uterine myoma Threatened abortion	Endometriosis Fibroids Adenomyosis Adhesions and retroversion of the uterus Pelvic malignancy Vulvodynia Chronic pelvic inflammatory disease Tuberculous salpingitis History of sexual abuse Pelvic congestion syndrome

TREATMENT

Acute Pelvic Pain

Treatment of acute pelvic pain depends on the suspected etiology but may require surgical or gynecologic intervention. Immediate treatment of PID is indicated upon diagnosis, even if the diagnosis is presumed or the symptoms are mild, due to long-term complications resulting in increased risk of ectopic pregnancy and infertility. Treatment in patents eligible for outpatient management

includes 250 mg IM ceftriaxone and a 14-day course of oral doxycycline 100 mg twice daily. If the presentation is acute with high fever, nausea, vomiting, severe abdominal pain, or presence of tubo-ovarian abscess, inpatient therapy is recommended **(Chap. 136)**. Conservative management is an important consideration for *ovarian cysts*, if torsion is not suspected, to avoid unnecessary surgery and associated risks of reduced fertility due to cystectomy or adhesions. If surgery is performed, it is preferable to perform a cystectomy, removing the cyst wall and leaving the remaining ovary, in a reproductive-age woman. Combined hormonal contraceptives are recommended in women with a history of recurrent ovarian cyst formation. Surgical treatment may be required for *ectopic pregnancies* when the patient presents with acute pain, is hemodynamically unstable, or has signs of intraperitoneal bleeding. The choice of salpingectomy versus salpingostomy is based on patient's presentation, desire for future child bearing, and prior pelvic infections. Clinically stable women presenting with unruptured ectopic pregnancies may be appropriate for treatment with methotrexate, which is effective in ~90% of cases when multiple doses are used. Threatened abortion is managed conservatively even in the presence of a subchorionic hemorrhage. The treatment of endometritis is similar to PID. Pain from a degenerating fibroid, if visualized on pelvic sonography, can be managed with nonsteroidal anti-inflammatory drugs (NSAIDs).

CHRONIC PELVIC PAIN

Chronic pelvic pain is a complex condition resulting from gynecologic, urologic, or gastrointestinal organs and contributes to significant frustration and burden of disease. Common gynecologic conditions contributing to chronic pain are endometriosis, fibroids, adenomyosis, and adnexal pathology. Estimated prevalence rates range from 5 to 20% for cyclic and noncyclic pain. In addition to a detailed history and physical exam, the evaluation of chronic pelvic pain typically includes a pelvic ultrasound. As causes other than those related to the female reproductive system are common, referral should be made to other specialists, as appropriate. Neuromuscular and psychosomatic etiologies should also be considered.

Some women experience discomfort at the time of ovulation (*mittelschmerz* or *ovulation pain*). The pain can be quite intense but is generally of short duration. The mechanism is thought to involve rapid expansion of the dominant follicle, although it also may be caused by peritoneal irritation by follicular fluid released at the time of ovulation.

Dysmenorrhea typically refers to the crampy lower abdominal midline discomfort that begins with the onset of menstrual bleeding and gradually decreases over 12–72 h. It may be associated with nausea, diarrhea, fatigue, and headache and occurs in 60–93% of adolescents, beginning with the establishment of regular ovulatory cycles. Its prevalence decreases after pregnancy and with the use of oral contraceptives. *Primary dysmenorrhea* results, in a majority of cases, from hormone-dependent prostaglandin (PG) pathway mechanisms that cause intense uterine contractions, decreased blood flow, and increased peripheral nerve hypersensitivity, resulting in pain. However, variability in response to cyclooxygenase inhibitors suggests that PG-independent pathways, such as platelet activating factor, may also mediate inflammation. *Secondary dysmenorrhea* is caused by underlying pelvic pathology.

Endometriosis results from the presence of endometrial glands and stroma outside the uterus. These deposits of ectopic endometrium respond to hormonal stimulation and are associated with dysmenorrhea, painful intercourse, painful bowel movements, and tender nodules that may be palpated along the uterosacral ligaments during pelvic exam. The stage/severity of endometriosis does not always correlate with the extent of pain, and pain associated with endometriosis can be cyclic or continuous. Transvaginal pelvic ultrasound is part of the initial workup and may detect an endometrioma within the ovary or, in severe cases, rectovaginal or bladder nodules. The CA125 level may be increased, but it has low negative predictive value. Diagnostic laparoscopy is performed when patients do not respond to empiric treatment. If endometriosis is detected, the severity can be staged and the endometriotic lesions ablated or excised. The prevalence is lower in black and Hispanic women than in Caucasians and Asians.

Large *fibroids* can cause chronic pelvic pain or pressure, and submucosal fibroids may be associated with dysmenorrhea. *Other secondary causes* of dysmenorrhea include adenomyosis, a condition caused by the presence of ectopic endometrial glands and stroma within the myometrium. Chronic PID maybe associated with ongoing pelvic pain and is associated with tuberculosis or actinomycosis. *Pelvic congestion syndrome* is associated with pelvic varicosities with low blood flow, resulting in pelvic venous congestion. However, this is no clear evidence to indicate that this finding is associated with chronic pelvic pain.

TREATMENT

Chronic Pelvic Pain

DYSMENORRHEA

Local application of heat is of some benefit. Exercise, sexual activity, a vegetarian diet, use of vitamins D, B_1, B_6, and E and fish oil, acupuncture, and yoga have all been suggested to be of benefit, but studies are not adequate to provide recommendations. However, NSAIDs are very effective and provide >80% sustained response rates. Ibuprofen, naproxen, ketoprofen, mefanamic acid, and nimesulide are all superior to placebo. For best response, treatment should be initiated prior to the onset of menses and continued for at least 2–3 days. Combined oral contraceptives taken cyclically or continuously effectively reduce symptoms of dysmenorrhea.

ENDOMETRIOSIS

Combined hormonal contraceptives or continuous progestin (either orally or a levonorgestrel IUD) are used for the treatment of endometriosis. Evidence of an endometrioma on ultrasound imaging can be medically managed and does not require surgical removal unless symptomatic. Patients who do not respond to medical management and laparoscopic resection of endometriotic lesions can be offered GnRH agonist suppression with add-back therapy or aromatase inhibitors.

Chronic pain and dysmenorrhea associated with *fibroids* can be managed surgically depending on the number and location of fibroids and associated symptoms. Chronic pain and dysmenorrhea associated with adenomyosis can be managed with combined hormonal treatment, levonorgestrel IUD, or hysterectomy after child bearing is complete.

394 Hirsutism

David A. Ehrmann

DEFINING HIRSUTISM

Body hair can be categorized as either *vellus* (fine, soft, and not pigmented) or *terminal* (long, coarse, and pigmented). Approximately 10% of reproductive age women have hirsutism, defined by the presence of excessive terminal hair growth. Hirsutism is most often idiopathic or the consequence of androgen excess associated with polycystic ovary syndrome (PCOS). Less frequently, it results from adrenal androgen overproduction as occurs in nonclassic congenital adrenal hyperplasia (CAH) (Table 394-1). *Androgenization* or *virilization* refers to a condition in which androgen levels are sufficiently high to cause deepening of the voice, breast atrophy, increased muscle bulk, clitoromegaly, and increased libido. Androgenization may be caused by benign hyperplasia of ovarian theca and stroma cells (e.g., *hyperthecosis*); it may also be a harbinger of a serious underlying condition, such as an ovarian or adrenal neoplasm. Cutaneous manifestations commonly associated with hirsutism include acne and hair thinning or pattern hair loss (androgenic alopecia).

HAIR FOLLICLE GROWTH AND DIFFERENTIATION

The number of hair follicles remains unchanged over the life span, but follicle size and the type of hair can change in response to numerous factors, particularly androgens. Androgens are necessary for terminal hair and sebaceous gland development and mediate differentiation of pilosebaceous units (PSUs) into a terminal hair follicle and/or a sebaceous gland. In the former case, androgens transform the vellus hair into a terminal hair; in the latter case, the sebaceous component proliferates and the hair remains vellus.

There are three phases in the cycle of hair growth: (1) *anagen* (growth phase), (2) *catagen* (involution phase), and (3) *telogen* (rest phase). Depending on the body site, hormonal regulation may play an important role in the hair growth cycle. Hair growth on the face, chest, upper abdomen, and back typically requires elevated androgen concentrations. However, there is only a modest correlation between androgen levels and the quantity of hair growth. This is due to the fact that hair growth from the follicle also depends on local growth factors, and the variability in end-organ (PSU) sensitivity to androgens. Genetic factors and ethnic background also influence hair growth. Androgen excess in women may result in hair thinning or loss because androgens cause scalp hairs to spend less time in the anagen phase.

In general, dark-haired individuals tend to be more hirsute than blond or fair individuals. Asians and Native Americans have relatively sparse hair in regions sensitive to high androgen levels, whereas people of Mediterranean descent are more hirsute.

CLINICAL ASSESSMENT

Historic elements relevant to the assessment of hirsutism include the age at onset and rate of progression of hair growth and associated symptoms or signs (e.g., menstrual irregularity and acne). Depending on the cause, excess hair growth typically is first noted during the second and third decades of life. The growth is usually slow but progressive. Sudden development and rapid progression of hirsutism suggest the possibility of an androgen-secreting neoplasm, in which case androgenization may also be present.

The age at onset of menstrual cycles (menarche) and the pattern of the menstrual cycle should be ascertained; oligomenorrhea (<8 cycles per calendar year) from the time of menarche onward is more likely to result from ovarian than adrenal androgen excess. Associated symptoms such as galactorrhea should prompt evaluation for hyperprolactinemia (Chap. 380) or possibly hypothyroidism (Chap. 382). Hypertension, striae, easy bruising, and centripetal weight gain suggest hypercortisolism (Cushing's syndrome; Chap. 386). Rarely, patients with acromegaly present with hirsutism. Medications such as phenytoin, minoxidil, and cyclosporine may be associated with androgen-independent excess hair growth (i.e., hypertrichosis). A family history of infertility and/or hirsutism may indicate inherited disorders such as nonclassic CAH (Chap. 386).

Physical examination should include measurement of height and weight and calculation of body mass index (BMI). A BMI >25 kg/m^2 is indicative of excess weight for height, and values >30 kg/m^2 are often seen in association with hirsutism, probably the result of increased conversion of androgen precursors to testosterone. Notation should be made of blood pressure, as adrenal causes may be associated with hypertension. Cutaneous signs sometimes associated with androgen excess and insulin resistance include acanthosis nigricans and skin tags.

An objective clinical assessment of hair distribution and quantity is central to the evaluation in any woman presenting with concerns about excessive hair growth. This assessment permits the distinction between hirsutism and hypertrichosis and provides a baseline reference point to gauge the response to treatment. A simple and commonly used method to grade hair growth is the modified scale of Ferriman and Gallwey (Fig. 394-1), in which each of nine androgen-sensitive sites is graded from 0 (no hair growth) to 4 (hair growth typically seen in adult men). Although it is normal for most women to have some hair growth in androgen-sensitive sites, ~95% of non-hispanic white and African-American women have a score <8 on this scale. Scores >8 suggest excess androgen-mediated hair growth, a finding that should be assessed further by means of hormonal evaluation (see below). Asian and Native American women are less likely to manifest hirsutism, and the only cutaneous evidence of androgen excess may be pustular acne and thinning scalp hair.

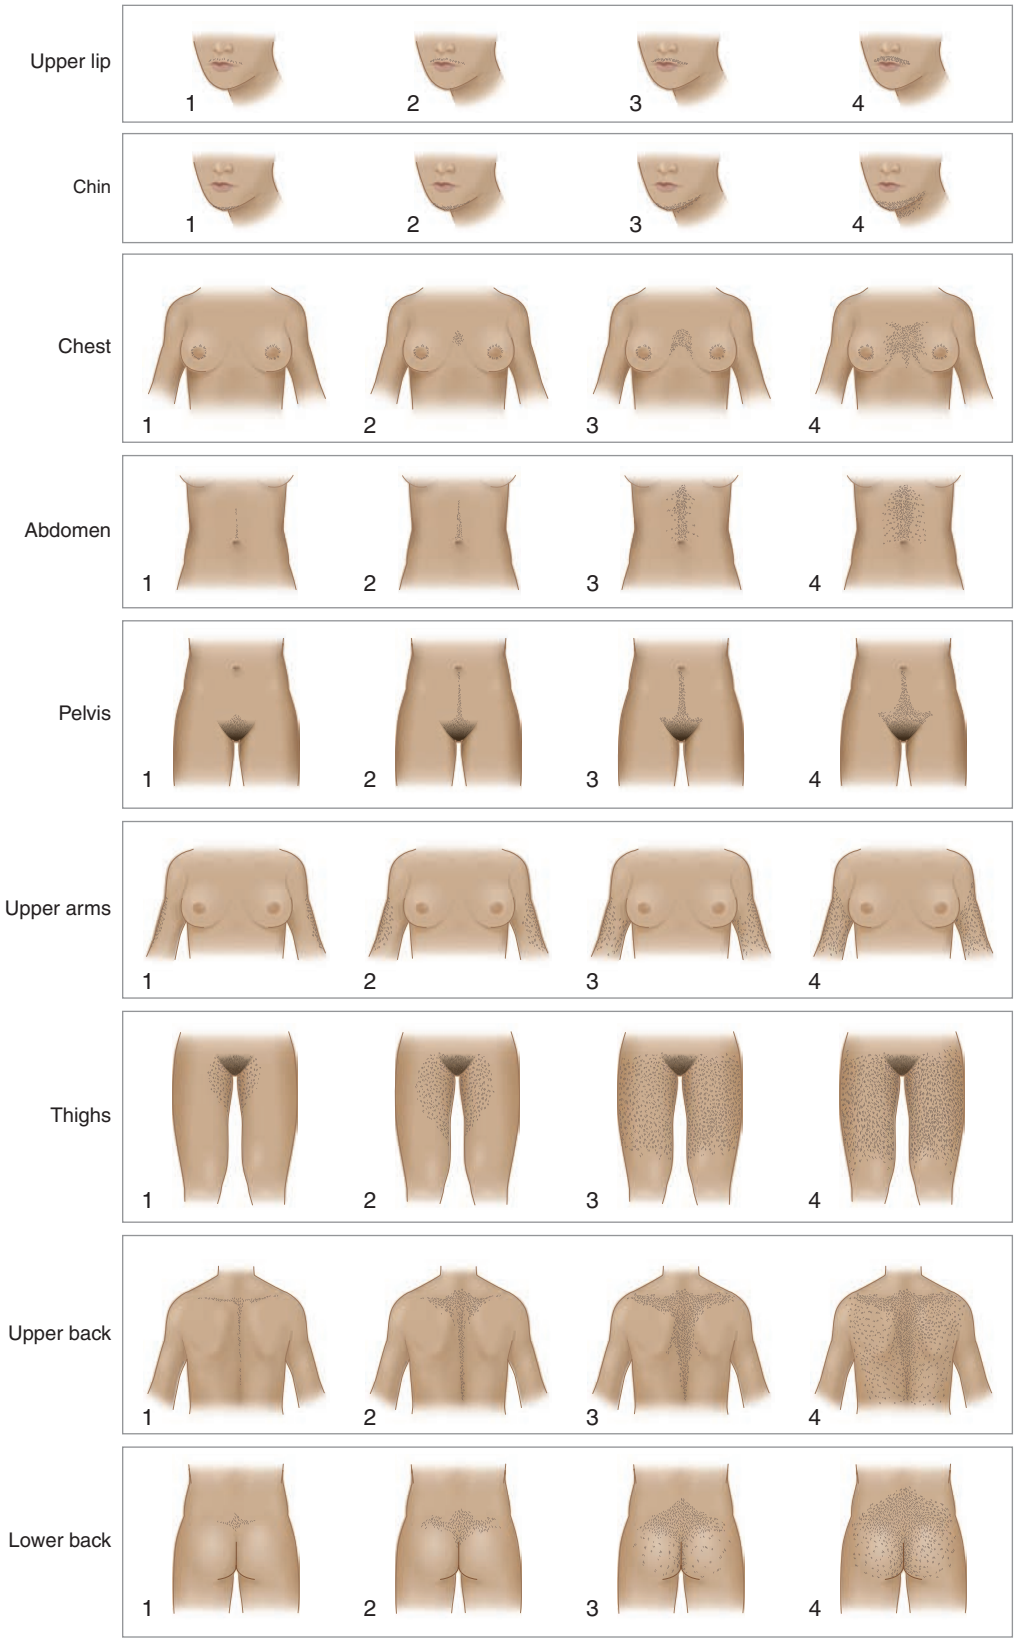

FIGURE 394-1 Hirsutism scoring scale of Ferriman and Gallwey. The nine body areas that have androgen-sensitive areas are graded from 0 (no terminal hair) to 4 (frankly virile) to obtain a total score. A normal hirsutism score is <8. *(Modified with permission from LJ DeGroot, JL Jameson: Endocrinology, 5th ed. Philadelphia, PA: Saunders; 2006.)*

HORMONAL EVALUATION

Androgens are secreted by the ovaries and adrenal glands in response to their respective tropic hormones: luteinizing hormone (LH) and adrenocorticotropic hormone (ACTH). Testosterone is the principal circulating steroid involved in the etiology of hirsutism; other steroids that may contribute to the development of hirsutism include androstenedione and dehydroepiandrosterone (DHEA) and its sulfated form (DHEAS). The ovaries and adrenal glands normally contribute about equally to testosterone production. Approximately half of the total testosterone originates from direct glandular secretion, and the remainder is derived from the peripheral conversion of androstenedione and DHEA **(Chap. 381)**.

Testosterone is the most important circulating androgen, but it is a precursor hormone in mediating hirsutism. Testosterone is converted to dihydrotestosterone (DHT) by the enzyme 5α-reductase, which is located in the PSU. DHT is more potent than testosterone as it has a higher affinity for, and slower dissociation from, the androgen receptor. The local production of DHT allows it to serve as the primary mediator of androgen action at the level of the PSU. There are two isoenzymes of 5α-reductase: type 2 is found in the prostate gland and in hair follicles, and type 1 is found primarily in sebaceous glands.

One approach to the evaluation and treatment of hirsutism is depicted in **Fig. 394-2**. In addition to measuring blood levels of testosterone and DHEAS, it is often important to measure the level of free (or unbound) testosterone, i.e., the fraction of testosterone that is not bound to its carrier protein, sex hormone–binding globulin (SHBG). Unbound testosterone is biologically available for conversion to DHT and binding to androgen receptors. Both hyperinsulinemia and androgen excess decrease hepatic production of SHBG, resulting in levels of total testosterone within the high-normal range, whereas the unbound hormone is elevated more substantially. Although there is a decline in ovarian testosterone production after menopause, ovarian estrogen production decreases to an even greater extent, and the concentration of SHBG is reduced. Consequently, there is an increase in the relative proportion of unbound testosterone, and it may exacerbate hirsutism after menopause.

A baseline plasma total testosterone level >12 nmol/L (>3.5 ng/mL) usually indicates an androgen-producing tumor, whereas a level >7 nmol/L (>2 ng/mL) is suggestive of tumor but may also be observed in women with hyperthecosis. A basal DHEAS level >18.5 μmol/L (>7000 μg/L) suggests an adrenal tumor. Although DHEAS has been proposed as a "marker" of predominant adrenal androgen excess, it is not unusual to find modest elevations in DHEAS among women with PCOS. Computed tomography (CT) or magnetic resonance imaging (MRI) should be used to localize an adrenal mass, and ultrasound usually suffices to identify an ovarian mass if clinical evaluation and hormonal levels suggest these possibilities.

PCOS is the most common cause of ovarian androgen excess **(Chap. 392)**. An increased ratio of LH to follicle-stimulating hormone (FSH) is characteristic in carefully studied patients with PCOS. However, because of the pulsatile nature of gonadotropin secretion, a random measurement of LH and FSH may be misleading and is not recommended. Transvaginal ultrasound classically shows enlarged ovaries, increased stroma, and multiple "cysts" in women with PCOS. These so-called cysts are, in fact, preantral and early antral follicles that result from abnormal follicular maturation. "Cystic" ovaries also may be found in women with hypothalamic amenorrhea **(Chap. 392)** and even among women without clinical or laboratory features of PCOS. Thus, ultrasonography is often not needed to diagnose PCOS given its relatively low specificity and its high degree of operator dependence.

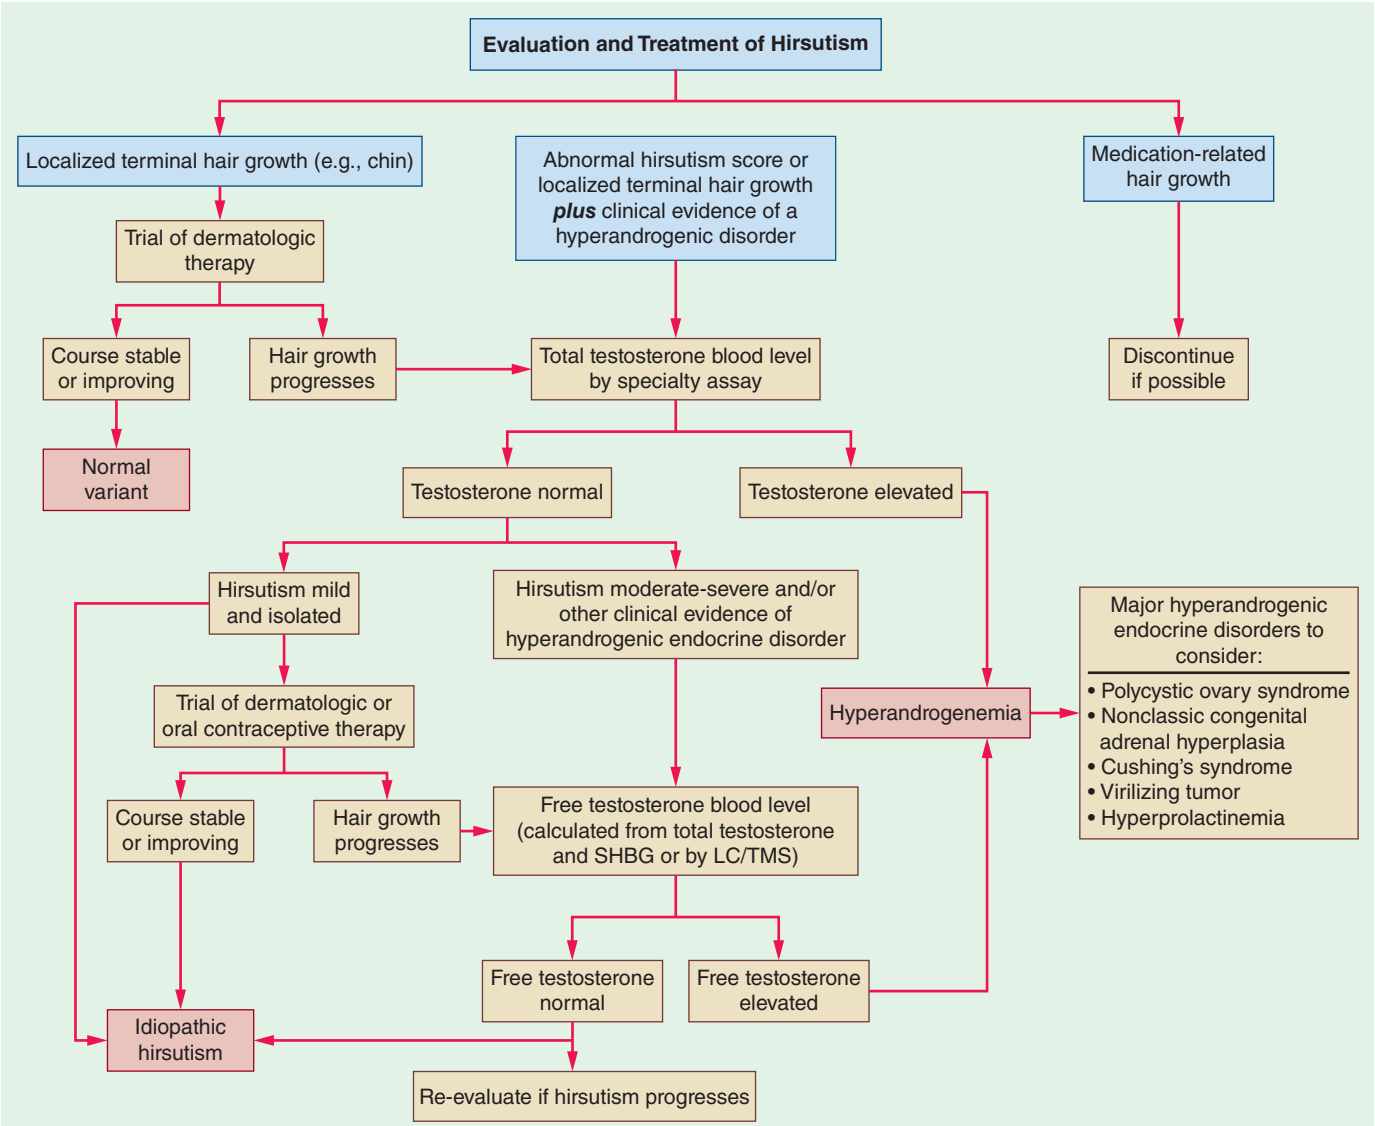

FIGURE 394-2 Algorithm for the evaluation and treatment of hirsutism. LC/TMS, liquid chromatography/tandem mass spectrometry; SHBG, sex hormone–binding globulin. *(Reproduced with permission from KA Martin et al: Evaluation and treatment of hirsutism in premenopausal women: An endocrine society clinical practice guideline. J Clin Endocrinol Metab 103:1233, 2018.)*

Because adrenal androgens are readily suppressed by low doses of glucocorticoids, the dexamethasone androgen-suppression test may broadly distinguish ovarian from adrenal androgen overproduction. A blood sample is obtained before and after the administration of dexamethasone (0.5 mg orally every 6 h for 4 days). An adrenal source is suggested by suppression of unbound testosterone into the normal range; incomplete suppression suggests ovarian androgen excess. An overnight 1-mg dexamethasone suppression test, with measurement of 8:00 A.M. serum cortisol, is useful when there is clinical suspicion of Cushing's syndrome **(Chap. 386)**.

Nonclassic CAH is most commonly due to 21-hydroxylase deficiency but also can be caused by autosomal recessive defects in other steroidogenic enzymes necessary for adrenal corticosteroid synthesis **(Chap. 386)**. Because of the enzyme defect, the adrenal gland cannot secrete glucocorticoids (especially cortisol) efficiently. This results in diminished negative feedback inhibition of ACTH, leading to compensatory adrenal hyperplasia and the accumulation of steroid precursors that subsequently are converted to androgen. Deficiency of 21-hydroxylase can be reliably excluded by determining a morning 17-hydroxyprogesterone level <6 nmol/L (<2 μg/L) (drawn in the follicular phase). Alternatively, 21-hydroxylase deficiency can be diagnosed by measurement of 17-hydroxyprogesterone 1 h after the administration of 250 μg of synthetic ACTH (cosyntropin) intravenously.

TREATMENT

Hirsutism

Treatment of hirsutism may be accomplished pharmacologically or by mechanical means of hair removal. Nonpharmacologic treatments should be considered in all patients either as the only treatment or as an adjunct to drug therapy.

Nonpharmacologic treatments include (1) bleaching, (2) depilatory (removal from the skin surface) such as shaving and chemical treatments, and (3) epilatory (removal of the hair including the root) such as plucking, waxing, electrolysis, laser, and intense pulsed light (IPL). Despite perceptions to the contrary, shaving does not increase the rate or density of hair growth. Chemical depilatory treatments may be useful for mild hirsutism that affects only limited skin areas, although they can cause skin irritation. Wax treatment removes hair temporarily but is uncomfortable. Electrolysis is effective for more permanent hair removal, particularly in the hands of a skilled electrologist. Laser and IPL are used to treat large areas of pigmented, terminal hair. Light of specific wavelength, duration, and energy is absorbed by melanin in the hair shaft and follicle leading to photothermolysis. Properly delivered, this treatment delays hair regrowth and causes permanent hair removal in many patients.

Pharmacologic therapy is directed at interrupting one or more of the steps in the pathway of androgen synthesis and action: (1) suppression of adrenal and/or ovarian androgen production, (2) enhancement of androgen-binding to plasma-binding proteins, particularly SHBG, (3) impairment of the peripheral conversion of androgen precursors to active androgen, and (4) inhibition of androgen action at the target tissue level. Attenuation of hair growth is typically not evident until 4–6 months after initiation of medical treatment and, in most cases, leads to only a modest reduction in hair growth.

Combination estrogen-progestin therapy in the form of an oral contraceptive is usually the first-line endocrine treatment for hirsutism and acne, after cosmetic and dermatologic management. The estrogenic component of most oral contraceptives currently in use is either ethinyl estradiol or mestranol. The suppression of LH leads to reduced production of ovarian androgens. The reduced androgen levels also result in a dose-related increase in SHBG, thus lowering the fraction of unbound plasma testosterone. Estrogens also have a direct, dose-dependent suppressive effect on sebaceous cell function.

The choice of a specific oral contraceptive should be predicated on the progestational component, as progestins vary in their suppressive effect on SHBG levels and in their androgenic potential. Ethynodiol diacetate has relatively low androgenic potential, whereas progestins such as norgestrel and levonorgestrel are particularly androgenic, as judged from their attenuation of the estrogen-induced increase in SHBG. Norgestimate exemplifies the newer generation of progestins that are virtually nonandrogenic. Drospirenone, an analogue of spironolactone that has both antimineralocorticoid and antiandrogenic activities, is commonly used as a progestational agent in combination with ethinyl estradiol.

Oral contraceptives are contraindicated in women with a history of thromboembolic disease and women with increased risk of breast or other estrogen-dependent cancers **(Chap. 395)**. There is a relative contraindication to the use of oral contraceptives in smokers and those with hypertension or a history of migraine headaches. In most trials, estrogen-progestin therapy alone improves the extent of acne by a maximum of 50–70%. The effect on hair growth may not be evident for 6 months, and the maximum effect may require 9–12 months owing to the length of the hair growth cycle. Improvements in hirsutism are typically in the range of 20%, but there may be an arrest of further progression of hair growth.

Because oral contraceptives are efficacious and have fewer side effects, they are recommended over glucocorticoids as first-line treatment of hirsutism in CAH. If the response to oral contraceptives is inadequate, glucocorticoids may be used. The lowest effective dose of glucocorticoid should be used (e.g., dexamethasone [0.2–0.5 mg] or prednisone [5–10 mg]) taken at bedtime to achieve maximal suppression by inhibiting the nocturnal surge of ACTH.

Cyproterone acetate is the prototypic antiandrogen. It acts mainly by competitive inhibition of the binding of testosterone and DHT to the androgen receptor. In addition, it may enhance the metabolic clearance of testosterone by inducing hepatic enzymes. Although not available for use in the United States, cyproterone acetate is widely used in Canada, Mexico, and Europe. Cyproterone (50–100 mg) is given on days 1–15, and ethinyl estradiol (50 μg) is given on days 5–26 of the menstrual cycle. Side effects include irregular uterine bleeding, nausea, headache, fatigue, weight gain, and decreased libido.

Spironolactone, which usually is used as a mineralocorticoid antagonist, is also a weak antiandrogen. It is almost as effective as cyproterone acetate when used at high enough doses (100–200 mg daily). Patients should be monitored intermittently for hyperkalemia or hypotension, though these side effects are uncommon. Pregnancy should be avoided because of the risk of feminization of a male fetus. Spironolactone can also cause menstrual irregularity. It often is used in combination with an oral contraceptive, which suppresses ovarian androgen production and helps prevent pregnancy.

Flutamide is a potent nonsteroidal antiandrogen that is effective in treating hirsutism, but concerns about the induction of hepatocellular dysfunction preclude its use. Finasteride is a competitive inhibitor of 5α-reductase type 2. Beneficial effects on hirsutism have been reported, but the predominance of 5α-reductase type 1 in the PSU appears to account for its limited efficacy. Finasteride would also be expected to impair sexual differentiation in a male fetus, and it should not be used in women who may become pregnant. Although studies of dutasteride are limited in number, it appears that this agent may have efficacy in treating scalp hair thinning and loss as well as hirsutism. Dutasteride differs from finasteride as it targets 5α-reductase types 1 and 2.

Ultimately, the choice of any specific agent(s) must be tailored to the unique needs of the patient being treated. As noted previously, pharmacologic treatments for hirsutism should be used in conjunction with nonpharmacologic approaches. It is also helpful to review the pattern of female hair distribution in the normal population to dispel unrealistic expectations.

395 Menopause and Postmenopausal Hormone Therapy

JoAnn E. Manson, Shari S. Bassuk

Menopause is the permanent cessation of menstruation due to loss of ovarian follicular function. It is diagnosed retrospectively after 12 months of amenorrhea. The average age at menopause is 51 years among U.S. women. *Perimenopause* refers to the time period preceding menopause, when fertility wanes and menstrual cycle irregularity increases, until the first year after cessation of menses. The onset of perimenopause precedes the final menses by 2–8 years, with a mean duration of 4 years. Smoking accelerates the menopausal transition by 2 years.

Although the peri- and postmenopausal transitions share many symptoms, the physiology and clinical management of the two differ. Low-dose oral contraceptives have become a therapeutic mainstay in perimenopause, whereas postmenopausal hormone therapy (HT) has been a common method of symptom alleviation after menstruation ceases.

PERIMENOPAUSE

PHYSIOLOGY

Ovarian mass and fertility decline sharply after age 35 and even more precipitously during perimenopause; depletion of primary follicles, a process that begins before birth, occurs steadily until menopause (Chap. 392). In perimenopause, intermenstrual intervals shorten significantly (typically by 3 days) as a result of an accelerated follicular phase. Follicle-stimulating hormone (FSH) levels rise because of altered folliculogenesis and reduced inhibin secretion. In contrast to the consistently high FSH and low estradiol levels seen in menopause, perimenopause is characterized by "irregularly irregular" hormone levels. The propensity for anovulatory cycles can produce a hyperestrogenic, hypoprogestagenic environment that may account for the increased incidence of endometrial hyperplasia or carcinoma, uterine polyps, and leiomyoma observed among women of perimenopausal age. Mean serum levels of selected ovarian and pituitary hormones during the menopausal transition are shown in Fig. 395-1. With transition into menopause, estradiol levels fall markedly, whereas estrone levels are relatively preserved, a pattern reflecting peripheral aromatization of adrenal and ovarian androgens. Levels of FSH increase more than those of luteinizing hormone, presumably because of the loss of inhibin as well as estrogen feedback.

DIAGNOSTIC TESTS

The Stages of Reproductive Aging Workshop +10 (STRAW+10) classification provides a comprehensive framework for the clinical assessment of ovarian aging. As shown in Fig. 395-2, menstrual cycle characteristics are the principal criteria for characterizing the menopausal transition, with biomarker measures as supportive criteria. Because of their extreme intraindividual variability, FSH and estradiol levels are imperfect diagnostic indicators of perimenopause in menstruating women. However, a consistently low FSH level in the early follicular phase (days 2–5) of the menstrual cycle does not support a diagnosis of perimenopause, while levels >25 IU/L in a random blood sample are characteristic of the late menopause transition. FSH measurement can also aid in assessing fertility; levels of <20 IU/L, 20 to <30 IU/L, and ≥30 IU/L measured on day 3 of the cycle indicate a good, fair, and poor likelihood of achieving pregnancy, respectively. Anti-müllerian hormone and inhibin B may also be useful for assessing reproductive aging.

SYMPTOMS

Determining whether symptoms that develop in midlife are due to ovarian senescence or to other age-related changes is difficult. There is strong evidence that the menopausal transition can cause hot flashes, night sweats, irregular bleeding, and vaginal dryness, and there is moderate evidence that it can cause sleep disturbances in some women. There is inconclusive or insufficient evidence that ovarian aging is a major cause of mood swings, depression, impaired memory or concentration, somatic symptoms, urinary incontinence, or sexual dysfunction. In one U.S. study, nearly 60% of women reported hot flashes in the 2 years before their final menses. Symptom intensity, duration, frequency, and effects on quality of life are highly variable.

TREATMENT

Perimenopause

PERIMENOPAUSAL THERAPY

For women with irregular or heavy menses or hormone-related symptoms that impair quality of life, low-dose combined oral contraceptives are a staple of therapy. Static doses of estrogen and progestin (e.g., 20 μg of ethinyl estradiol and 1 mg of norethindrone acetate daily for 21 days each month) can eliminate vasomotor symptoms and restore regular cyclicity. Oral contraceptives provide other benefits, including protection against ovarian and endometrial cancers and increased bone density, although it is not clear whether use during perimenopause decreases fracture risk later in life. Moreover, the contraceptive benefit is important, given that the unintentional pregnancy rate among women in their forties rivals that of adolescents. Contraindications to oral contraceptive use include cigarette smoking, liver disease, a history

of thromboembolism or cardiovascular disease, breast cancer, or unexplained vaginal bleeding. Progestin-only formulations (e.g., 0.35 mg of norethindrone daily) or medroxyprogesterone (Depo-Provera) injections (e.g., 150 mg IM every 3 months) may provide an alternative for the treatment of perimenopausal menorrhagia in women who smoke or have cardiovascular risk factors. Although progestins neither regularize cycles nor reduce the number of bleeding days, they reduce the volume of menstrual flow.

Nonhormonal strategies to reduce menstrual flow include the use of nonsteroidal anti-inflammatory agents such as mefenamic acid (an initial dose of 500 mg at the start of menses, then 250 mg qid for 2–3 days) or, when medical approaches fail, endometrial ablation. It should be noted that menorrhagia requires an evaluation to rule out uterine disorders. Transvaginal ultrasound with saline enhancement is useful for detecting leiomyomata or polyps, and endometrial aspiration can identify hyperplastic changes.

TRANSITION TO MENOPAUSE

For sexually active women using contraceptive hormones to alleviate perimenopausal symptoms, the question of when and if to switch to HT must be individualized. Doses of estrogen and progestogen (either synthetic progestins or natural forms of progesterone) in HT are lower than those in oral contraceptives and have not been documented to prevent pregnancy. Although a 1-year absence of spontaneous menses reliably indicates ovulation cessation, it is not possible to assess the natural menstrual pattern while a woman is taking an oral contraceptive. Women willing to switch to a barrier method of contraception should do so; if menses occur spontaneously, oral contraceptive use can be resumed. The average age of final menses among relatives can serve as a guide for when to initiate this process, which can be repeated yearly until menopause has occurred.

MENOPAUSE AND POSTMENOPAUSAL HT

One of the most complex health care decisions facing women is whether to use postmenopausal HT. Once prescribed primarily to relieve vasomotor symptoms, HT has been promoted as a strategy to forestall various disorders that accelerate after menopause, including osteoporosis and cardiovascular disease. In 2000, nearly 40% of postmenopausal women aged 50–74 in the United States had used HT. This widespread use occurred despite the paucity of conclusive data, until recently, on the health consequences of such therapy. Although many women rely on their health care providers for a definitive answer to the question of whether to use postmenopausal hormones, balancing the benefits and risks for an individual patient is challenging.

Although observational studies suggest that HT prevents cardiovascular and other chronic diseases, the apparent benefits may result at least in part from differences between women who opt to take postmenopausal hormones and women who do not. Those choosing HT tend to be healthier, have greater access to medical care, are more compliant with prescribed treatments, and maintain a more health-promoting lifestyle. Randomized trials, which eliminate these confounding factors, have not consistently confirmed the benefits found in observational studies. Indeed, the largest HT trial to date, the Women's Health Initiative (WHI), which examined >27,000 postmenopausal women aged 50–79 (mean age, 63) for an average of 5–7 years, was stopped early because of an overall unfavorable benefit-risk ratio in the estrogen-progestin arm and an excess risk of stroke that was not offset by a reduced risk of coronary heart disease (CHD) in the estrogen-only arm.

The following summary offers a decision-making guide based on a synthesis of currently available evidence. Prevention of cardiovascular disease is eliminated from the equation due to lack of evidence for such benefits in randomized clinical trials.

BENEFITS AND RISKS OF POSTMENOPAUSAL HT

See Table 395-1.

Definite Benefits • **SYMPTOMS OF MENOPAUSE** Compelling evidence, including data from randomized clinical trials, indicates that estrogen therapy is highly effective for controlling vasomotor and genitourinary symptoms. Alternative approaches, including the use of antidepressants (such as paroxetine, 10–25 mg/d; paroxetine salt, 7.5 mg/d; or venlafaxine, 37.5–75 mg/d), γ-aminobutyric acid analogues (such as gabapentin, 300 mg nightly, up to 900 mg in divided doses; or pregabalin, 75–150 mg/d twice per day), or clonidine patch (0.1–0.3 mg weekly), may also alleviate vasomotor symptoms, although they are less effective than HT. Paroxetine is the only nonhormonal drug approved by the U.S. Food and Drug Administration for treatment of vasomotor symptoms. Bazedoxifene, an estrogen agonist/antagonist, in combination with conjugated estrogens has also received approval for this use. Cognitive behavioral therapy and clinical hypnosis have been shown in randomized trials to help with vasomotor symptom management. Weight loss, mindfulness-based stress reduction, stellate ganglion block, and the consumption of S-equol soy derivatives are also promising strategies, although more trials are needed. For genitourinary syndrome of menopause, the efficacy of low-dose vaginal estrogen is similar to that of oral or transdermal estrogen; oral ospemifene or vaginal prasterone are additional options.

OSTEOPOROSIS (See also Chap. 411)

Bone density By reducing bone turnover and resorption rates, estrogen slows the aging-related bone loss experienced by most postmenopausal women. More than 50 randomized trials have demonstrated that postmenopausal estrogen therapy, with or without a progestogen, rapidly increases bone mineral density at the spine by 4–6% and at the hip by 2–3% and that those increases are maintained during treatment.

Fractures Data from observational studies indicate a 50–80% lower risk of vertebral fracture and a 25–30% lower risk of hip, wrist, and other peripheral fractures among current estrogen users; addition of a progestogen does not appear to modify this benefit. In the WHI, 5–7 years of either combined estrogen-progestin or estrogen-only therapy was associated with a 33% reduction in hip fractures and 25–30% fewer total fractures among a population unselected for osteoporosis. Bisphosphonates (such as alendronate, 10 mg/d or 70 mg once per week; risedronate, 5 mg/d or 35 mg once per week; ibandronate, 2.5 mg/d or 150 mg once per month or 3 mg every 3 months IV; or zoledronic acid, 5 mg once per year IV) and denosumab (60 mg twice per year SC) increase bone mass density by reducing bone resorption and have been shown in randomized trials to decrease fracture rates. Other treatment options include bazedoxifene in combination with conjugated estrogens; the selective estrogen receptor modulator (SERM) raloxifene (60 mg/d); and parathyroid hormone (teriparatide, 20 μg/d SC). Unlike estrogen, these alternative therapies do not appear to have adverse effects on the endometrium or breast. Increased weight-bearing and resistance exercise; adequate calcium intake (1000–1200 mg/d through diet or supplements in two or three divided doses); and adequate vitamin D intake (600–1000 IU/d) may also reduce the risk of osteoporosis-related fractures. According to a 2011 report by the Institute of Medicine (now the National Academy of Medicine), 25-hydroxyvitamin D blood levels of ≥50 nmol/L are sufficient for bone-density maintenance and fracture prevention. The Fracture Risk Assessment (FRAX®) score, an algorithm that combines an individual's bone-density score with age and other risk factors to predict her 10-year risk of hip and major osteoporotic fracture, may be of use in guiding decisions about pharmacologic treatment (see *https://www.sheffield.ac.uk/FRAX/*).

Definite Risks • **ENDOMETRIAL CANCER (WITH ESTROGEN ALONE)** A combined analysis of 30 observational studies found a tripling of endometrial cancer risk among short-term users (1–5 years) of unopposed estrogen and a nearly tenfold increased risk among long-term users (≥10 years). These findings are supported by results from the randomized Postmenopausal Estrogen/Progestin Interventions (PEPI) trial, in which 24% of women assigned to unopposed estrogen for 3 years developed atypical endometrial hyperplasia—a premalignant lesion—as opposed to only 1% of women assigned to placebo. Use of a progestogen, which opposes the effects of estrogen on the endometrium, eliminates these risks and may even reduce risk (see later).

VENOUS THROMBOEMBOLISM A meta-analysis of observational studies found that current oral estrogen use was associated with a 2.5-fold increase in risk of venous thromboembolism in postmenopausal women. A meta-analysis of randomized trials, including the WHI, found a 2.1-fold increase in risk. Results from the WHI indicate a nearly twofold increase in risk of pulmonary embolism and deep-vein thrombosis with estrogen-progestin and a 35–50% increase in these risks with estrogen-only therapy. Transdermal estrogen, taken alone or with certain progestogens (micronized progesterone or pregnane derivatives), appears to be a safer alternative with respect to thrombotic risk.

BREAST CANCER (WITH ESTROGEN-PROGESTIN) An increased risk of breast cancer has been found among current or recent estrogen users in observational studies; this risk is directly related to duration of use. In a meta-analysis of 51 case-control and cohort studies, short-term use (<5 years) of postmenopausal HT did not appreciably elevate breast cancer incidence, whereas long-term use (≥5 years) was associated with a 35% increase in risk. In contrast to findings for endometrial cancer, combined estrogen-progestin regimens appear to increase breast cancer risk more than estrogen alone. Data from randomized trials also indicate that estrogen-progestin raises breast cancer risk. In the WHI, women assigned to receive combination hormones for an average of 5.6 years were 24% more likely to develop breast cancer than women assigned to placebo, but 7.1 years of estrogen-only therapy did not increase risk. Indeed, the WHI showed a trend toward a reduction in breast cancer risk with estrogen alone, although it is unclear whether this finding would pertain to formulations of estrogen other than conjugated equine estrogens or to treatment durations of >7 years. In the Heart and Estrogen/Progestin Replacement Study (HERS), combination therapy for 4 years was associated with a 27% increase in breast cancer risk. Although the latter finding was not statistically significant, the totality of evidence strongly implicates estrogen-progestin therapy in breast carcinogenesis.

Some observational data suggest that the length of the interval between menopause onset and HT initiation may influence the association between such therapy and breast cancer risk, with a "gap time" of <3–5 years conferring a higher HT-associated breast cancer risk. (This pattern of findings contrasts with that for CHD, as discussed later in this chapter.) However, this association remains inconclusive and may be a spurious finding attributable to higher rates of screening mammography and thus earlier cancer detection in HT users than in nonusers, especially in early menopause. Indeed, in the WHI trial, hazard ratios for HT and breast cancer risk did not differ among women 50–59, those 60–69, and those 70–79 years of age at trial entry. (There was insufficient power to examine finer age categories.) Additional research is needed to clarify the issue.

GALLBLADDER DISEASE Large observational studies report a two- to threefold increased risk of gallstones or cholecystectomy among postmenopausal women taking oral estrogen. In the WHI, women randomized to estrogen-progestin or estrogen alone were ~55% more likely to develop gallbladder disease than those assigned to placebo. Risks were also increased in HERS. Transdermal HT might be a safer alternative, but further research is needed.

Probable or Uncertain Risks and Benefits • **CORONARY HEART DISEASE/STROKE** Until recently, HT had been enthusiastically recommended as a possible cardioprotective agent. In the past three decades, multiple observational studies suggested, in the aggregate, that estrogen use leads to a 35–50% reduction in CHD incidence among postmenopausal women. The biologic plausibility of such an association is supported by data from randomized trials demonstrating that exogenous estrogen lowers plasma low-density lipoprotein (LDL) cholesterol levels and raises high-density lipoprotein (HDL) cholesterol

TABLE 395-1 Benefits and Risks of Postmenopausal Hormone Therapy in the Overall Study Population of Women aged 50–79 Years in the Intervention Phase of the Women's Health Initiative (WHI) Estrogen-Progestin and Estrogen-Alone Trials[a]

		ESTROGEN-PROGESTIN		ESTROGEN ALONE	
OUTCOME	EFFECT	RELATIVE BENEFIT OR RISK	ABSOLUTE BENEFIT OR RISK[b]	RELATIVE BENEFIT OR RISK	ABSOLUTE BENEFIT OR RISK[b]
Definite Benefits					
Symptoms of menopause	Definite improvement	↓65–90% decreased risk[c]		↓65–90% decreased risk[c]	
Osteoporosis	Definite increase in bone mineral density and decrease in fracture risk	↓33% decreased risk for hip fracture	6 fewer cases (11 vs 17) of hip fracture	↓33% decreased risk for hip fracture	6 fewer cases (13 vs 19) of hip fracture
Definite Risks[h]					
Endometrial cancer	Definite increase in risk with estrogen alone (see below for estrogen-progestin)	See below	See below		4.6 excess cases (observational studies)
Pulmonary embolism	Definite increase in risk	↑98% increased risk	9 excess cases (18 vs 9)	↑35% increased risk (n.s.)	4 excess cases (14 vs 10)
Deep-vein thrombosis	Definite increase in risk	↑87% increased risk	11.5 excess cases (25 vs 14)	↑48% increased risk	7.5 excess cases (23 vs 15)
Breast cancer	Definite increase in risk with long-term use (≥5 years) of estrogen-progestin	↑24% increased risk	8.5 excess cases (43 vs 35)	↓21% decreased risk (n.s.)	7 fewer cases (28 vs 35)
Gallbladder disease	Definite increase in risk	↑57% increased risk	47 excess cases (131 vs 84)	↑55% increased risk	58 excess cases (164 vs 106)
Probable or Uncertain Risks and Benefits[h]					
Coronary heart disease[d]	Probable increase in risk among older women and women many years past menopause; possible decrease in risk or no effect in younger or recently menopausal women[e]	↑18% increased risk (n.s.)	6 excess cases (41 vs 35)	No increase in risk	No difference in risk
Myocardial infarction	Significant interaction by age group for estrogen alone, with reduced risk in younger—but not older—women (*p* for trend by age = .02)	↑24% increased risk (n.s.)	6 excess cases (35 vs 29)	No increase in risk[e]	No difference in risk[e]
Stroke	Probable increase in risk	↑37% increased risk	9 excess cases (33 vs 24)	↑35% increased risk	11 excess cases (45 vs 34)
Ovarian cancer	Probable increase in risk with long-term use (≥5 years)	↑41% increased risk (n.s.)	1 excess case (5 vs 4)	Not available	Not available
Endometrial cancer	Probable decrease in risk with estrogen-progestin during long-term follow-up (see above for estrogen alone)	↓33% decreased risk[f]	3 fewer cases (7 vs 10)	See above	See above
Urinary incontinence	Probable increase in risk	↑49% increased risk	549 excess cases (1661 vs 1112)	↑61% increased risk	852 excess cases (2255 vs 1403)
Colorectal cancer	Probable decrease in risk with estrogen-progestin; possible increase in risk in older women with estrogen alone (*p* for trend by age = .02 for estrogen alone)	↓38% decreased risk	6.5 fewer cases (10 vs 17)	No increase or decrease in risk[e]	No difference in risk[e]
Type 2 diabetes	Probable decrease in risk	↓19% decreased risk	16 fewer cases (72 vs 88)	↓14% decreased risk	21 fewer cases (134 vs 155)
Dementia (age ≥65)	Increase in risk in older women (but inconsistent data from observational studies and randomized trials)	↑101% increased risk	23 excess cases (46 vs 23)	↑47% increased risk (n.s.)	15 excess cases (44 vs 29)
Total mortality	Possible increase in risk among older women and women many years past menopause; possible decrease in risk or no effect in younger or recently menopausal women (*p* for trend by age <.05 for both trials combined)	No increase in risk	No difference in risk	No increase in risk[e]	No difference in risk[e]
Global index[g]	Probable increase in risk or no effect among older women and women many years past menopause; possible decrease in risk or no effect in younger or recently menopausal women (*p* for trend by age = .02 for estrogen alone)	↑12% increased risk	20.5 excess cases (189 vs 168)	No increase in risk[e]	No difference in risk[e]

[a]The estrogen-progestin arm of the WHI assessed 5.6 years of conjugated equine estrogens (0.625 mg/d) plus medroxyprogesterone acetate (2.5 mg/d) versus placebo. The estrogen-alone arm of the WHI assessed 7.1 years of conjugated equine estrogens (0.625 mg/d) versus placebo. [b]Number of cases per 10,000 women per year. [c]The WHI was not designed to assess the effect of hormone therapy (HT) on menopausal symptoms. Data from other randomized trials suggest that HT reduces risk for menopausal symptoms by 65–90%. [d]*Coronary heart disease* is defined as nonfatal myocardial infarction or coronary death. [e]There was a significant interaction by age; that is, the association between HT and the specified outcome was different in younger women and older women. [f]This is the risk reduction that was observed during a cumulative 13-year follow-up period (5.6 years of treatment plus 8.2 years of postintervention observation). [g]The *global index* is a composite outcome representing the first event for each participant from among the following: coronary heart disease, stroke, pulmonary embolism, breast cancer, colorectal cancer, endometrial cancer (estrogen-progestin arm only), hip fracture, and death. Because participants can experience more than one type of event, the global index cannot be derived by a simple summing of the component events. [h]Includes some outcomes where results were divergent between the estrogen-progestin arm and the estrogen-alone arm.

Abbreviation: n.s., not statistically significant.

levels by 10–15%. Administration of estrogen also favorably affects lipoprotein(a) levels, LDL oxidation, endothelial vascular function, fibrinogen, and plasminogen activator inhibitor 1. However, estrogen therapy has unfavorable effects on other biomarkers of cardiovascular risk: it boosts triglyceride levels; promotes coagulation via factor VII, prothrombin fragments 1 and 2, and fibrinopeptide A elevations; and raises levels of the inflammatory marker C-reactive protein.

Randomized trials of estrogen or combined estrogen-progestin in women with preexisting cardiovascular disease have not confirmed the benefits reported in observational studies. In HERS (a secondary-prevention trial designed to test the efficacy and safety of estrogen-progestin therapy with regard to clinical cardiovascular outcomes), the 4-year incidence of coronary death and nonfatal myocardial infarction was similar in the active-treatment and placebo groups, and a 50% increase in risk of coronary events was noted during the first year among participants assigned to the active-treatment group. Although it is possible that progestin may mitigate estrogen's benefits, the Estrogen Replacement and Atherosclerosis (ERA) trial indicated that angiographically determined progression of coronary atherosclerosis was unaffected by either opposed or unopposed estrogen treatment. Moreover, no cardiovascular benefit was found in the Papworth Hormone Replacement Therapy Atherosclerosis Study, a trial of transdermal estradiol with and without norethindrone; the Women's Estrogen for Stroke Trial (WEST), a trial of oral 17β-estradiol; or the Estrogen in the Prevention of Reinfarction Trial (ESPRIT), a trial of oral estradiol valerate. Thus, in clinical trials, HT has not proved effective for the secondary prevention of cardiovascular disease in postmenopausal women.

Primary-prevention trials also suggest an early increase in cardiovascular risk and an absence of cardioprotection with postmenopausal HT. In the WHI, women assigned to 5.6 years of estrogen-progestin therapy were 18% more likely to develop CHD (defined in primary analyses as nonfatal myocardial infarction or coronary death) than those assigned to placebo, although this risk elevation was not statistically significant. However, during the trial's first year, there was a significant 80% increase in risk, which diminished in subsequent years (p for trend by time = .03). In the estrogen-only arm of the WHI, no overall effect on CHD was observed during the 7.1 years of the trial or in any specific year of follow-up. This pattern of results was similar to that for the outcome of total myocardial infarction.

However, a closer look at available data suggests that timing of initiation of HT may critically influence the association between such therapy and CHD. Estrogen may slow early stages of atherosclerosis but have adverse effects on advanced atherosclerotic lesions. It has been hypothesized that the prothrombotic and proinflammatory effects of estrogen manifest themselves predominantly among women with subclinical lesions who initiate HT well after the menopausal transition, whereas women with less arterial damage who start HT early in menopause may derive cardiovascular benefit because they have not yet developed advanced lesions. Data from experiments in nonhuman primates and from some recent randomized trials in humans support this concept. Conjugated estrogens had no effect on the extent of coronary artery plaque in cynomolgus monkeys assigned to receive estrogen alone or combined with progestin starting 2 years (~6 years in human terms) after oophorectomy and well after the establishment of atherosclerosis. However, administration of exogenous hormones immediately after oophorectomy, during the early stages of atherosclerosis, reduced the extent of plaque by 70%. In the Early versus Late Intervention Trial with Estradiol (ELITE), a 6-year trial among 643 healthy postmenopausal women that was designed to test whether effects of estrogen on the development and progression of atherosclerosis depend on age at initiation of therapy, oral 17β-estradiol administered with or without vaginal micronized progesterone significantly slowed carotid atherosclerotic progression in women within 6 years of menopause onset (mean age, 55.4 years) but not in women >10 years past menopause onset (mean age, 65.4 years) (p for interaction = .007). On the other hand, in the Kronos Early Estrogen Prevention Study (KEEPS), a 4-year trial among 729 healthy postmenopausal women within 3 years of menopause onset at trial entry (mean age, 53 years), neither oral conjugated estrogens nor transdermal estradiol, administered with oral micronized progesterone, affected carotid atherosclerotic progression. However, the low prevalence of this endpoint in the overall study population may have curtailed power to detect a treatment difference.

Lending further credence to the timing hypothesis are results of subgroup analyses of data from observational studies and large clinical trials. For example, among women who entered the WHI trial with a relatively favorable cholesterol profile, estrogen with or without progestin led to a 40% lower risk of incident CHD. Among women who entered with a worse cholesterol profile, therapy resulted in a 73% higher risk (p for interaction = .02). The presence or absence of the metabolic syndrome **(Chap. 408)** also strongly influenced the relation between HT and incident CHD. Among women with the metabolic syndrome, HT more than doubled CHD risk, whereas no association was observed among women without the syndrome. Moreover, although there was no association between estrogen-only therapy and CHD in the WHI trial cohort as a whole, such therapy was associated with a CHD risk reduction of 40% among participants aged 50–59; in contrast, a risk reduction of only 5% was observed among those aged 60–69, and a risk increase of 9% was found among those aged 70–79 (p for trend by age = .08). For the outcome of total myocardial infarction, estrogen alone was associated with a borderline-significant 45% reduction and a nonsignificant 24% increase in risk among the youngest and oldest women, respectively (p for trend by age = .02). Estrogen was also associated with lower levels of coronary artery calcified plaque in the younger age group. Although age did not have a similar effect in the estrogen-progestin arm of the WHI, CHD risks increased with years since menopause (p for trend = .08), with a significantly elevated risk among women who were ≥20 years past menopause. For the outcome of total myocardial infarction, estrogen-progestin was associated with a 9% risk reduction among women <10 years past menopause as opposed to a 16% increase in risk among women 10–19 years past menopause and a twofold increase in risk among women >20 years past menopause (p for trend = .01). In the large observational Nurses' Health Study, women who chose to start HT within 4 years of menopause experienced a lower risk of CHD than did nonusers, whereas those who began therapy ≥10 years after menopause appeared to receive little coronary benefit. Observational studies include a high proportion of women who begin HT within 3–4 years of menopause, whereas clinical trials include a high proportion of women ≥12 years past menopause; this difference helps to reconcile some of the apparent discrepancies between the two types of studies.

For the outcome of stroke, WHI participants assigned to estrogen-progestin or estrogen alone were ~35% more likely to suffer a stroke than those assigned to placebo. Whether or not age at initiation of HT influences stroke risk is not well understood. In the WHI and the Nurses' Health Study, HT was associated with an excess risk of stroke in all age groups. Further research is needed on age, time since menopause, and other individual characteristics (including biomarkers) that predict increases or decreases in cardiovascular risk associated with exogenous HT. Furthermore, it remains uncertain whether different doses, formulations, or routes of administration of HT will produce different cardiovascular effects.

COLORECTAL CANCER Observational studies have suggested that HT reduces risks of colon and rectal cancer, although the estimated magnitudes of the relative benefits have ranged from 8 to 34% in various meta-analyses. In the WHI (the sole trial to examine the issue), estrogen-progestin was associated with a significant 38% reduction in colorectal cancer over a 5.6-year period, although no benefit was seen with 7 years of estrogen-only therapy. However, a modifying effect of age was observed, with a doubling of risk with HT in women aged 70–79 but no risk elevation in younger women (p for trend by age = .02).

COGNITIVE DECLINE AND DEMENTIA A meta-analysis of 10 case-control and two cohort studies suggested that postmenopausal HT is associated with a 34% decreased risk of dementia. Subsequent randomized trials (including the WHI), however, have failed to demonstrate any benefit of estrogen or estrogen-progestin therapy on the progression of

mild to moderate Alzheimer's disease and/or have indicated a potential adverse effect of HT on the incidence of dementia, at least in women ≥65 years of age. Among women randomized to HT (as opposed to placebo) at age 50–55 in the WHI, no effect on cognition was observed during the postintervention phase. Determining whether timing of initiation of HT influences cognitive outcomes will require further study.

OVARIAN CANCER AND OTHER DISORDERS On the basis of limited observational and randomized data, it has been hypothesized that HT increases the risk of ovarian cancer and reduces the risk of type 2 diabetes mellitus. Results from the WHI support these hypotheses. The WHI also found that HT use was associated with an increased risk of urinary incontinence and that estrogen-progestin was associated with increased rates of lung cancer mortality.

ENDOMETRIAL CANCER (WITH ESTROGEN-PROGESTIN) In the WHI, use of estrogen-progestin was associated with a nonsignificant 17% reduction in risk of endometrial cancer. A significant reduction in risk emerged during the postintervention period (see later).

ALL-CAUSE MORTALITY In the overall WHI cohort, estrogen with or without progestin was not associated with all-cause mortality. However, there was a trend toward reduced mortality in younger women, particularly with estrogen alone. For women aged 50–59, 60–69, and 70–79 years, relative risks (RRs) associated with estrogen-only therapy were 0.70, 1.01, and 1.21, respectively (p for trend = .04).

OVERALL BENEFIT-RISK PROFILE Estrogen-progestin was associated with an unfavorable benefit-risk profile (excluding relief from menopausal symptoms) as measured by a "global index"—a composite outcome including CHD, stroke, pulmonary embolism, breast cancer, colorectal cancer, endometrial cancer, hip fracture, and death (Table 395-1)—in the WHI cohort as a whole, and this association did not vary by 10-year age group. Estrogen-only therapy was associated with a neutral benefit-risk profile in the WHI cohort as a whole. However, there was a significant trend toward a more favorable benefit-risk profile among younger women and a less favorable profile among older women, with RRs of 0.84, 0.99, and 1.17 for women aged 50–59, 60–69, and 70–79 years, respectively (p for trend by age = .02). The balance of benefits and risks of estrogen with and without progestin among women aged 50–59 is shown in **Fig. 395-3**.

CHANGES IN HEALTH STATUS AFTER DISCONTINUATION OF HT In the WHI, many but not all risks and benefits associated with active use of HT dissipated within 5–7 years after discontinuation of therapy. For estrogen-progestin, an elevated risk of breast cancer persisted (RR = 1.28; 95% confidence interval [CI], 1.11–1.48) during a median cumulative 13-year follow-up period (5.6 years of treatment plus 8.2 years of postintervention observation), but most cardiovascular disease risks became neutral. A reduction in hip fracture risk persisted (RR = 0.81; 95% CI, 0.68–0.97), and a significant reduction in endometrial cancer risk emerged (RR = 0.67; 95% CI, 0.49–0.91). For estrogen alone,

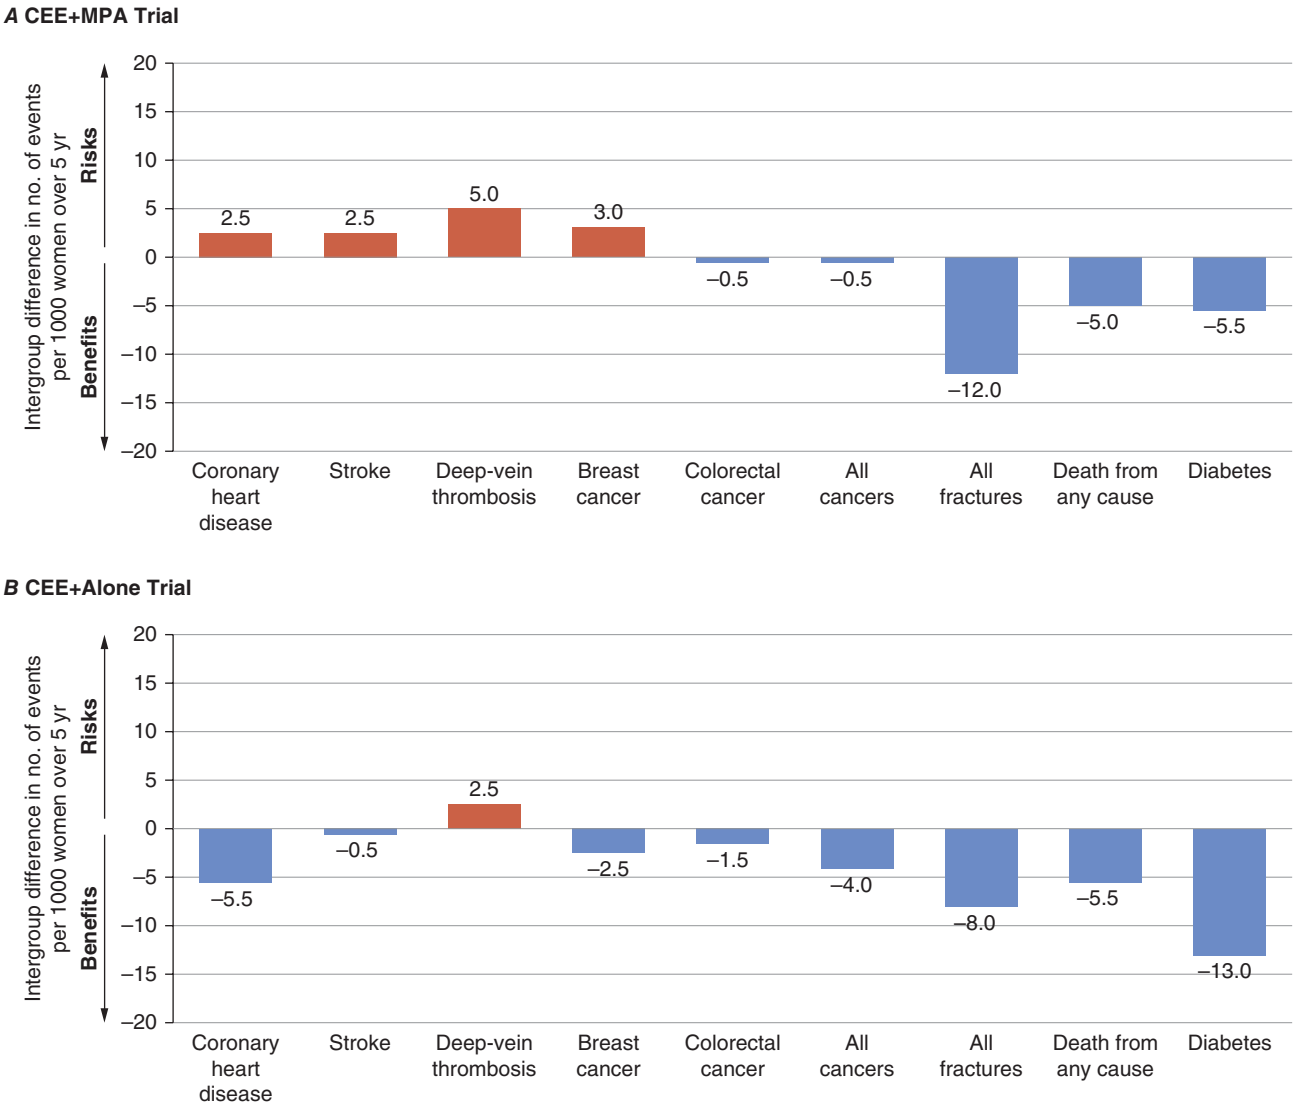

FIGURE 395-3 Benefits and risks of the two hormone therapy (HT) formulations evaluated in the Women's Health Initiative, in women aged 50–59 years. Results are shown for the two formulations, conjugated equine estrogens (CEE) alone or in combination with medroxyprogesterone acetate (MPA). Risks and benefits are expressed as the difference in number of events (number in the HT group minus the number in the placebo group) per 1000 women over 5 years. *(Reproduced with permission from JE Manson, AM Kaunitz. Menopause Management--Getting Clinical Care Back on Track. N Engl J Med 374:803, 2016.)*

the reduction in breast cancer risk became statistically significant (RR = 0.79; 95% CI, 0.65–0.97) during a median cumulative 13-year follow-up period (6.8 years of treatment plus 6.6 years of postintervention observation), and significant differences by age group persisted for total myocardial infarction and the global index, with more favorable results for younger women. During a median cumulative 18-year follow-up, estrogen alone was associated with a significant reduction in all-cause mortality in women aged 50–59 years (RR = 0.79; 95% CI, 0.64–0.96); the protective effect was seen primarily in those with bilateral oophorectomy (RR = 0.68; 95% CI, 0.48–0.96).

APPROACH TO THE PATIENT

Postmenopausal HT

The rational use of postmenopausal HT requires balancing the potential benefits and risks. Table 395-2 provides one approach to decision-making. This approach applies to women with menopausal symptoms who are age 45 years and older or to women who have had removal of both ovaries, regardless of age. Women below age 45 years or those with uncertain menopausal status may need additional clinical evaluation before determining a management plan. The clinician should first assess whether the patient has moderate to severe hot flashes and/or night sweats—the primary indication for initiation of systemic HT—that do not subside in response to behavioral/lifestyle modifications. (A patient handout with suggested lifestyle modifications can be found at *http://www.menopause.org/docs/for-women/mnflashes.pdf*.) Systemic HT may also be used to prevent osteoporosis in women at high risk of fracture who cannot tolerate alternative osteoporosis therapies. (Vaginal estrogen or other medications may be used to treat genitourinary syndrome of menopause in the absence of vasomotor symptoms [see below].) The benefits and risks of such therapy should be reviewed with the patient, giving more emphasis to absolute than to relative measures of effect and pointing out uncertainties in clinical knowledge where relevant. Because chronic disease rates generally increase with age, absolute risks tend to be greater in older women, even when RRs remain similar. Potential side effects—especially vaginal bleeding that may result from use of the combined estrogen-progestogen formulations recommended for women with an intact uterus—should be noted. The patient's own preference regarding therapy should be elicited and factored into the decision. Contraindications should be assessed routinely and include unexplained vaginal bleeding; liver dysfunction or disease; venous thromboembolism; known blood clotting disorder or thrombophilia (transdermal estrogen may be an option); untreated hypertension; history of endometrial cancer (except stage 1 without deep invasion), breast cancer, or other estrogen-dependent cancer; and history of CHD, stroke, or transient ischemic attack. Relative contraindications to systemic HT include an elevated risk of breast cancer (e.g., women who have one or more first-degree relatives with breast cancer, susceptibility genes such as *BRCA1* or *BRCA2*, a personal history of cellular atypia detected by breast biopsy); hypertriglyceridemia (>400 mg/dL); an elevated risk of cardiovascular disease; and active gallbladder disease (transdermal estrogen may be an option in the latter three cases because it has a less adverse effect on triglyceride levels, clotting factors, and inflammation factors than oral HT). Primary prevention of heart disease should not be viewed as an expected benefit of HT, and an increase in the risk of stroke as well as a small early increase in the risk of coronary artery disease should be considered. Nevertheless, such therapy may be appropriate if the noncoronary benefits of treatment clearly outweigh the risks. Reassess benefits and risks at least once every 6–12 months, assuming the patient's continued preference for HT, or if the patient's health status changes. A woman who suffers an acute coronary event or stroke while taking HT should discontinue therapy immediately.

Many options for systemic HT are available. Estrogen alone is recommended for women with hysterectomy, whereas estrogen plus progestogen is recommended for women with a uterus. In the United States, the most commonly prescribed oral estrogens for systemic treatment of vasomotor symptoms are 17β-estradiol (1.0 or 0.5 mg/d or other doses) and conjugated equine estrogens (CEE; 0.625, 0.45, or 0.3 mg/d or other doses). The most commonly prescribed transdermal estrogen products are 17β-estradiol skin patches (0.035 or 0.05 mg/d or other doses). The most commonly prescribed progestogens are medroxyprogesterone acetate (MPA; 2.5, 5, or 10 mg/d) and micronized progesterone (100 or 200 mg/d). Also available are oral estrogen-progestin combinations, such as oral CEE and MPA, oral 17β-estradiol or ethinyl estradiol with norethindrone acetate, oral estradiol with progesterone, and other options. CEE/bazedoxifene may be an option for women with a uterus, especially those with concerns about breast tenderness, breast density, or uterine bleeding. Contraindications to CEE/bazedoxifene are similar to those for systemic HT.

Short-term use (<5 years for estrogen-progestogen and <7 years for estrogen alone) is appropriate for relief of menopausal symptoms among women without contraindications to such use. However, such therapy should be avoided by women with an elevated baseline risk of future cardiovascular events. Women who have contraindications for or are opposed to HT may derive benefit from the use of certain antidepressants (including venlafaxine, fluoxetine, or paroxetine), gabapentin or pregabalin, or clonidine.

Long-term use (≥5 years for estrogen-progestogen and ≥7 years for estrogen alone) is more problematic because a heightened risk of breast cancer must be factored into the decision, especially for estrogen-progestogen. Reasonable candidates for such use include postmenopausal women who have persistent severe vasomotor symptoms

TABLE 395-2 Approach to Initiating Menopausal Hormone Therapy for Vasomotor Symptom Management

1. Vasomotor symptom assessment
Confirm that hot flashes and/or night sweats are adversely affecting sleep, daytime functioning, or quality of life
2. Risk factor assessment
Confirm that there are no absolute contraindications to menopausal hormone therapy
Breast, endometrial, or other estrogen-dependent cancer
Cardiovascular disease (heart disease, stroke, transient ischemic attack)
Active liver disease
Undiagnosed vaginal bleeding
3. Menopausal hormone therapy initiation

along with an increased risk of osteoporosis (e.g., those with osteopenia, a personal or family history of nontraumatic fracture, or a weight <125 lb), who also have no personal or family history of breast cancer in a first-degree relative or other contraindications, and who have a strong personal preference for therapy. Poor candidates are women with elevated cardiovascular risk, those at increased risk of breast cancer, and those at low risk of osteoporosis. Even for reasonable candidates, strategies to minimize dose and duration of use should be employed. For example, women using HT to relieve intense vasomotor symptoms in early postmenopause should consider discontinuing therapy within 5 years, resuming it only if such symptoms persist. Because of the role of progestogens in increasing breast cancer risk, regimens that employ cyclic rather than continuous progestogen exposure as well as formulations other than MPA should be considered if treatment is extended. For prevention of osteoporosis, alternative therapies such as bisphosphonates or SERMs should be considered. Research on alternative progestogens and androgen-containing preparations has been limited, particularly with respect to long-term safety. Additional research on the effects of these agents on cardiovascular disease, glucose tolerance, and breast cancer will be of particular interest.

For genitourinary symptoms such as vaginal dryness or pain with intercourse/sexual activity, intravaginal estrogen creams, tablets, or rings; prasterone (vaginal dehydroepiandrosterone); and ospemifene are options. Contraindications to low-dose vaginal estrogen include unexplained vaginal bleeding or breast cancer, endometrial cancer, or other estrogen-dependent cancer. Contraindications to ospemifene and prasterone are the same as those for low-dose vaginal estrogen, and contraindications for ospemifene additionally include venous or arterial thromboembolic disease, severe liver disease, and use of estrogens or estrogen agonists-antagonists.

In addition to HT, lifestyle choices such as smoking abstention, adequate physical activity, and a healthy diet can play a role in controlling symptoms and preventing chronic disease. An expanding array of pharmacologic options (e.g., bisphosphonates, SERMs, and other agents for osteoporosis; cholesterol-lowering or antihypertensive agents for cardiovascular disease) should also reduce the widespread reliance on hormone use. However, short-term HT may still benefit some women.

396 Infertility and Contraception

Anuja Dokras, Janet E. Hall

INFERTILITY

The World Health Organization (WHO) categorizes infertility as a disease of the reproductive system. Infertility is the third most common disease worldwide, affecting ~48 million couples. It is defined as the inability to achieve a pregnancy over 12 months of unprotected intercourse. The prevalence of infertility, ~15% globally, has remained relatively stable over the past few decades. Primary infertility occurs in couples who have never achieved a pregnancy, whereas secondary infertility refers to infertility after achieving at least one pregnancy. During the first year of attempting pregnancy, the fecundability rate, defined as the ability to achieve a pregnancy within one menstrual cycle, is highest in the first 3 months and declines over the next 9 months. Approximately 85% of couples will achieve pregnancy after 12 months, and 95% will achieve pregnancy after 24 months. Increasing trends toward later childbearing can have significant implications due to age-related decrease in the fecundability rate. Compared to women aged 30–31 years of age, fecundability is reduced by 14% in women aged 34–35 years, 19% in women aged 36–37 years, 53% in women aged 40–41 years, and 59% in women aged 42–44 years.

ETIOLOGY

The causes for infertility are generally classified as female, male, and unexplained **(Fig. 396-1)**. The female causes include tubal factors (pelvic inflammatory disease, salpingitis isthmica nodosum, endometriosis, prior surgery), uterine etiology (congenital malformations, fibroids, uterine scarring), ovulatory dysfunction (polycystic ovary syndrome [PCOS], diminished ovarian reserve, premature ovarian insufficiency), and endocrine dysfunction (hypothyroidism, hyperprolactinemia). Although the probability of achieving a pregnancy decreases after the age of 35 in women, primarily due to chromosomal abnormalities in the oocyte during meiosis, a similar decline has not been observed in men aged <50 years. The male causes of infertility include anatomic factors in the reproductive system (vasectomy, infection, absence of the vas), endocrine factors (hypogonadotropic hypogonadism, hypothyroidism, hyperprolactinemia, morbid obesity, medications), sexual dysfunction (erectile or ejaculatory dysfunction, decreased libido), and genetic factors contributing to primary testicular dysfunction, including defects in spermatogenesis (Klinefelter's syndrome, Y chromosome microdeletions). The distribution of these causes varies significantly in couples across the world. Overall, female factors are present in 30–40% of couples with infertility, male factors are present in 40–50%, and both male and female factors are identified in 20–30%. Unexplained infertility refers to the absence of any identified abnormality after completing the fertility workup and occurs in 10–15% of couples. As a result, a complete workup of both partners is recommended in all couples presenting with infertility.

FERTILITY EVALUATION

Diagnostic evaluation for infertility is typically initiated after 1 year of unprotected intercourse because 80–85% of couples will achieve a pregnancy over this time period. Evaluation of the couple can be initiated even prior to meeting the definition of infertility, especially if they have risk factors for infertility. If the female partner's age is >35 years, it is recommended to initiate evaluation after 6 months of attempting pregnancy. If the age of the female partner is >40 years, it is recommended to start evaluating the couple immediately. The initial evaluation should include detailed medical history, laboratory testing, and preconception counseling for both partners. As multiple causes for infertility may be identified, it is best to perform the complete diagnostic evaluation prior to initiating treatment.

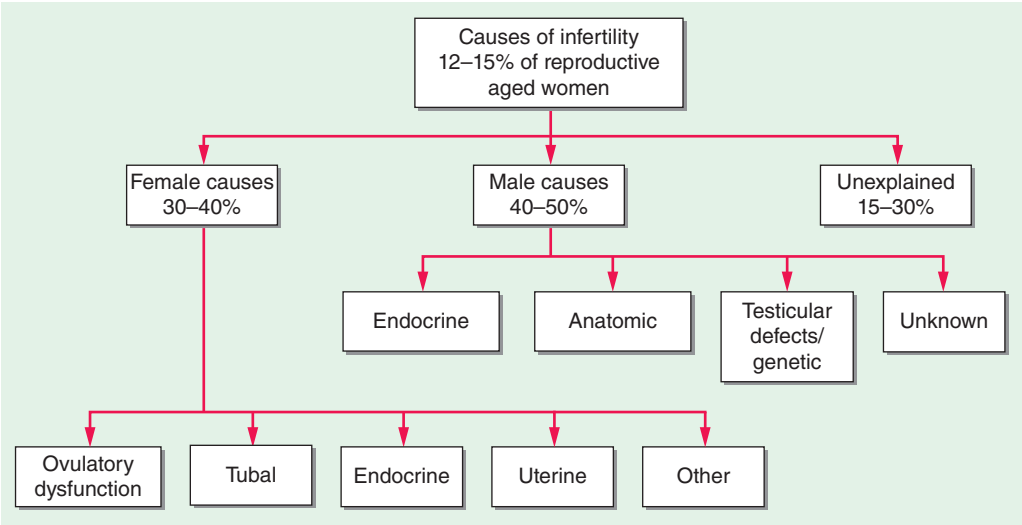

FIGURE 396-1 Causes of infertility. FSH, follicle-stimulating hormone; LH, luteinizing hormone.

History and Physical Exam A detailed history obtained from both partners is essential to identify risk factors for infertility. In the female partner, gynecologic history (menstrual frequency, menorrhagia, dysmenorrhea, history of sexually transmitted infections, endometriosis), medical and endocrine history, exposure to pelvic radiation, abdominal or pelvic surgeries, tobacco and alcohol use, medication use including cytotoxic drugs, family history of early menopause, and prior history of pregnancy should be assessed. In addition, frequency of intercourse, timing of intercourse, use of methods to detect ovulation, and concerns regarding sexual dysfunction over the past several months should be ascertained. Physical exam in the female partner should include assessment of weight and blood pressure (BP), thyroid and breast exam, assessment for signs of hyperandrogenism, and pelvic exam to assess uterine size, adnexal masses, and factors that might impact intercourse. Similarly, a detailed history should be obtained in the male partner with specific questions regarding injuries and surgery in the male reproductive tract; mumps orchitis; exposure to pelvic radiation; use of androgens, cytotoxic drugs, and other medications; and fertility with any prior partner. The exam in the male partner should include body mass index (BMI), BP, and complete physical exam including testicular exam.

Ultrasound An abdominal and transvaginal pelvic ultrasound can assess uterine (myomas, adenomyosis, müllerian anomalies) and adnexal abnormalities (endometriosis, polycystic-appearing ovaries) and evaluate ovarian reserve (number of antral follicles in both ovaries).

Ovulation Assessment Women who have regular menstrual cycles between 25 and 35 days will typically have ovulatory cycles. Ovulation can be assessed by using ovulation detection strips at home to detect urinary luteinizing hormone (LH) or by measuring a serum progesterone level 7 days after ovulation. Basal body temperatures can also be used to confirm ovulation when a rise in temperature is noted in the luteal phase. However, basal body temperature measurements are less reliable than the above methods.

Hysterosalpingogram An hysterosalpingogram (HSG) is performed during the follicular phase to assess the patency of fallopian tubes by injecting radiopaque contrast through the cervix into the uterus and imaging the flow of contrast through one or both tubes. In addition to identifying tubal pathology, an HSG may identify intrauterine abnormalities such as polyps, submucosal myomas, and adhesions. Although the negative predictive value of HSG for assessing tubal patency is high, the positive predictive value is relatively low. Interestingly, pregnancy rates have been shown to be higher in women after an HSG test compared to those who did not have the test, likely related to tubal flushing. Alternate options that are increasingly used include injection of agitated saline contrast through the cervix into the uterus. Tubal patency is assessed by demonstrating passage of agitated saline contrast through the tubes or accumulation in the cul de sac as visualized by ultrasonography. A saline infusion sonogram is more accurate in assessing intrauterine pathology such as polyps and intrauterine scarring compared to HSG and can be combined with ultrasound assessment of the pelvis.

Ovarian Reserve Evaluation Assessment of ovarian reserve includes measurement of serum FSH and estradiol on day 2 or 3 of the menstrual cycle and serum anti-müllerian hormone (AMH). These screening tests combined with age of the female partner and antral follicle counts measured by ultrasound can identify diminished ovarian reserve and provide information on the urgency to initiate treatment. AMH and antral follicle counts are also used to determine starting doses of gonadotropins for fertility treatments. These markers of ovarian reserve, however, do not predict the likelihood of pregnancy and live birth.

Endocrine Tests In women with irregular menses, serum TSH, prolactin, and androgens should be measured to identify other causes for anovulation.

Semen Analysis (see Chap. 391) The semen sample is collected after 2–7 days of abstinence and provides an assessment of sperm count, motility, morphology, volume, and pH. Although there is significant overlap between semen parameters of fertile and infertile men, those with abnormal sperm parameters based on the WHO criteria (*oligoasthenozoospermia* is defined as sperm counts <15 million/mL, motility <40%, and normal morphology <4%) should have a physical exam and further endocrine (serum follicle-stimulating hormone [FSH], LH, prolactin, and thyroid-stimulating hormone [TSH]) and genetic evaluation (karyotype and Y chromosome microdeletion).

Genetic Screening All couples can be offered preconception genetic screening based on ethnicity, family history, or common autosomal recessive conditions.

Of note, diagnostic laparoscopy, postcoital test, endometrial biopsy, thrombophilia, and immunologic testing and karyotype are not indicated as part of the initial workup of infertility.

COUNSELING AND TREATMENT

Preconception Counseling All patients seeking fertility care should be provided with preconception counseling. This includes counseling about eating disorders or lifestyle modifications for weight management as obesity in women is associated with an increase in anovulatory cycles, miscarriage rates, and maternal and fetal complications in pregnancy. Obesity in men is associated with abnormal sperm parameters. Preconception counseling regarding smoking cessation is

important as there is evidence to suggest that smoking cessation can reverse the detrimental impact of smoking on fecundity. Smoking decreases fertility rates by a direct impact on oocyte DNA and also increases the risk of miscarriage and ectopic pregnancy. In addition, smoking during pregnancy is associated with an increased risk of placental abruption and intrauterine growth restriction (IUGR). Moreover, the impact of smoking on ovarian reserve has been shown to accelerate the time to menopause by 1–4 years. As high levels of caffeine consumption increase the risk of infertility and miscarriage rates, women should be counseled to restrict caffeine consumption to ≤2 cups while attempting pregnancy and during pregnancy. Use of testosterone products, which are widely used for the treatment of hypoandrogenism and sexual dysfunction in men, should be stopped. Inquiries should be made about possible misuse of androgens for physical appearance or performance enhancement **(Chap. 399)**. As part of the preconception counseling, patients should be informed that the fertile window is typically 5–6 days prior to ovulation, and therefore, intercourse every 1–2 days during this time period will increase the chance of pregnancy. Various methods are used by women to detect ovulation, including basal body temperature measurements, assessment of changes in cervical mucus, and urinary LH kits. A rise in basal body temperatures indicates that ovulation has occurred and therefore cannot be used to time intercourse. LH kits can be used to detect the start of ovulation and subsequently time intercourse on the day of the LH surge and the following day.

Treatment Treatment recommendations depend on the results of the fertility evaluation described above **(Table 396-1)**. The success of different treatments depends on several factors including age of the female partner, assessment of ovarian reserve, history of smoking, BMI, and race.

Tubal Factor Infertility Tubal factor infertility constitutes 30–35% of cases of female infertility, and a large majority are secondary to tubal obstruction resulting from STIs. In vitro fertilization (IVF) was first developed as a treatment for tubal factor infertility as it bypasses the fallopian tubes and allows fertilization of oocytes in the laboratory prior to transfer into the uterus. IVF offers the highest success rates for couples with tubal factor infertility. Tubal repair or reconstruction is not recommended in most cases associated with underlying tubal infections or hydrosalpinx due to both the low success rate in achieving tubal patency and increased risk of ectopic pregnancy. In fact, removal of hydrosalpinges by salpingectomy will improve pregnancy rates in subsequent IVF treatments. If a proximal tubal blockage is observed on HSG, radiographically guided cannulation of fallopian tubes can be attempted. In women with bilateral tubal ligation, the decision between microsurgical reanastomosis versus IVF will depend on a number of factors including patient's age, ovarian reserve, number of children desired, partner's semen parameters, and experience of the surgeon.

TABLE 396-1 Assisted Reproductive Technologies

Ovulation induction Oral agents Injectable hormones	Clomiphene citrate (selective estrogen response modulator) Letrozole (aromatase inhibitor) FSH, LH (gonadotropins)
Intrauterine insemination (IUI)	Office-based procedure by which washed and concentrated ejaculated sperm is deposited in the uterine cavity via a soft catheter passed through the cervix
In vitro fertilization (IVF)	Oocytes are harvested transvaginally under local anesthesia or intravenous sedation and incubated with sperm to facilitate fertilization. The fertilized embryos are cultured for 3 days (cleavage stage) or 5 days (blastocyst stage) prior to transcervical placement of one or more embryos, depending on the age of the female patient, into the uterine cavity under ultrasound guidance.
Intracytoplasmic sperm injection (ICSI)	In cases of severe male factor infertility, a single motile sperm is injected into the oocyte in order to facilitate fertilization.

Abbreviations: FSH, follicle-stimulating hormone; LH, luteinizing hormone.

Ovulatory Dysfunction Endocrine conditions such as hypothyroidism and hyperprolactinemia should be treated prior to use of ovulation induction medications. Lifestyle modifications should be recommended in patients with low BMI or obesity. Weight loss in obese women has been shown to increase the likelihood of spontaneous or drug-induced ovulation. First-line treatment for women with anovulatory infertility (most common etiology is PCOS) includes use of medications such as letrozole and clomiphene citrate to induce ovulation. A large majority of women with PCOS (60–80%) respond to these oral medications, and the addition of metformin, as a second-line agent, may further increase the chance of ovulation, particularly in obese women. In women with hypothalamic amenorrhea, behavioral modifications such as weight gain and decreased exercise may resume ovulation. If there is no response, judicious use of low-dose injectable gonadotropins can induce monofollicular growth. In women with diminished ovarian reserve, treatment can be escalated from ovulation induction with oral medications and intrauterine insemination (IUI) to IVF as the overall pregnancy rates are lower. In both women with diminished ovarian reserve and women with premature ovarian insufficiency, the option of using donor oocytes can be offered. In that case, the egg donor will undergo the IVF procedure, the harvested eggs are fertilized with the male partner's sperm, and the fertilized embryos will be transferred to the patient's uterus.

Male Infertility Given the high prevalence of male factor infertility (40–50%), timely evaluation and treatment are recommended. In men with no sperm (azoospermia) in the ejaculate, further evaluation including a physical examination, endocrine tests, and genetics studies should be performed to identify obstructive (40% prevalence among men with azoospermia) versus nonobstructive etiology. First-line treatment for mild to moderate male factor infertility includes IUI alone or IUI combined with ovulation induction, depending on the female partner's age and other causes of infertility. In men with severe male factor infertility, IVF with intracytoplasmic sperm injection is recommended. In men with obstructive azoospermia, sperm can be procured by direct aspiration from the epididymis or testis. In men with congenital bilateral absence of the vas deferens (CBAVD), testing for *CFTR* mutations and genetic counseling are indicated. In men with nonobstructive azoospermia, sperm retrieval from the testes may be less successful, and the use of donor sperm for IUI is an alternate option. Men with hypogonadotropic hypogonadism (e.g., Kallmann's syndrome) can be treated with gonadotropins to initiate spermatogenesis followed by IUI or IVF. Treatment of male sexual dysfunction and avoidance of exogenous androgens are effective strategies for addressing male factor infertility. Repair of a moderate to large varicocele is recommended when associated with abnormal semen parameters or if the patient is symptomatic from the varicocele.

Unexplained Infertility In 15–30% of couples, no clear causes of infertility are identified. In such cases, it is appropriate to initiate ovarian stimulation with oral medications to increase the number of developing oocytes and combine this with IUI timed to ovulation in order to increase the number of motile sperm in the reproductive tract. Depending on the age of the female partner, this approach offers modest success rates and can be used for 3–6 months before recommending IVF. Overall, IVF is associated with a low risk of complications; the risk of ovarian hyperstimulation syndrome has been significantly decreased by judiciously monitoring stimulation and using alternate protocols. Multiple pregnancy remains the highest risk associated with IVF despite improvements in cryopreservation of embryos and age-based guidelines for the number of embryos to transfer. In some couples, the IVF treatment may reveal an underlying cause of infertility such as lower fertilization or embryo cleavage rates. Of note, guidelines from different medical societies around the world vary in the rapidity of offering IVF for unexplained infertility.

Uterine Factors Fibroids are the most common benign tumors of the reproductive tract and occur in 50–70% of reproductive-age

women. It is not clear whether fibroids decrease the likelihood of pregnancy; submucosal fibroids and intramural fibroids that distort the endometrial cavity may lower pregnancy rates and increase the risk of pregnancy loss. Removal of submucosal fibroids, uterine polyps, and adhesions hysteroscopically may improve subsequent pregnancy rates.

Endometriosis Endometriosis is a common gynecologic condition associated with pelvic pain and dysmenorrhea, and in severe cases, it is associated with tubo-ovarian infertility. Approximately 25–50% of infertile women have endometriosis, and 30–50% of women with endometriosis have infertility. Prolonged medical management to suppress endometriotic lesions and surgical treatment of stage 1 and 2 endometriosis have not been shown to improve subsequent fertility rates. Surgical removal of endometriotic lesions in women with stage 3 or 4 endometriosis may improve subsequent pregnancy rates. First-line treatment of infertility associated with endometriosis alone includes use of oral ovulation induction medications and IUI.

PSYCHOLOGICAL ASPECTS OF INFERTILITY

It is well recognized that infertility is associated with psychological stress related not only to the diagnostic and therapeutic procedures themselves but also to repeated cycles of hope and loss associated with each new procedure or cycle of treatment that does not result in the birth of a child. These feelings are often combined with a sense of isolation from friends and family. Counseling and stress-management techniques should be offered early in the evaluation of infertility. Importantly, infertility and its treatment do not appear to be associated with long-term psychological sequelae.

CONTRACEPTION

The desired ideal number of children per family varies around the globe and is approximately 2.6 in the United States. Couples not using any form of contraception have an 85% chance of achieving a pregnancy over 1 year. Based on these data, couples spend most of their reproductive life preventing a pregnancy and a much smaller proportion attempting to become or being pregnant. It is therefore not surprising that a majority of women who have been sexually active will have used some form of contraception to prevent a pregnancy. Unintended pregnancies primarily occur due to lack of use or inconsistent use of contraceptives rather than failure of the contraceptive method used. Of the different forms of contraception used worldwide in 2019, tubal sterilization was the most common (~219 million) followed by use of male condom (189 million), intrauterine device (IUD) (159 million), and the (birth control) pill (151 million). The rates of female sterilization increased steadily in the last century and now show a slight decrease, likely due to the increasing use of long-acting reversible contraceptive (LARC) agents, such as IUDs and implants, which are as effective as sterilization. The convenience of use of contraceptives determines their compliance and efficacy; contraceptives requiring daily and coitus-related use have higher failure rates compared to long-acting reversible and permanent methods. The U.S. Medical Eligibility Criteria (USMEC) for contraceptive use are evidence-based guidelines to help health care providers recommend appropriate contraceptives to women with chronic medical conditions (Table 396-2). This excellent resource is adapted from the WHO guidance and is kept up to date through continual review of published literature.

TABLE 396-2 U.S. Medical Eligibility Criteria (USMEC) for Contraceptive Use

USMEC Category 4 (a condition that represents an unacceptable health risk if the contraceptive method is used)
Women age >35 years who smoke ≥15 cigarettes per day
Known ischemic heart disease or multiple risk factors for cardiovascular disease (older age, smoking, diabetes, and hypertension)
Acute DVT
Previous thromboembolic event; high risk of recurrent DVT
Stroke or known thrombogenic mutations
Complicated valvular heart disease
Peripartum cardiomyopathy
Complicated solid organ transplantation
Hypertension (systolic ≥160 mmHg or diastolic ≥100 mmHg, vascular disease)
Systemic lupus erythematous (positive or unknown antiphospholipid antibodies)
Cirrhosis, hepatic adenoma or hepatoma
Viral hepatitis, acute flare
Pregnancy and early postpartum (<21 days)
Breast-feeding <21days postpartum
Breast cancer
USMEC Category 3 (a condition for which the theoretical or proven risks outweigh the advantages for using the method)
Previous thromboembolic event; lower risk of recurrent DVT
Past history of breast cancer and no evidence for 5 years
Hypertension (adequately controlled or systolic 140–159 mmHg or diastolic 90–99 mmHg)
Women receiving anticonvulsant drug therapy
Women receiving antiretroviral therapy for prevention or treatment of HIV
Women following bariatric surgery (Roux-en-Y gastric bypass or biliopancreatic diversion)
Breast-feeding 21–42 days postpartum

Abbreviation: DVT, deep-vein thrombosis.

TYPES OF CONTRACEPTION

These can be classified in a number of ways, such as permanent versus reversible, hormonal versus nonhormonal, or barrier versus nonbarrier (Table 396-3).

Permanent Contraception The permanent forms of contraception include tubal sterilization and vasectomy, with twice as many women choosing permanent sterilization compared to men. Vasectomy is a low-risk procedure typically performed in an outpatient setting with a very low failure rate of 0.1 pregnancies per 100 women per year. It is not immediately effective, and patients should be told to use other forms of contraception for a minimum of 3 months after the procedure. Tubal sterilization can be performed in the postpartum period or as an interval procedure and has a failure rate of 0.5 pregnancies per 100 women per year. Postpartum sterilization can be performed during a cesarean section or after a vaginal delivery via mini-laparotomy. Interval procedures can be performed laparoscopically or via mini-laparotomy and include partial or complete salpingectomy or occlusion of the fallopian tubes using electrocoagulation or mechanical devices such as clips. These permanent methods of contraception are highly effective as they avoid the need for user-dependent contraception. All patients should undergo preprocedure counseling regarding risk of failure, permanence of the procedure, regret, and alternatives.

Hormonal Contraceptives • COMBINED ESTROGEN- AND PROGESTIN-CONTAINING CONTRACEPTIVES The mechanism of action of the hormonal contraceptives involves negative feedback from continuous estrogen administration, thereby decreasing FSH secretion, follicular development, and formation of a dominant follicle. The continuous progestin suppresses LH secretion and inhibits ovulation, alters endometrial receptivity, thickens the cervical mucus, and impairs tubal motility. These hormones can be delivered via oral pills to be taken daily, as a transdermal patch that is changed weekly, or a vaginal ring that is replaced monthly or annually. There are numerous *pills* available containing different doses of estrogen (<50 μg) and types of progestins and varying doses within a pack (monophasic vs multiphasic); the pills can be taken in a cyclic or extended cycle schedule. The contraceptive efficacy is similar with varying doses of estrogen and progestin. Decreasing the duration of hormone-free days may decrease some side effects associated with menses, such as menstrual migraines and dysmenorrhea. The overall failure rate for combined hormonal contraceptives is 8 pregnancies per 100 women per year, although compliance with daily use of pills may be lower, affecting efficacy. The contraceptive patch and vaginal ring have higher compliance compared to daily pills. Use of the *contraceptive patch* is associated with a low risk

TABLE 396-3 Effectiveness of Different Forms of Contraception

METHOD OF CONTRACEPTION	THEORETICAL EFFECTIVENESS (%)	ACTUAL EFFECTIVENESS (%)	CONTINUED USE AT 1 YEAR (%)	USE OF METHOD BY U.S. WOMEN AT RISK OF UNINTENDED PREGNANCY (%)
No method	15	15		10
Fertility awareness	96	76	47	1.2
Withdrawal	96	78	46	4.4
Barrier methods				
Condoms	98	82	43	13.7
Diaphragm	94	82	57	2
Spermicides	82	72	43	1
Sterilization				
Female	99.5	99.5	100	22.6
Male	99.5	99.9	100	7.4
Intrauterine device				9.3
Copper T	99.4	99.8	85	
Progestin-containing	99.8	99.8	88	
Hormonal contraceptives				
Combined and progestin only	99.7	91	67	23.3
Transdermal patch	99.7	91	67	0.5
Vaginal ring	99.7	91	67	1.8
Implant				1.2
Depo-Provera	99.8	94	56	
Subdermal implant	99.5	99.5	84	
Emergency contraception	95	-	-	11

of skin reactions and a lower efficacy in women weighing >90 kg. The transdermal mode of delivery is associated with a higher steady state comparable to that of a 40-μg ethinyl estradiol oral contraceptive. Hormonal contraceptives offer additional benefits such as regulation of menstrual cycles; suppression of ovarian cysts; and decrease in menorrhagia, dysmenorrhea, and hyperandrogenism symptoms; in addition, they reduce the risk of both endometrial (50% reduction) and ovarian cancer (40% reduction). Common side effects include nausea, breast tenderness, bloating, and intermenstrual bleeding. There may be a mild increase in BP in some patients, and it is recommended to check BP at follow-up visits. In large studies and meta-analyses, hormonal contraceptives are not associated with significant weight gain, mood changes, or effect on libido. Prior to administering hormonal contraceptives, a detailed patient history should be obtained to determine any absolute or relative contraindications to their use. Due to the low but slightly increased risk of deep-vein thrombosis (DVT) associated with estrogen-containing hormonal contraceptives (3–15 per 10,000 women-years), they are contraindicated in the immediate postpartum period, in smokers over the age of 35 years, and in women with a history of hereditary thrombophilias or DVT. The association between risk of DVT and different doses of estrogen (ethinyl estradiol <35 μg) or different routes of administration (transdermal patch) is weak. There is, however, some association between third- and fourth-generation progestins and risk of DVT. Routine screening for familial thrombotic disorders is not recommended prior to prescribing hormonal contraceptives. Although obesity is associated with decreased fertility, the vast majority of women with obesity do not experience infertility. The USMEC classifies obesity alone as risk category 2, where the benefits of taking hormonal contraceptives outweigh any theoretical risk.

PROGESTIN-ONLY HORMONAL CONTRACEPTION Different types of progestins are used for contraception in oral pills, injectable forms, subdermal implants, and IUDs and may be an option for women who have contraindications to the use of estrogen-containing contraceptives (e.g., migraine with aura, DVT, stroke, breast-feeding). The failure rate with *progestin-only pills* is 9 pregnancies per 100 women per year, whereas the failure rate of progestin IUDs is 0.1 pregnancies per 100 women per year. In addition to acting as a spermicidal, the *levonorgestrel IUD* also thickens the cervical mucus and thins the endometrium, thereby decreasing its receptivity. The common side effect is irregular bleeding, pain, and rarely expulsion. Breakthrough bleeding or unscheduled bleeding is commonly reported, as estrogen usually serves to stabilize the endometrial lining and prolonged exposure to progestin alone results in a thinner decidualized lining. Depending on the device used, the progestin IUD is effective for 3–7 years. The *injectable form of progesterone* (medroxyprogesterone acetate) is administered every 3 months with a failure rate of 3 pregnancies per 100 women per year. Its side effects include weight gain, irregular menses, amenorrhea, and mood changes, and there is a slow return to ovulation and fertility after discontinuation (6–9 months). The *subdermal implant* contains etonogestrel and is placed easily over the triceps muscle in the inner arm using local anesthesia. It lasts up to 5 years and has a failure rate of 0.05 pregnancies per 100 women per year. Findings from the Contraceptive Choice research project showed that continuation rates were higher for LARC (IUDs and implants) compared to short-acting methods. LARCs are the most effective reversible form of contraception with high continuation and satisfaction rates; hence, they are a good choice in adolescents and nulliparous women.

Nonhormonal IUD IUDs are a commonly used form of contraception worldwide and are available as hormonal and nonhormonal devices. The nonhormonal copper IUD works as a spermicidal and is effective for up to 12 years with a failure rate of <1 pregnancy per 100 women per year. Patients should be counseled regarding the increased risk of heavy vaginal bleeding and dysmenorrhea resulting in higher discontinuation rates compared to the levonorgestrel-containing IUDs. IUDs can be used in adolescents and adult women and are typically inserted and removed as an office procedure with use of mild analgesics. They can be inserted anytime during a menstrual cycle, referred to as interval insertion, and in the immediate postpartum and postabortion period.

Barrier Contraception The barrier forms of contraception include condoms (male, female) and diaphragm and cervical cap and

have lower effectiveness secondary to inconsistent and incorrect use. They offer several advantages including minimal side effects, lower cost, no requirement for a prescription, and protection from sexually transmitted infections. The failure rate for male and female condoms is 17–21 pregnancies per 100 women per year. Spermicidals can be used in conjunction with barrier methods to improve effectiveness.

Lactational Contraception Lactation may serve as an effective form of contraception during the first 6 postpartum months if there is exclusive breast-feeding and menstrual cycles have not resumed. The contraceptive effect occurs due to suppression of gonadotropin-releasing hormone pulsatility associated with suckling. The failure rate under these circumstances can be as low as 0.5–1.5 pregnancies per 100 women per year.

Fertility Awareness The standard days method is typically used by women with regular menstrual cycles whereby they track their cycles to avoid intercourse from cycle days 8–19.

Emergency Contraception Also known as postcoital contraception, this method is used after an unprotected or inadequately protected act of intercourse. The probability of pregnancy independent of the time of the month is 8%, but the probability varies significantly in relation to proximity to ovulation and may be as high has 30%. Many women are not aware of the availability of emergency contraception and its appropriate use. As the probability of pregnancy is highest if there has been unprotected intercourse during the 3 days prior to ovulation, the timing of administration and type of emergency contraceptive used determine the efficacy. The emergency contraception options include the copper IUD and oral medications such as ulipristal acetate, levonorgestrel, and combined hormonal pills. The copper IUD prevents fertilization and implantation and is the most effective choice if inserted within 5 days of unprotected intercourse. It can also be offered to obese women in whom other hormonal forms of emergency contraceptive may be less effective. Ulipristal acetate, a progesterone receptor antagonist, blocks the ability of endogenous progesterone to act on its receptors and inhibits the LH surge, delaying or inhibiting ovulation, and may directly inhibit follicular rupture. It is administered as a 30-mg single dose up to 5 days after unprotected intercourse. Levonorgestrel administered as a single dose will prevent or delay ovulation and is associated with fewer side effects compared to combined hormonal pills. Overall, the failure rate for all hormonal emergency contraception is 1–3%, with ulipristal acetate being the most effective. Emergency contraception should be offered to all women who ask for it up to 5 days after unprotected intercourse and not delayed in order to obtain a pregnancy test or perform a clinical examination. Although body weight can affect the efficacy of emergency hormonal contraception, it should not be withheld from overweight and obese women.

CONTRACEPTION COUNSELING

Patients should be provided information regarding the different methods of contraception, side effects, noncontraceptive benefits, efficacy, need for strict compliance, and impact on future fertility. In order to facilitate patient-centric care, the provider should discuss plans for future pregnancy and whether childbearing is complete. A detailed patient history should be reviewed to identify potential contraindications such as migraines with aura, smoking, and hypertension. Providers should refer to the most updated USMEC or WHO Medical Eligibility Criteria for Contraceptive Use guidelines when counseling patients with associated comorbidities. As part of the shared decision-making approach, the patient's choice should be the guiding factor, and the discussion should be nonjudgmental. Adolescents should be offered access to the full range of contraceptive options. In a low-risk patient, hormonal contraceptives can be prescribed from menarche to menopause; regular evaluation of side effects and assessment of changes in the patient's medical history, however, are required.

397 Sexual Dysfunction

Kevin T. McVary

Male sexual dysfunction affects up to 31% of middle-aged and elderly men, whereas female sexual dysfunction, although studied less intensely, has a higher prevalence (43%) than male sexual dysfunction. Demographic changes, the popularity of newer treatments, and greater awareness of sexual dysfunction by patients and society have led to increased diagnosis and associated health care expenditures for the management of this common disorder. Sexual health and satisfaction with sex life are important aspects of quality of life for many, including those in poor health. Because many patients are reluctant to initiate discussion of their sex lives, physicians should address this topic directly to elicit a history of sexual dysfunction. Specifically addressing sexual health should be a routine part of the clinical encounter.

MALE SEXUAL DYSFUNCTION

PHYSIOLOGY OF MALE SEXUAL RESPONSE

Normal male sexual function includes (1) sufficient libido, (2) the ability to achieve and maintain penile erection, (3) ejaculation, and (4) detumescence. *Libido* refers to sexual desire and is influenced by a variety of visual, olfactory, tactile, auditory, imaginative, and hormonal stimuli. Sex steroids, particularly testosterone, act to increase libido. Libido can be diminished by emotional context, systemic illness, hormonal disturbances, psychiatric disorders, and medications.

Penile tumescence leading to erection depends on an increased flow of blood into the lacunar network accompanied by complete relaxation of the arteries and corporal smooth muscle. The microarchitecture of the corpora is composed of a mass of smooth muscle (trabecula) that contains a network of endothelial-lined vessels (lacunar spaces). Subsequent compression of the trabecular smooth muscle against the fibroelastic tunica albuginea causes a passive closure of the emissary veins and accumulation of blood in the corpora. In the presence of a full erection and a competent valve mechanism, the corpora become noncompressible cylinders from which blood does not escape. This cascade of relaxation and venous occlusion culminates in a rigid erection.

The central nervous system (CNS) exerts an important influence by either stimulating or antagonizing spinal pathways that mediate erectile function and ejaculation. The erectile response is mediated

by a combination of central (psychogenic) innervation and peripheral (reflexogenic) innervation. Sensory nerves that originate from receptors in the penile skin and glans converge to form the dorsal nerve of the penis, which travels to the S2-S4 dorsal root ganglia via the pudendal nerve. Parasympathetic nerve fibers to the penis arise from neurons in the intermediolateral columns of the S2-S4 sacral spinal segments. Sympathetic innervation originates from the T-11 to the L-2 spinal segments and descends through the hypogastric plexus.

Neural input to smooth-muscle tone is crucial to the initiation and maintenance of an erection. There is also an intricate interaction between the corporal smooth-muscle cell and its overlying endothelial cell lining **(Fig. 397-1)**. Nitric oxide, which induces vascular relaxation, promotes erection and is opposed by endothelin 1 (ET-1) and Rho kinase, which mediate vascular contraction. Nitric oxide is synthesized from L-arginine by nitric oxide synthase (NOS) and is released from the nonadrenergic, noncholinergic (NANC) autonomic nerve supply to act postjunctionally on smooth-muscle cells. Nitric oxide increases the production of cyclic 3′,5′-guanosine monophosphate (cyclic GMP), which induces relaxation of smooth muscle **(Fig. 397-2)**. Cyclic GMP is metabolized by phosphodiesterase type 5 (PDE-5). Inhibitors of PDE-5 such as the oral medications sildenafil, tadalafil, vardenafil, and avanafil maintain erections by reducing the breakdown of cyclic GMP. However, if nitric oxide is not produced at some level, PDE-5 inhibitors are ineffective, as these drugs facilitate, but do not initiate, the initial enzyme cascade. In addition to nitric oxide, vasoactive prostaglandins (PGE_1, $PGF_{2\alpha}$) are synthesized within the cavernosal tissue and increase cyclic AMP levels, also leading to relaxation of cavernosal smooth-muscle cells.

Ejaculation is stimulated by the sympathetic nervous system; this results in contraction of the epididymis, vas deferens, seminal vesicles, and prostate, causing seminal fluid to enter the urethra. Seminal fluid emission is followed by rhythmic contractions of the bulbocavernosus and ischiocavernosus muscles, leading to ejaculation. This is followed by expulsion, characterized by stereotypic rhythmic contractions of the striated perineal muscles, leading to forceful expulsion of semen with the bladder neck closed. This emission and expulsion are controlled by the autonomic (parasympathetic and sympathetic) and somatic spinal centers, respectively. The synchronization between autonomic and somatic spinal centers is orchestrated by interneurons that form a spinal ejaculation generator that is present in mammals including man.

Premature ejaculation usually is related to anxiety or a learned behavior and is amenable to behavioral therapy or treatment with medications such as selective serotonin reuptake inhibitors (SSRIs).

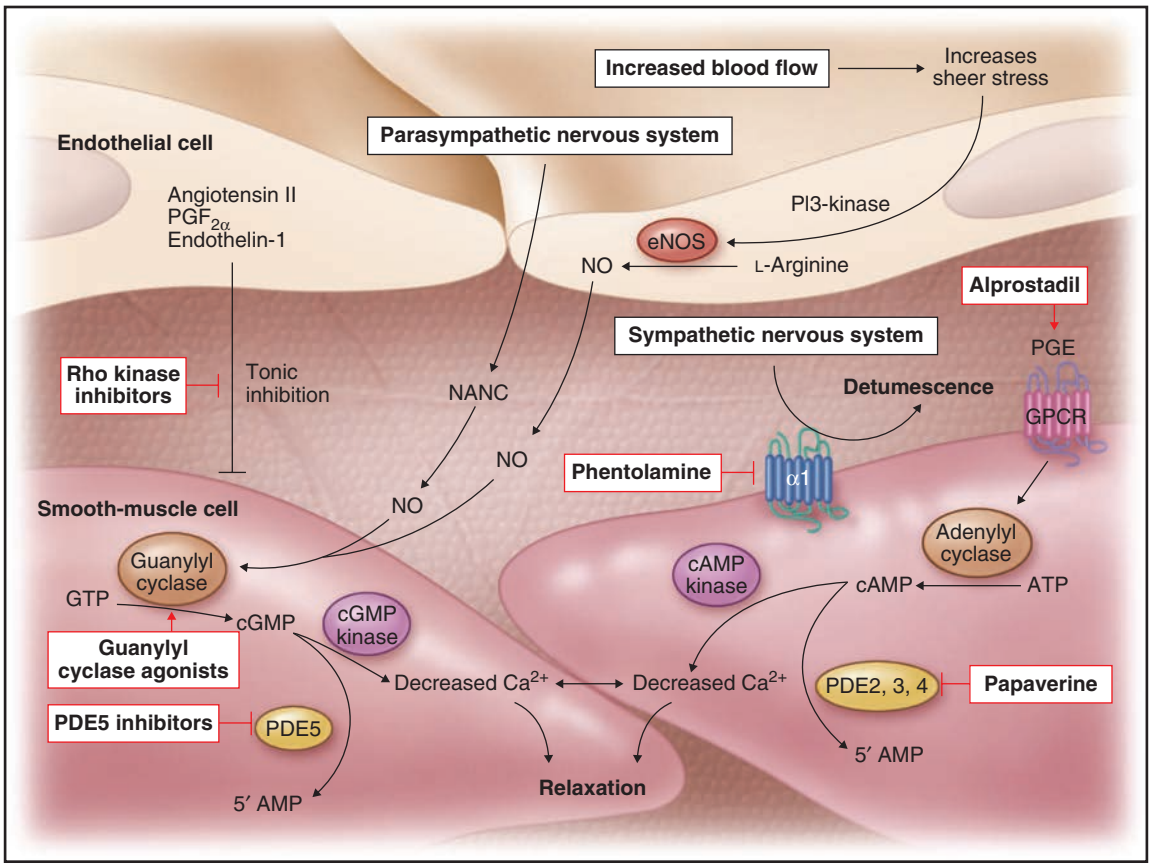

FIGURE 397-1 Pathways that control erection and detumescence. Outflow from the parasympathetic nervous system leads to relaxation of the cavernous sinusoids in two ways, both of which increase the concentration of nitric oxide (NO) in smooth-muscle cells. First, NO is the neurotransmitter in nonadrenergic, noncholinergic (NANC) fibers; second, stimulation of endothelial nitric oxide synthase (eNOS) through cholinergic output causes increased production of NO. The NO produced in the endothelium then diffuses into the smooth-muscle cells and decreases its intracellular calcium concentration through a pathway mediated by cyclic guanosine monophosphate (cGMP), leading to relaxation. A separate mechanism that decreases the intracellular calcium level is mediated by cyclic adenosine monophosphate (cAMP). With increased cavernosal blood flow, as well as increased levels of vascular endothelial growth factor (VEGF), the endothelial release of NO is further sustained through the phosphatidylinositol 3 (PI3) kinase pathway. Active treatments (red boxes) include drugs that affect the cGMP pathway (phosphodiesterase type 5 [PDE-5] inhibitors and guanylyl cyclase agonists), the cAMP pathway (alprostadil), or both pathways (papaverine), along with neural-tone mediators (phentolamine and Rho kinase inhibitors). Agents that are being developed include guanylyl cyclase agonists (to bypass the need for endogenous NO) and Rho kinase inhibitors (to inhibit tonic contraction of smooth-muscle cells mediated through endothelin). α1, α-adrenergic receptor; GPCR, G protein–coupled receptor; GTP, guanosine triphosphate; iCa^{2+}, intracellular calcium; NOS, nitric oxide synthase; PGE, prostaglandin E; PGF, prostaglandin F. *(Reproduced with permission from KT McVary: Clinical practice. Erectile dysfunction. N Engl J Med 357:2472, 2007.)*

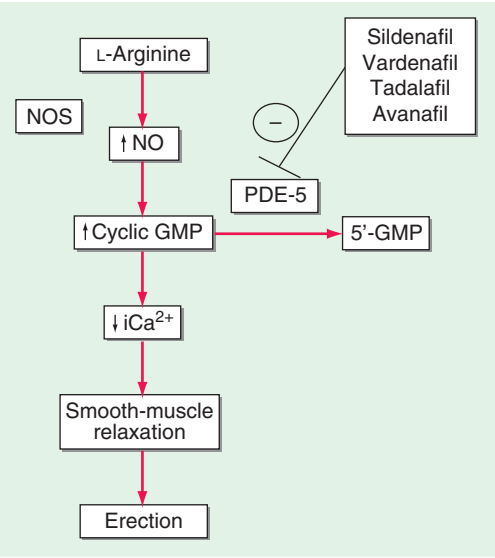

FIGURE 397-2 Biochemical pathways modified by phosphodiesterase type 5 (PDE-5) inhibitors. Sildenafil, vardenafil, tadalafil, and avanafil enhance erectile function by inhibiting PDE-5, thereby maintaining high levels of cyclic 3′,5′-guanosine monophosphate (cyclic GMP). iCa^{2+}, intracellular calcium; NO, nitric oxide; NOS, nitric oxide synthase.

Retrograde ejaculation (RE) results when the internal urethral sphincter does not close; it may occur in men with diabetes or after surgery involving the bladder neck. *Anejaculation*, the failure of a portion or the whole of the emission process often confused with RE, is commonly the result of selective alpha blockers used in male voiding dysfunction (e.g., tamsulosin, silodosin).

Detumescence is mediated by norepinephrine from the sympathetic nerves, endothelin from the vascular surface, and smooth-muscle contraction induced by postsynaptic α-adrenergic receptors and activation of Rho kinase. These events increase venous outflow and restore the flaccid state. Venous leak can cause premature detumescence and is caused by insufficient relaxation of the corporal smooth muscle rather than a specific anatomic defect. *Priapism* refers to a persistent and painful erection and may be associated with sickle cell anemia, hypercoagulable states, spinal cord injury, or injection of vasodilator agents into the penis.

ERECTILE DYSFUNCTION

Epidemiology Erectile dysfunction (ED) is not considered a normal part of the aging process. Nonetheless, it is associated with certain physiologic and psychological changes related to age. In the Massachusetts Male Aging Study (MMAS), a community-based survey of men aged 40–70, 52% of responders reported some degree of ED. Complete ED occurred in 10% of respondents, moderate ED in 25%, and minimal ED in 17%. The incidence of moderate or severe ED more than doubled between the ages of 40 and 70. In the National Health and Social Life Survey (NHSLS), which included a sample of men and women aged 18–59, 10% of men reported being unable to maintain an erection (corresponding to the proportion of men in the MMAS reporting severe ED). Incidence was highest among men in the age group 50–59 (21%) and men who were poor (14%), divorced (14%), and less educated (13%).

The incidence of ED is also higher among men with certain medical disorders, such as diabetes mellitus, obesity, lower urinary tract symptoms secondary to benign prostatic hyperplasia (LUTS/BPH), heart disease, hypertension, decreased high-density lipoprotein (HDL) levels, and diseases associated with general systemic inflammation (e.g., rheumatoid arthritis). Cardiovascular disease and ED share etiologies as well as pathophysiology (e.g., endothelial dysfunction), and the degree of ED appears to correlate with the severity of cardiovascular disease. Consequently, ED represents a "sentinel symptom" in patients with occult cardiovascular and peripheral vascular disease.

Smoking is also a significant risk factor in the development of ED. Medications used in treating diabetes or cardiovascular disease are additional risk factors (see below). There is a higher incidence of ED among men who have undergone radiation or surgery for prostate cancer and in those with a lower spinal cord injury. Psychological causes of ED include depression, anger, stress from employment or relationships, anxiety, and other stress-related causes.

Pathophysiology ED may result from three basic mechanisms: (1) failure to initiate (psychogenic, endocrinologic, or neurogenic), (2) failure to fill (arteriogenic), and (3) failure to store adequate blood volume within the lacunar network (veno-occlusive dysfunction). These categories are not mutually exclusive, and multiple factors contribute to ED in many patients. For example, diminished filling pressure can lead secondarily to venous leak. Psychogenic factors frequently coexist with other etiologic factors and should be considered in all cases. Diabetic, atherosclerotic, and drug-related causes account for >80% of cases of ED in older men.

Vasculogenic The most common organic cause of ED is a disturbance of blood flow to and from the penis. Atherosclerotic or traumatic arterial disease can decrease flow to the lacunar spaces, resulting in decreased rigidity and an increased time to full erection. Excessive outflow through the veins despite adequate inflow also may contribute to ED. Structural alterations to the fibroelastic components of the corpora may cause a loss of compliance and inability to compress the tunical veins. This condition may result from aging, increased cross-linking of collagen fibers induced by nonenzymatic glycosylation, hypoxemia, or altered synthesis of collagen associated with hypercholesterolemia.

Neurogenic Disorders that affect the sacral spinal cord or the autonomic fibers to the penis preclude nervous system relaxation of penile smooth muscle, thus leading to ED. In patients with spinal cord injury, the degree of ED depends on the completeness and level of the lesion. Patients with incomplete lesions or injuries to the upper part of the spinal cord are more likely to retain erectile capabilities than are those with complete lesions or injuries to the lower part. Although 75% of patients with spinal cord injuries have some erectile capability, only 25% have erections sufficient for penetration. Other neurologic disorders commonly associated with ED include multiple sclerosis and peripheral neuropathy. The latter is often due to either diabetes or alcoholism. Pelvic surgery may cause ED through disruption of the autonomic nerve supply.

Endocrinologic Androgens increase libido, but their exact role in erectile function is unclear. Individuals with castrate levels of testosterone can achieve erections from visual or sexual stimuli. Nonetheless, normal levels of testosterone appear to be important for erectile function, in which the upregulation of nitric oxide synthase and the nitric oxide cascade is optimized (Fig. 397-1*A*). Androgen replacement therapy can improve depressed erectile function when it is secondary to hypogonadism; however, it is not useful for ED when endogenous testosterone levels are normal. Increased prolactin may decrease libido by suppressing gonadotropin-releasing hormone (GnRH) resulting in decreased testosterone levels. Treatment of hyperprolactinemia with dopamine agonists can restore libido and eugonadism.

Diabetic ED occurs in 35–75% of men with diabetes mellitus. Pathologic mechanisms are related primarily to diabetes-associated vascular and neurologic complications. Diabetic macrovascular complications are related mainly to age, whereas microvascular complications correlate with the duration of diabetes and the degree of glycemic control (Chap. 403). Individuals with diabetes also have reduced amounts of nitric oxide synthase in both endothelial and neural tissues.

Psychogenic Two mechanisms contribute to the inhibition of erections in psychogenic ED. First, psychogenic stimuli to the sacral cord may inhibit reflexogenic responses, thereby blocking activation of vasodilator outflow to the penis. Second, excess sympathetic stimulation in an anxious man may increase penile smooth-muscle tone. The most common causes of psychogenic ED are performance anxiety, depression, relationship conflict, loss of attraction, sexual inhibition, conflicts over sexual preference, sexual abuse in childhood, and fear of pregnancy or sexually transmitted disease. Almost all patients with ED, even when it has a defined organic basis, develop a psychogenic component as a reaction to ED.

Medication-Related Medication-induced ED **(Table 397-1)** is estimated to occur in 25% of men seen in general medical clinics. The adverse effects related to drug therapy are additive, especially in older men. In addition to the drug itself, the underlying disease being treated is likely to contribute to sexual dysfunction (e.g., hypertension). Among the antihypertensive agents, the thiazide diuretics and beta blockers have been implicated most frequently. Calcium channel blockers and angiotensin-converting enzyme inhibitors are cited less frequently. These drugs may act directly at the corporal level (e.g., calcium channel blockers) or indirectly by reducing pelvic blood pressure, which is important in the development of penile rigidity. α-Adrenergic blockers are less likely to cause ED. Estrogens, GnRH agonists, H_2 antagonists, and spironolactone cause ED by suppressing gonadotropin production or by blocking androgen action. Antidepressant and antipsychotic agents—particularly neuroleptics, tricyclics, and SSRIs—are associated with erectile, ejaculatory, orgasmic, and sexual desire difficulties. Among the SSRIs, paroxetine and escitalopram have been associated with the highest risk of sexual dysfunction. Bupropion, nefazodone, and mirtazapine appear less likely to cause sexual dysfunction. A number of molecular pathways have been implicated in antidepressant-induced sexual adverse events. Serotonin has been hypothesized to inhibit normal sexual response by decreasing dopamine-enhanced libido, arousal, and erection and by increasing prolactin release. SSRIs have also been shown to be potent inhibitors of nitric oxide synthase.

If there is a strong association between the institution of a drug and the onset of ED, alternative medications should be considered. Otherwise, it is often practical to treat the ED without attempting multiple changes in medications as it may be difficult to establish a causal role for a drug.

TABLE 397-1 Drugs Associated with Erectile Dysfunction

CLASSIFICATION	DRUGS	POSSIBLE SUBSTITUTES
Diuretics	Thiazides Spironolactone	
Antihypertensives	Calcium channel blockers	α-Adrenergic blockers Prazosin Terazosin Doxazosin ACE inhibitors
	Methyldopa Clonidine Reserpine Beta blockers Guanethidine	
Cardiac/ antihyperlipidemics	Digoxin Gemfibrozil Clofibrate	
Antidepressants	Selective serotonin reuptake inhibitors	Bupropion Nefazodone Mirtazapine
	Tricyclic antidepressants Lithium Monoamine oxidase inhibitors	
Tranquilizers	Butyrophenones Phenothiazines	
H_2 antagonists	Ranitidine	Proton pump inhibitors (PPI) Omeprazole Esomeprazole Pantoprazole Rabeprazole
	Cimetidine	
Hormones	Progesterone Estrogens Corticosteroids GnRH agonists 5α-Reductase inhibitors Cyproterone acetate	
Cytotoxic agents	Cyclophosphamide Methotrexate Roferon-A	
Anticholinergics	Disopyramide Anticonvulsants	
Recreational	Ethanol Cocaine Marijuana	

Abbreviations: ACE, angiotensin-converting enzyme; GnRH, gonadotropin-releasing hormone.

APPROACH TO THE PATIENT

Erectile Dysfunction

A good physician–patient relationship helps unravel the possible causes of ED, many of which require discussion of personal and sensitive topics. For this reason, a primary care provider is often ideally suited to initiate the evaluation. However, a significant percentage of men experience ED and remain undiagnosed unless specifically questioned about this issue. By far the two most common reasons for underreporting of ED are patient embarrassment and perceptions of physicians' inattention to the disorder. Once the topic is initiated by the physician, patients are more willing to discuss their potency issues. A complete medical and sexual history should be taken in an effort to assess whether the cause of ED is organic, psychogenic, or multifactorial **(Fig. 397-3)**.

Both the patient and his sexual partner should be interviewed regarding sexual history. ED should be distinguished from other sexual problems, such as premature ejaculation. Lifestyle factors such as sexual orientation, the patient's distress from ED, performance anxiety, and details of sexual techniques should be addressed. Validated questionnaires are available to assess ED, including the International Index of Erectile Function (IIEF) and the more easily administered Sexual Health Inventory for Men (SHIM), a validated abridged version of the IIEF. These can assess the severity of ED, measure treatment effectiveness, and guide future management. The initial evaluation of ED begins with a review of the patient's medical, surgical, sexual, and psychosocial histories. The history should note whether the patient has experienced pelvic trauma, surgery, or radiation. In light of the increasing recognition of the relationship between lower urinary tract symptoms (LUTS/BPH) and ED, it is advisable to evaluate for the presence of associated urinary symptoms. Questions should focus on the onset of symptoms, the presence and duration of partial erections, and the progression

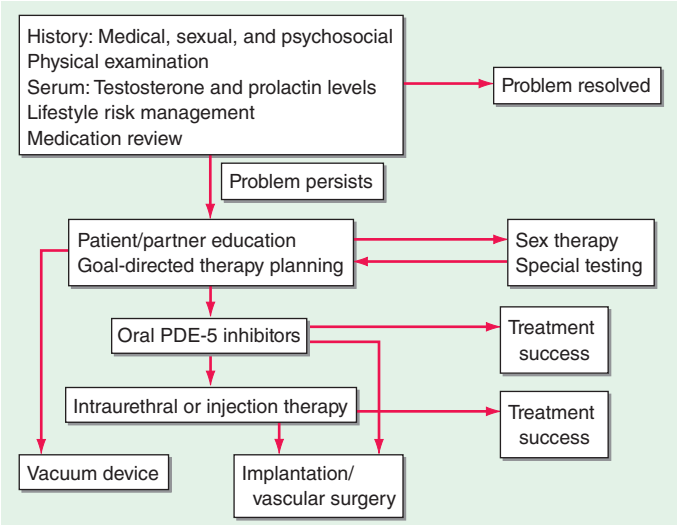

FIGURE 397-3 Algorithm for the evaluation and management of patients with erectile dysfunction. PDE, phosphodiesterase.

of ED. A history of nocturnal or early morning erections may be useful for distinguishing physiologic ED from psychogenic ED. Nocturnal erections occur during rapid eye movement (REM) sleep and require intact neurologic and circulatory systems. Organic causes of ED generally are characterized by a gradual and persistent change in rigidity or the inability to sustain nocturnal, coital, or self-stimulated erections. The patient should be questioned about the presence of penile curvature or pain with coitus. It is also important to address libido, as decreased sexual drive and ED are sometimes the earliest signs of endocrine abnormalities (e.g., increased prolactin, decreased testosterone levels). It is useful to ask whether the problem is confined to coitus with one partner or also involves other partners; ED not uncommonly arises with new or extramarital sexual relationships. Situational ED, as opposed to consistent ED, suggests psychogenic causes. For men being treated for ED, referral to a mental health professional should be considered to promote treatment adherence, reduce performance anxiety, and integrate treatments into a sexual relationship. Ejaculation is much less commonly affected than erection, but questions should be asked about whether ejaculation is normal, premature, delayed, or absent. Relevant risk factors should be identified, such as diabetes mellitus, coronary artery disease (CAD), and neurologic disorders. The patient's surgical history should be explored with an emphasis on bowel, bladder, prostate, and vascular procedures. A complete drug history, including tobacco, alcohol, marijuana, and illicit drug inquiries, is also important. Social changes that may precipitate ED are also crucial to the evaluation, including health worries, spousal death, divorce, relationship difficulties, and financial concerns.

Because ED commonly involves a host of endothelial cell risk factors, men with ED report higher rates of overt and silent myocardial infarction. Therefore, ED in an otherwise asymptomatic male warrants consideration of other vascular disorders, including CAD.

Men who suffer from ED are at high risk for concomitant LUTS from BPH and vice versa. Given that some treatments of one disorder will impact the other, the clinician should consider an assessment of LUTS in any man with ED.

The physical examination is an essential element in the assessment of ED. Signs of hypertension as well as evidence of thyroid, hepatic, hematologic, cardiovascular, or renal diseases should be sought. An assessment should be made of the endocrine and vascular systems, the external genitalia, and the prostate gland. The penis should be palpated carefully along the corpora to detect fibrotic plaques. Reduced testicular size and loss of secondary sexual characteristics are suggestive of hypogonadism. Neurologic examination should include assessment of anal sphincter tone, investigation of the bulbocavernosus reflex, and testing for peripheral neuropathy.

Although hyperprolactinemia is uncommon, a serum prolactin level should be measured in hypogonadal men, as decreased libido and/or ED may be the presenting symptoms of a prolactinoma or another mass lesion of the sella **(Chap. 380)**. The serum testosterone level should be measured, and if it is low, gonadotropins should be measured to determine whether hypogonadism is primary (testicular) or secondary (hypothalamic-pituitary) in origin **(Chap. 391)**. If not performed recently, serum chemistries, complete blood count (CBC), hemoglobin A_{1c}, and lipid profiles may be of value, as they can yield evidence of anemia, diabetes, hyperlipidemia, or other systemic diseases associated with ED.

Additional diagnostic testing is rarely necessary in the evaluation of ED. However, in selected patients, specialized testing may provide insight into pathologic mechanisms of ED and aid in the selection of treatment options. Optional specialized testing includes (1) studies of nocturnal penile tumescence and rigidity, (2) vascular testing (in-office injection of vasoactive substances, penile Doppler ultrasound, penile angiography, dynamic infusion cavernosography/cavernosometry), (3) neurologic testing (biothesiometry-graded vibratory perception, somatosensory-evoked potentials), and (4) psychological diagnostic tests. The information potentially gained from these procedures must be balanced against their invasiveness, cost, and impact on ultimate treatment outcome.

Clinicians should counsel men with ED who have comorbidities known to negatively affect erectile function that lifestyle modifications, including changes in diet and increased physical activity, improve overall health and may improve erectile function.

TREATMENT

Male Sexual Dysfunction

PATIENT EDUCATION

Patient and partner education is essential in the treatment of ED. In goal-directed therapy, education facilitates understanding of the disease, the results of the tests, and the selection of treatment. Discussion of treatment options helps clarify how treatment is best offered and stratify first- and second-line therapies. Patients with high-risk lifestyle issues such as obesity, smoking, alcohol abuse, and recreational drug use should be counseled on the role those factors play in the development of ED.

Therapies currently employed for the treatment of ED include oral phosphodiesterase type 5 inhibitor (PDE-5i) therapy (most commonly used), injection therapies, testosterone therapy, penile devices, and psychological therapy. In addition, limited data suggest that treatments for underlying risk factors and comorbidities—for example, weight loss, exercise, stress reduction, and smoking cessation—may improve erectile function. Decisions regarding therapy should take into account the preferences and expectations of patients and their partners.

ORAL AGENTS

Sildenafil, tadalafil, vardenafil, and avanafil are the only approved and effective oral agents for the treatment of ED. These four medications have markedly improved the management of ED because they are effective for the treatment of a broad range of causes, including psychogenic, diabetic, vasculogenic, post radical prostatectomy (nerve-sparing procedures), and post spinal cord injury. They belong to a class of medications that are selective and potent inhibitors of PDE-5, the predominant phosphodiesterase isoform found in the penis. They are administered in graduated doses and enhance erections after sexual stimulation (Fig. 397-2). The onset of action is ~30–120 min, depending on the medication used and other factors, such as recent food intake. Reduced initial

doses should be considered for patients who are elderly, are taking concomitant alpha blockers, have renal insufficiency, or are taking medications that inhibit the CYP3A4 metabolic pathway in the liver (e.g., erythromycin, cimetidine, ketoconazole, clarithromycin, diltiazem, itraconazole, ritonavir, verapamil, grapefruit, and possibly itraconazole and mibefradil), as they may increase the serum concentration of the PDE-5i or promote hypotension.

Initially, there were concerns about the cardiovascular safety of these drugs. It is known that these agents can act as mild vasodilators, and warnings exist about orthostatic hypotension with concomitant use of alpha blockers. The use of PDE-5is is not contraindicated in men who are also receiving alpha blockers, but they must be stabilized on the medication prior to initiating PDE-5i therapy. Earlier concerns that the use of PDE-5is would increase cardiovascular events have been mitigated by the results of several controlled trials showing no increase in myocardial ischemic events or overall mortality compared to the general population.

Several randomized trials have demonstrated the efficacy of this class of medications. There are no compelling data to support the superiority of one PDE-5i over another. Subtle differences between agents have variable clinical relevance **(Table 397-2)**.

Patients may fail to respond to a PDE-5i for several reasons **(Table 397-3)**. Some patients may not tolerate PDE-5i secondary to adverse events from vasodilation in nonpenile tissues expressing PDE-5 or from the inhibition of homologous nonpenile isozymes (i.e., PDE-6 found in the retina). Abnormal vision attributed to the effects of PDE-5i on retinal PDE-6 is of short duration, reported only with sildenafil, and not thought to be clinically significant. A more serious concern is the possibility that PDE-5is may cause nonarteritic anterior ischemic optic neuropathy (NAION); although data to support that association are limited, it is prudent to avoid the use of these agents in men with a prior history of NAION.

Testosterone supplementation combined with a PDE-5i may be beneficial in improving erectile function in hypogonadal men with ED who are unresponsive to PDE-5i alone. These drugs do not affect ejaculation, orgasm, or sexual drive. Side effects associated with PDE-5is include headaches (19%), facial flushing (9%), dyspepsia (6%), and nasal congestion (4%). Approximately 7% of men using sildenafil may experience transient altered color vision (blue halo effect), and 6% of men taking tadalafil may experience loin pain. PDE-5i is contraindicated in men receiving nitrate therapy for cardiovascular disease, including agents delivered by the oral, sublingual, transnasal, and topical routes. These agents can potentiate its hypotensive effect and may result in profound shock. Likewise, amyl/butyl nitrate "poppers" may have a fatal synergistic effect on blood pressure. PDE-5is also should be avoided in patients with congestive heart failure and cardiomyopathy because of the risk of vascular collapse. Because sexual activity leads to an increase in physiologic expenditure (5–6 metabolic equivalent tasks [METs]), physicians have been advised to exercise caution in prescribing any drug for sexual activity to those with active coronary disease, heart failure, borderline hypotension, or hypovolemia and to those on complex antihypertensive regimens.

Although the various forms of PDE-5is have a common mechanism of action, there are a few differences among the four agents (Table 397-2). Tadalafil is unique in its longer half-life, and avanafil appears to have the fastest onset of action. All four drugs are effective for patients with ED of all ages, severities, and etiologies. Although there are pharmacokinetic and pharmacodynamic differences among these agents, clinically relevant differences are not clear.

TABLE 397-3 Issues to Consider if Patients Report Failure of Phosphodiesterase Type 5 Inhibitor (PDE-5i) to Improve Erectile Dysfunction

1. A trial of medication on at least 6 different days at the maximal dose should be performed before declaring patient nonresponsive to PDE-5i use.
2. Confirm that the patient did not partake in a high-fat meal prior to taking medication; pertains to sildenafil.
3. Failure to include physical and psychic stimulation at the time of foreplay to induce endogenous NO.
4. Took medications at an appropriate time frame *prior* to step 3: half-hour prior for avanafil, 1 h for sildenafil/vardenafil, or 2.5 h for tadalafil.
5. Unrecognized hypogonadism.

Abbreviation: NO, nitric oxide.

ANDROGEN THERAPY

Testosterone replacement is used to treat both primary and secondary causes of hypogonadism **(Chap. 391)**. Men with ED and testosterone deficiency (TD) who are considering ED treatment with a PDE-5i should be informed that PDE-5is may be more effective if combined

TABLE 397-2 PDE-5 Inhibitors[a]

DRUG	ONSET OF ACTION	$T_{1/2}$	DOSE	ADVERSE EFFECTS	CONTRAINDICATIONS
Sildenafil	T_{max} 30–120 min Duration 4 h High-fat meal decreases absorption Alcohol use may affect efficacy	2–5 h	25–100 mg Starting dose 50 mg	Headache, flushing, dyspepsia, nasal congestion, altered vision	Nitrates Hypotension Cardiovascular risk factors Retinitis pigmentosa Change dose with some antiretrovirals Should be on stable dose of alpha blockers
Vardenafil	T_{max} 30–120 min Duration 4–5 h High-fat meal decreases absorption ETOH may affect efficacy	4.5 h	5–10 mg	Headache, flushing, rhinitis, dyspepsia	Same as sildenafil May have minor prolongation of QT interval Concomitant use of class I anti-arrhythmic
Tadalafil	T_{max} 30–60 min Duration 12–36 h Plasma concentration not affected by food or ETOH	17.5 h	10 or 20 mg; 2.5 or 5 mg for daily dose	Headache, dyspepsia, backpain, nasal congestion, myalgia	Same as sildenafil
Avanafil	T_{max} 30 min Duration 2 h Plasma concentration not affected by food	3–5 h	50, 100, and 200 mg dose	Headache, flushing, nasal congestion nasopharyngitis back pain	Same as sildenafil

[a]Sildenafil, vardenafil, tadalafil, and the newest option, avanafil, appear to be equally effective, but tadalafil has a longer duration of action and avanafil has a more rapid onset.

Abbreviation: ETOH, ethanol; PDE-5, phosphodiesterase type 5.

with testosterone therapy. Androgen supplementation in the setting of normal testosterone is not efficacious in the treatment of ED and is discouraged secondary to additional risk for toxicity without benefit. Methods of androgen replacement include transdermal patches and gels, including cutaneous nasal and axillary gels. Parenteral long-acting testosterone esters (enanthate and cypionate), long-acting subcutaneous pellets, and oral preparations (17 α-alkylated derivatives) are also available **(Chap. 391)**. With the possible exception a newer oral testosterone undecanoate, oral androgen preparations have the potential for hepatotoxicity and should be avoided.

The increased scrutiny of testosterone caused the U.S. Food and Drug Administration (FDA) to issue a warning that there is a "weak signal" that testosterone replacement therapy increases the risk of thromboembolic events and may have addictive properties. Although testosterone therapy has known risks, such as water retention in heart failure patients and worsening sleep apnea, increasing evidence suggests that, when monitored appropriately, this therapy decreases the risk for metabolic syndrome, changes body composition by increasing lean muscle mass, and improves insulin sensitivity and average hemoglobin A_{1c}. This evidence, combined with the fact that hypogonadism is a known risk factor for metabolic syndrome and cardiovascular disease, has led to the conclusion that testosterone therapy for age-related hypogonadism in fact improves overall health and decreases the risk of cardiovascular events. It is important to note that men with secondary hypogonadism who desire fertility should not be treated directly with testosterone, but with an alternative such as the selective estrogen receptor modulator (SERM) clomiphene citrate, which increases gonadotropin levels, stimulating testicular testosterone production.

Testosterone circulates in the body in two forms: free and unbound or that bound to proteins such as albumin or sex hormone–binding globulin (SHBG). SHBG has a very high affinity for testosterone, and thus, testosterone bound to SHBG does not bind to the androgen receptor and is not bioavailable. Bioavailable testosterone is any testosterone that is not bound to SHBG. Unfortunately, reliable assays to directly measure bioavailable testosterone or free testosterone are expensive, difficult to perform, and thus not offered by most laboratories. However, direct measurement of SHBG is inexpensive and reliable, allowing free and bioavailable testosterone to be calculated.

Men who receive testosterone should be reevaluated after 3–6 months and at least annually thereafter for testosterone levels, erectile function, and adverse effects, which may include gynecomastia, sleep apnea, development or exacerbation of LUTS or BPH, prostate cancer, lowering of HDL, erythrocytosis, elevations of liver function tests, and reduced fertility. Periodic reevaluation should include measurement of hemoglobin and prostate-specific antigen and digital rectal examination. Therapy should be discontinued in patients who do not respond within 6 months without an alternate explanation (e.g., elevated estradiol).

VACUUM CONSTRICTION DEVICES

Vacuum constriction devices (VCDs) are a well-established noninvasive therapy. They are a reasonable treatment alternative for select patients who cannot take PDE-5is or do not desire other interventions. VCDs draw venous blood into the penis and use a constriction ring to restrict venous return and maintain tumescence. Adverse events with VCD include pain, numbness, bruising, and altered ejaculation. Additionally, many patients complain that the devices are cumbersome and that the induced erections have a nonphysiologic appearance and feel.

INTRAURETHRAL ALPROSTADIL

If a patient fails to respond to oral agents, a reasonable next choice is intraurethral or self-injection of vasoactive substances. Intraurethral prostaglandin E_1 (alprostadil), in the form of a semisolid pellet (doses of 125–1000 μg), is delivered with an applicator. Approximately 65% of men receiving intraurethral alprostadil respond with an erection when tested in the office, but <50% achieve successful coitus at home. Intraurethral insertion is associated with a markedly reduced incidence of priapism in comparison to intracavernosal injection.

INTRACAVERNOSAL SELF-INJECTION

Injection of synthetic formulations of alprostadil is effective in 70–80% of patients with ED, but discontinuation rates are high because of the invasive nature of administration. Doses range between 1 and 40 μg. Injection therapy is contraindicated in men with a history of hypersensitivity to the drug and men at risk for priapism (hypercoagulable states, sickle cell disease). Side effects include local adverse events, prolonged erections, pain, and fibrosis with chronic use. Various combinations of alprostadil, phentolamine, and/or papaverine sometimes are used.

SURGERY

An important but less frequently used form of therapy for ED involves the surgical implantation of a semirigid or inflatable penile prosthesis. Because of the permanence of prosthetic devices, patients should first consider less invasive options for treatment. These surgical treatments are associated with a low rate of complications and are used for those who do not want the less spontaneous medical treatments, in PDE-5i–refractory ED, or in men who cannot tolerate such medications. Despite the requirement for surgery, penile prostheses are associated with very high rates of patient and partner satisfaction.

SEX THERAPY

A course of sex therapy may be useful for addressing specific interpersonal factors that may affect sexual functioning. These approaches may be useful in patients who have psychogenic or social components to their ED, although data from randomized trials are scanty and inconsistent. It is preferable to include both partners in therapy if the patient is involved in an ongoing relationship.

FEMALE SEXUAL DYSFUNCTION

Female sexual dysfunction (FSD) has traditionally included disorders of desire, arousal, pain, and muted orgasm. The associated risk factors for FSD are similar to those in males: cardiovascular disease, endocrine disorders, hypertension, neurologic disorders, and smoking **(Table 397-4)**. Women with hypertension report significantly lower sexual satisfaction (especially younger women).

EPIDEMIOLOGY

Epidemiologic data are limited, but the available estimates suggest that as many as 43% of women complain of at least one sexual problem. Despite the recent interest in organic causes of FSD, desire and arousal phase disorders (including lubrication complaints) remain the most

TABLE 397-4 Risk Factors for Female Sexual Dysfunction

Neurologic disease: stroke, spinal cord injury, parkinsonism
Trauma, genital surgery, radiation
Endocrinopathies: diabetes, hyperprolactinemia
Liver and/or renal failure
Cardiovascular disease, especially hypertension
Psychological factors and interpersonal relationship disorders: sexual abuse, life stressors
Medications
Antiandrogens: cimetidine, spironolactone
Antidepressants, alcohol, hypnotics, sedatives
Antiestrogens or GnRH antagonists
Antihistamines, sympathomimetic amines
Antihypertensives: diuretics, calcium channel blockers
Alkylating agents
Anticholinergics

Abbreviation: GnRH, gonadotropin-releasing hormone.

common presenting problems when surveyed in a community-based population.

PHYSIOLOGY OF THE FEMALE SEXUAL RESPONSE

The normal female sexual response requires the presence of estrogens. A role for androgens is also likely but less well established. In the CNS, estrogens and androgens work synergistically to enhance sexual arousal and response. A number of studies report enhanced libido in women during preovulatory phases of the menstrual cycle, suggesting that hormones involved in the ovulatory surge (e.g., estrogens) increase desire.

Sexual motivation is heavily influenced by context, including the environment and partner factors. Once sufficient sexual desire is reached, sexual arousal is mediated by the central and autonomic nervous systems. Cerebral sympathetic outflow is thought to increase desire, and peripheral parasympathetic activity results in clitoral vasocongestion and vaginal secretion (lubrication).

The neurotransmitters for clitoral corporal engorgement are similar to those in the male penile tissues, with a prominent role for neural, smooth-muscle, and endothelial released nitric oxide (NO). A fine network of vaginal nerves and arterioles promotes a vaginal transudate. The major transmitters of this complex vaginal response are not certain, but roles for NO and vasoactive intestinal polypeptide (VIP) are suspected. Investigators studying the normal female sexual response have challenged the long-held construct of a linear and unmitigated relationship between initial desire, arousal, vasocongestion, lubrication, and eventual orgasm. Caregivers should consider a paradigm of a positive emotional and physical outcome with one, many, or no orgasmic peak and release.

Although there are anatomic differences as well as variation in the density of vascular and neural beds in males and females, the primary effectors of sexual response are strikingly similar. Intact sensation is important for arousal. Thus, reduced levels of sexual functioning are more common in women with peripheral neuropathies (e.g., diabetes). Vaginal lubrication is a transudate of serum that results from the increased pelvic blood flow associated with arousal. Vascular insufficiency from a variety of causes may compromise adequate lubrication and result in dyspareunia. Cavernosal and arteriole smooth-muscle relaxation occurs via increased NO synthase (NOS) activity and produces engorgement in the clitoris and the surrounding vestibule. Orgasm requires an intact sympathetic outflow tract; hence, orgasmic disorders are common in female patients with spinal cord injuries.

APPROACH TO THE PATIENT

Female Sexual Dysfunction

Many women do not volunteer information about their sexual response. Open-ended questions in a supportive atmosphere are helpful in initiating a discussion of sexual integrity in women who are reluctant to discuss such issues. Once a complaint has been voiced, a comprehensive evaluation should be performed, including a medical history, a psychosocial history, a physical examination, and limited laboratory testing.

The history should include the usual medical, surgical, obstetric, psychological, gynecologic, sexual, and social information. Past experiences, intimacy, knowledge, and partner availability should also be ascertained. Medical disorders that may affect sexual health should be delineated. They include diabetes, cardiovascular disease, gynecologic conditions, obstetric history, depression, anxiety disorders, and neurologic disease. Medications should be reviewed as they may affect arousal, libido, and orgasm. The need for counseling and recognizing life stresses should be identified. The physical examination should assess the genitalia, including the clitoris. Pelvic floor examination may identify prolapse or other disorders. Laboratory studies are needed, especially if menopausal status is uncertain. Estradiol, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) are usually obtained, and dehydroepiandrosterone (DHEA) should be considered as it reflects adrenal androgen secretion. A CBC, liver function assessment, and lipid studies may be useful, if not otherwise obtained. Complicated diagnostic evaluation such as clitoral Doppler ultrasonography and biothesiometry require expensive equipment and are of uncertain utility. It is important for the patient to identify which symptoms are most distressing.

The evaluation of FSD previously occurred exclusively in a psychosocial context. However, inconsistencies between diagnostic categories based only on psychosocial considerations and the emerging recognition of organic etiologies have led to a new classification of FSD. This diagnostic scheme is based on four components that are not mutually exclusive: (1) *hypoactive sexual desire*—the persistent or recurrent lack of sexual thoughts and/or receptivity to sexual activity, which causes personal distress; hypoactive sexual desire may result from endocrine failure or may be associated with psychological or emotional disorders, (2) *sexual interest arousal disorder*—the persistent or recurrent inability to attain or maintain sexual excitement, which causes personal distress, (3) *orgasmic disorder*—the persistent or recurrent loss of orgasmic potential after sufficient sexual stimulation and arousal, which causes personal distress, and (4) *sexual pain disorder*—persistent or recurrent genital pain associated with noncoital sexual stimulation, which causes personal distress. This newer classification emphasizes "personal distress" as a requirement for dysfunction and provides clinicians with an organized framework for evaluation before or in conjunction with more traditional counseling methods.

TREATMENT

Female Sexual Dysfunction

GENERAL

An open discussion with the patient is important as couples may need to be educated about normal anatomy and physiologic responses, including the role of orgasm, in sexual encounters. Physiologic changes associated with aging and/or disease should be explained. Couples may need to be reminded that clitoral stimulation rather than coital intromission may be more beneficial.

Behavioral modification and nonpharmacologic therapies should be a first step. Patient and partner counseling may improve communication and relationship strains. Lifestyle changes involving known risk factors can be an important part of the treatment process. Emphasis on maximizing physical health and avoiding lifestyles (e.g., smoking, alcohol abuse) and medications likely to produce FSD is important (Table 397-3). The use of topical lubricants may address complaints of dyspareunia and dryness. Contributing medications such as antidepressants may need to be altered, including the use of medications with less impact on sexual function, dose reduction, medication switching, or drug holidays.

HORMONAL THERAPY

In postmenopausal women, estrogen replacement therapy may be helpful in treating vaginal atrophy, decreasing coital pain, and improving clitoral sensitivity **(Chap. 395)**. Menopause and its transition represent significant risk factors for the development of vulvovaginal atrophy–related sexual dysfunction. Available vaginal estrogen preparations include conjugated equine estrogens, estradiol vaginal cream, a sustained-release intravaginal estradiol ring, or a low-dose estradiol tablet. Vaginal estrogen preparations with the lowest systemic absorption rate may be preferred in women with history of breast cancer and severe vaginal atrophy. Vaginal lubricants and moisturizers applied on a regular basis have an efficacy comparable to that of local estrogen therapy and should be offered to women wishing to avoid the use of vaginal estrogens. If a hormonal supplement is chosen, then estrogen replacement in

the form of local cream is the preferred method as it avoids systemic side effects. Androgen levels in women decline substantially before menopause. However, low levels of testosterone or DHEA are not effective predictors of a positive therapeutic outcome with androgen therapy. The widespread use of exogenous androgens is not supported by the literature except in select circumstances (premature ovarian failure or menopausal states) and in secondary arousal disorders.

Atrophic vaginitis is very common in postmenopausal women and is most commonly treated with estrogen-based treatments. However, many women are hesitant to use estrogen-based treatments due to health concerns or are unable to use them due to a history of breast cancer or endometrial cancer. Hyaluronic acid vaginal gel has been found to be efficacious in treating atrophic vaginitis.

ORAL AGENTS

Flibanserin, originally developed as an antidepressant, has been approved by the FDA as a treatment for low sexual desire in premenopausal women. Flibanserin, a postsynaptic agonist of serotonin receptor 1A and antagonist of serotonin receptor 2A, increases sexual desire and reduces resultant stress in women with hyposexual desire disorder (HSDD) with few adverse effects. Flibanserin has two principal pharmacologic actions in neural microcircuits: it acts as a full agonist at postsynaptic 5-HT_{1A} receptors and an antagonist at postsynaptic 5-HT_{2A} receptors. Exclusive binding at these receptors differentiates flibanserin from buspirone and bupropion. This action in the prefrontal cortex causes the downstream release of dopamine and norepinephrine and reduction of serotonin. Flibanserin acts selectively on pyramidal neurons that excite brainstem 5-HT neurons yet also selectively on pyramidal neurons that inhibit brainstem norepinephrine and dopamine neurons.

Flibanserin may boost sex drive in women who experience low sexual desire and who find the experience distressing. The drug should be discontinued if there is no improvement in sex drive after 8 weeks. Potentially serious side effects include low blood pressure, dizziness, and fainting, particularly if it is mixed with alcohol. Other common adverse events include dizziness, nausea, fatigue, sleepiness, and insomnia. Health care professionals and pharmacies dealing with flibanserin have to undergo a certification (risk evaluation and mitigation strategy [REMS]) process, and patients need to submit a written agreement to abstain from alcohol. The goal of the flibanserin REMS is to inform patients about the increased risk of hypotension and syncope due to an interaction with alcohol.

Bremelanotide, a melanocortin 4 receptor agonist, has recently been approved for HSDD. It demonstrates significant improvement in desire and a significant decrease in distress related to lack of desire. The most common adverse effects include nausea (39.9%), facial flushing (20.4%), and headache (11%). Bremelanotide's place in therapy is unknown, as the trials met statistical significance for change in sexual desire elements and distress related to sexual desire, yet the clinical benefit may only be modest. It is a subcutaneous injection given 45 min prior to sexual activity. Bremelanotide has no clinically significant interactions with ethanol. Prescribing guidelines recommend no more than one dose in 24 h and no more than eight doses per month. Individuals should discontinue use after 8 weeks without benefit.

The efficacy of PDE-5is in FDS has been a marked disappointment in light of the proposed role of NO-dependent physiology in the normal female sexual response. The use of PDE-5is for FSD should be discouraged pending proof that they are effective.

CLITORAL VACUUM DEVICE

In patients with arousal and orgasmic difficulties, the option of using a clitoral vacuum device may be explored. This handheld battery-operated device has a small soft plastic cup that applies a vacuum over the stimulated clitoris. This causes increased cavernosal blood flow, engorgement, and vaginal lubrication.

398 Women's Health

Emily Nosova, Andrea Dunaif

The clinical discipline of women's health is well established. Indeed, its emphasis on greater attention to patient education and medical decision-making is a paradigm for what has become known as patient-centered health care. Moreover, the recognition of sex differences in gene expression, disease processes, and health outcomes is an important example of precision medicine. Sex difference refers to the biologic differences conferred by sex chromosomes and hormones. In contrast, gender differences are related to psychosocial roles and cultural expectations. The study of sex differences continues to grow as a scientific discipline. In 2016, the National Institutes of Health recognized its importance by implementing the expectation that sex should be considered as a biologic variable in study designs, analyses, and reporting in not only human but also vertebrate animal research. Strong scientific justification must be provided to limit research to only one sex.

DISEASE RISK: REALITY AND PERCEPTION

The leading causes of death are the same in women and men: (1) heart disease and (2) cancer **(Fig. 398-1)**. The leading cause of cancer death, lung cancer, is the same in both sexes. Breast cancer is the second leading cause of cancer death in women, but it causes ~70% fewer total deaths than does lung cancer. Men are more likely than women to die from suicide and accidents.

Maternal mortality continues to be higher in the United States than in other industrialized nations and is associated with substantial health disparities in maternal deaths. U.S. maternal mortality rates declined for the majority of the twentieth century given improvements in maternity care and safer surgical techniques; however, the rates began to rise again in 2000. The most current national data for maternal mortality were reported in 2018, over 10 years since the prior updated statistics. Over the past decade, the mortality rate has remained relatively stable. In 2018, the mortality rate was 17.4 deaths per 100,000 live births. The mortality rates for non-Hispanic black women were highest at 37.3 deaths per 100,000 live births (2.5 times the rate for non-Hispanic white women [14.9 deaths per 100,00 live births], 3.2 times the rate for Hispanic women [11.8 deaths], and 2.8 times the rate for Asian women [13.3 deaths]).

Women's risk for many diseases increases at menopause. The median age of menopause in Caucasian women from industrialized countries is between 50 and 52 years, where women spend one-third of their lives in the postmenopausal period. Menopause occurs at earlier ages in Hispanic and African-American women as well as in women of lower socioeconomic status. Estrogen levels fall abruptly at menopause, inducing a variety of physiologic and metabolic responses. Rates of

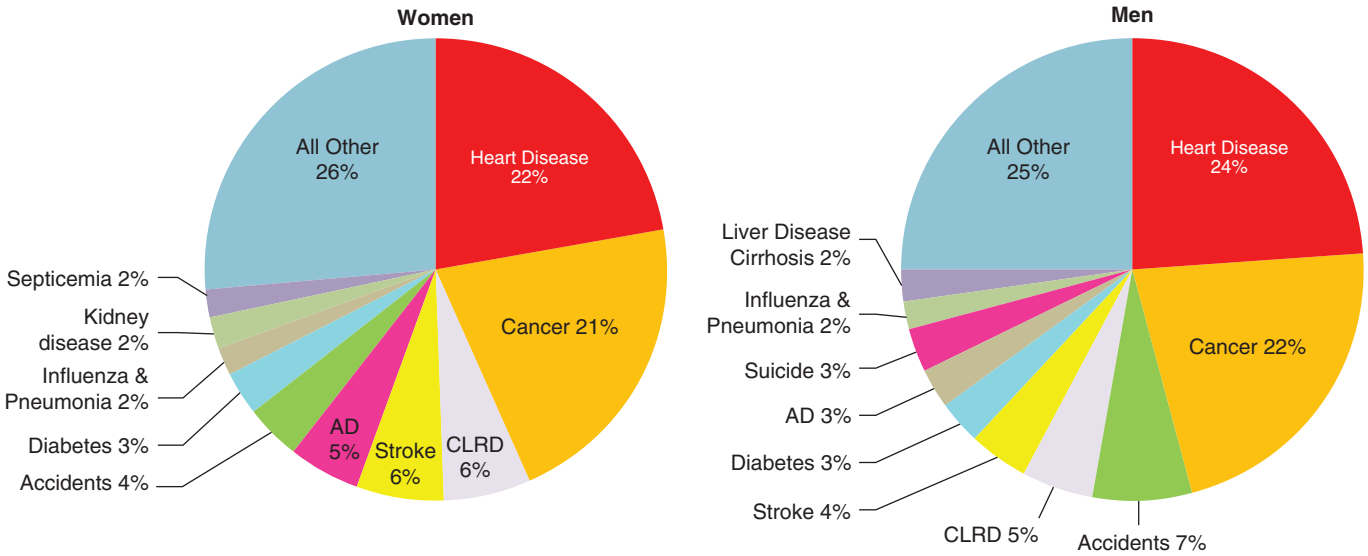

FIGURE 398-1 Percent distribution of 10 leading causes of death in (*A*) women compared to (*B*) men in the United States in 2018. In both women and men, the first and second leading causes of death are the same, heart disease and cancer, respectively. Causes of death then diverge by sex. For example, accidents are the third leading cause of death in men but the sixth leading cause of death in women. Chronic lower respiratory disease (CLRD), stroke, and Alzheimer's disease (AD) cause a larger percentage of deaths in women than in men. Suicide is among the 10 leading causes of death in men but not in women. *(Data from SL Murphy, J Xu, KD Kochanek, E Arias, B Tejada-Vera: Deaths: Final Data for 2018. Natl Vital Stat Rep 69:1, 2021.)*

cardiovascular disease (CVD) increase and bone density decreases rapidly after menopause.

In the United States, women live on average 5.0 years longer than men, with a life expectancy at birth in 2018 of 81.2 years in women compared with 76.2 years in men of all races. Life expectancy was lower in African Americans of both sexes and higher in Hispanics of both sexes than their Caucasian counterparts. Accordingly, elderly women outnumber elderly men, so that age-related conditions, such as hypertension, have a female preponderance.

SEX DIFFERENCES IN HEALTH AND DISEASE

ALZHEIMER'S DISEASE

(See also Chap. 431.) Alzheimer's disease (AD) affects approximately twice as many women as men. Because the risk for AD increases with age, part of this sex difference is accounted for by the fact that women live longer than men. However, even in relatively younger groups (60–70 years of age), there is still a higher incidence of AD among women. Additional factors may contribute to the increased risk for AD in women, including sex differences in brain size, structure, and functional organization. Multimodal neuroimaging has demonstrated that certain biomarkers of the preclinical phase of AD, including a decline in neuronal mitochondrial function and impaired cerebral glucose metabolism, are evident earlier in women and are even distinguishable during the perimenopausal endocrine transition. There is emerging evidence for sex-specific differences in gene expression, not only for genes on the X and Y chromosomes but also for some autosomal genes. These genetic differences may translate into variable severity of AD, with women experiencing greater deficits in cognition. The ε4 allele of the apolipoprotein E gene (*APOε4*), a cholesterol carrier integral for lipid transport in the brain, is a major risk factor for AD. Recent studies show that the *APOε4* genotype is strongly linked to development of sporadic AD in women (Fig. 398-2). Women who carry either the *APOε4* homo- or heterozygous isoform have an increased risk of progressing from healthy aging patterns to cognitive impairment or AD, whereas men who carry either isoform experience marginal impact on their memory or cognition.

Estrogens have pleiotropic genomic and nongenomic effects on the central nervous system, including neurotrophic actions in key areas involved in cognition and memory. Women with AD have lower endogenous estrogen levels than do women without AD. These observations have led to the hypothesis that estrogen is neuroprotective. The Women's Health Initiative Memory Study (WHIMS), an ancillary study in the Women's Health Initiative (WHI) in women aged ≥65 years, found significantly increased risk for both dementia and mild cognitive impairment in women receiving estrogen alone or estrogen with progestin compared to placebo. However, the Kronos Early Estrogen Prevention Study (KEEPS), a randomized clinical trial of early hormone therapy (HT) initiation after menopause that compared conjugated equine estrogen (CEE), transdermal estradiol (both estrogen arms included cyclic oral micronized progesterone), and placebo, found no adverse effect of HT on cognitive function. In summary, there is no evidence from placebo-controlled trials that HT improves cognitive function.

While studies have shown a link between female sex and AD, other neurodegenerative disorders, including Parkinson's disease (PD) and amyotrophic lateral sclerosis (ALS), exhibit a stronger association with male sex. Men are 1.5 times more likely to develop PD than women across all age groups. A possible explanation for the male predilection may be the effect of Y-chromosome exclusive gene sex-determining region Y (SRY) on nigrostriatal dopaminergic (NSDA) neurons: the SRY upregulates neuronal numbers, synthesis of dopamine, and metabolism of neurons.

ALS is a highly variable disease in symptomatology and age at onset. Men are diagnosed with ALS earlier in life and exhibit a more severe disease course, even though survival patterns are similar between the two sexes. Despite this variability, epidemiologic data have demonstrated that, in females, ALS starts in the bulbar tract, whereas in males, ALS tends to begin in the motor neurons of the lumbar tract. Reasons for the sex differences observed in ALS remain unclear. However, there is some evidence to suggest that a more prolonged reproductive condition, defined as a longer duration exposure to estrogen via oral contraceptive use versus natural menopause, may exert a neuroprotective role on motor neurons among women diagnosed with ALS.

CVD AND STROKE

(See also Chap. 273.) There are major sex differences in CVD, the leading cause of death in developed countries. However, there are also major gender differences because of perceptions by both women and their health care providers that women are at lower risk for CVD. As a result of these misconceptions, women are less likely to seek medical help when they experience symptoms of CVD. Health care providers are less likely to suspect CVD, so women receive fewer interventions for modifiable

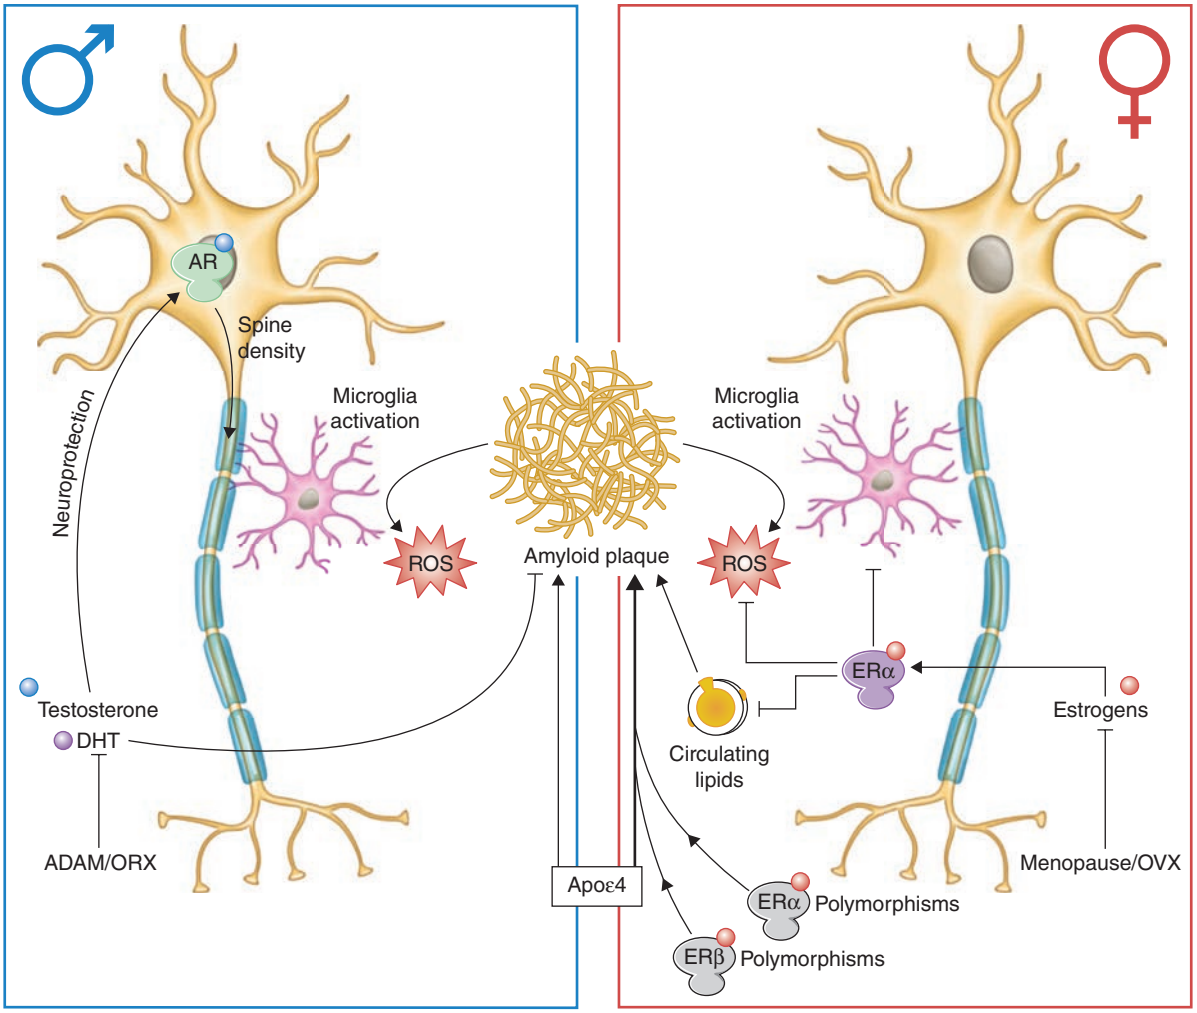

FIGURE 398-2 Sex differences and actions of sex steroid hormones on amyloid plaque deposition, neuroinflammation, and neuroprotection. The ε4 allele of the apolipoprotein E gene (*APOε4*), a cholesterol carrier integral for lipid transport in the brain, has been identified as a major genetic risk factor for the sporadic development of Alzheimer's disease (AD). Woman who carry either the homo- or heterozygous *APOε4* isoform have higher rates of amyloid plaque deposition. The *APOε4* variant has relatively limited effects in men with either the homo- or the heterozygous isoforms. AR, androgen receptor; DHT, dihydrotestosterone; ER, estrogen receptor; ROS, reactive oxygen species. *(Reproduced with permission from E Vegeto et al: The role of sex and sex hormones in neurodegenerative diseases. Endocr Rev 41:273, 2020.)*

risk factors as well as fewer acute interventions than do men. Women and their health care providers are also less aware that prodromal symptoms of cardiac disease differ in women compared to men. Women are less likely than men to present with chest pain and more likely to present with fatigue, shortness of breath, indigestion/nausea, and anxiety.

Sex steroids have major effects on the cardiovascular system and lipid metabolism. Estrogen increases high-density lipoprotein (HDL) and lowers low-density lipoprotein (LDL), whereas androgens have the opposite effect. Estrogen has direct vasodilatory effects on the vascular endothelium, enhances insulin sensitivity, and has antioxidant and anti-inflammatory properties. There is a striking increase in CVD after both natural and surgical menopause, suggesting that endogenous estrogens are cardioprotective. Women also have longer QT intervals on electrocardiograms, and this increases their susceptibility to certain arrhythmias.

CVD presents differently in women, who are usually 10–15 years older than their male counterparts and are more likely to have comorbidities such as hypertension, congestive heart failure, and diabetes mellitus (DM). In the Framingham study, angina was the most common initial symptom of CVD in women, whereas myocardial infarction (MI) was the most common initial presentation in men. Women more often have atypical symptoms such as fatigue, anxiety, nausea, indigestion, and upper back pain. Although awareness that heart disease is the leading cause of death in women has nearly doubled over the past 15 years, women remain less aware that its symptoms are often atypical and are less likely to contact 9-1-1 when they experience such symptoms.

Deaths from CVD had decreased markedly in men since 1980, whereas CVD deaths only started to decrease substantially in women beginning in 2000. After 2010, death rates from CVD among both sexes stabilized and even began to increase slightly in men. Women with MI are more likely to present with cardiac arrest or cardiogenic shock, whereas men are more likely to present with ventricular tachycardia. Further, younger women with MI are more likely to die than are men of similar age. However, this mortality gap has decreased in recent years because younger women have experienced greater improvements in survival after MI than men. The improvement in survival is due largely to a reduction in comorbidities, suggesting a greater attention to modifiable risk factors in women.

Sex differences account for more variable short-term outcomes observed among women with CVD who receive therapeutic intervention, as compared to men. Women undergoing CABG surgery have more advanced disease, a higher perioperative mortality rate, less relief of angina, and less graft patency; however, 5- and 10-year survival rates are similar. Women undergoing percutaneous transluminal coronary angioplasty have lower rates of initial angiographic and clinical success than men, but they also have a lower rate of restenosis and a better long-term outcome. Women may benefit less and have more frequent serious bleeding complications from thrombolytic therapy compared with men. Factors such as older age, more comorbid conditions,

smaller body size, and more severe CVD in women at the time of events or procedures account in part for the observed sex differences.

Elevated cholesterol levels, hypertension, smoking, obesity, low HDL cholesterol levels, DM, and lack of physical activity are important risk factors for CVD in both men and women. Total triglyceride levels are an independent risk factor for CVD in women but not in men. Low HDL cholesterol and DM are more important risk factors for CVD in women than in men. Several disorders affect women exclusively, such as pregnancy-associated hypertension, preeclampsia, gestational DM, and polycystic ovary syndrome, or predominantly, such as rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). Cholesterol-lowering drugs are equally effective in men and women for primary and secondary prevention of CVD. In contrast to men, randomized trials showed that aspirin was not effective in the primary prevention of CVD in women; it did significantly reduce the risk of ischemic stroke.

Recent studies demonstrate strong associations between certain adverse pregnancy outcomes (APO) and the development of CVD in postmenopausal women, a risk that has been previously underappreciated. In an analysis of WHI data, nearly 29% of women surveyed reported at least one APO, defined as a hypertensive disorder during pregnancy, low or high neonatal birth weight, gestational diabetes, or preterm delivery of 3 weeks or greater. Each outcome, when analyzed independently, was significantly associated with the development of CVD after menopause. When multivariate modeling incorporated all of the APO variables and accounted for body mass index (BMI), socioeconomic status, and parity, low birth weight and hypertensive disorders remained significantly associated with later-onset CVD. A recent meta-analysis examined the association of female reproductive factors and the development of future CVD. The greatest risk for CVD (at least 2-fold) was conferred by a history of stillbirth, preterm birth, or preeclampsia, followed by a 1.5- to 1.9-fold risk with gestational diabetes and hypertension, premature ovarian insufficiency, and placental abruption; the lowest risk (<1.5-fold) was associated with early menarche, early menopause, parity, and polycystic ovary syndrome. Given these strong associations, targeted counseling and increased surveillance of CVD risk factors is warranted for women in high-risk groups.

The sex differences in CVD prevalence, beneficial biologic effects of estrogen on the cardiovascular system, and reduced risk for CVD in observational studies led to the hypothesis that HT was cardioprotective. However, the WHI, which studied >16,000 women on CEE plus medroxyprogesterone acetate (MPA) or placebo and >10,000 women with hysterectomy on CEE alone or placebo, did not demonstrate a benefit of HT for the primary or secondary prevention of CVD. In addition, CEE plus MPA was associated with an increased risk for CVD, particularly in the first year of therapy, whereas CEE alone neither increased nor decreased CVD risk. Both HT groups were associated with an increased risk for ischemic stroke. In a subgroup analysis of the WHI estrogen-alone trial, a relatively younger age (50–59 years) combined with a history of bilateral salpingo-oophorectomy (BSO) was associated with a >30% CEE treatment–associated reduction in all-cause mortality, whereas CEE-treated older women with prior BSO did not see a significant reduction in any other outcomes, including incidence of coronary artery disease, invasive breast cancer, all-cause mortality, and a composite index of the aforementioned outcomes plus stroke, hip fracture, pulmonary embolism, and colorectal cancer. These results suggest that postmenopausal women younger than 60 with prior BSO may have mortality benefit from HT, while women older than 60 with BSO may suffer consequences associated with HT. More recent data from KEEPS indicate that even if estrogen therapy is initiated shortly after the menopausal transition, it does not reduce atherosclerotic progression or impact CVD outcomes. Additionally, HT and placebo groups have similar outcomes with respect to venous thromboembolism and breast cancer. Although HT does not slow CVD development as previously thought, findings from KEEPS suggest that treated women experience significant improvements in vasomotor symptoms, mood, sexual function, and bone density, especially when therapy is started sooner after menopause onset.

HT is discussed further in Chap. 395.

DIABETES MELLITUS

(See also Chap. 403.) Women are more sensitive to insulin than men. Despite this, the prevalence of type 2 DM is similar in men and women. There is a sex difference in the relationship between endogenous androgen levels and DM risk. Higher bioavailable testosterone levels are associated with increased risk in women, whereas lower bioavailable testosterone levels are associated with increased risk in men. This observation has been confirmed in a recent Mendelian randomization that found that genetically determined higher testosterone increases risk for DM in women but reduces risk in men. Polycystic ovary syndrome, preeclampsia, pregnancy-associated hypertension, and gestational DM—common conditions in premenopausal women—are associated with a significantly increased risk for type 2 DM. Among individuals with DM, women have a greater risk for MI than do men. Women with DM have a sixfold greater risk of dying of CVD compared to women without DM.

Premenopausal women with DM lose the cardioprotective effect of female sex and have rates of CVD identical to those in males. These women have impaired endothelial function and reduced coronary vasodilatory responses, which may predispose to cardiovascular complications. Women with DM are more likely to have left ventricular hypertrophy. Women with DM receive less aggressive treatment for modifiable CVD risk factors than men with DM.

HYPERTENSION

(See also Chap. 277.) After age 60, hypertension is more common in U.S. women than in men, largely because of the high prevalence of hypertension in older age groups and the longer survival of women. Isolated systolic hypertension is present in 30% of women >60 years old. Sex hormones affect blood pressure. Both normotensive and hypertensive women have higher blood pressure levels during the follicular phase than during the luteal phase. In the Nurses' Health Study, the relative risk of hypertension was 1.8 in current users of oral contraceptives, but this risk is lower with the newer low-dose contraceptive preparations. HT is not associated with hypertension. Among secondary causes of hypertension, there is a female preponderance of renal artery fibromuscular dysplasia.

The benefits of treatment for hypertension have been dramatic in both women and men. A meta-analysis of the effects of hypertension treatment, the Individual Data Analysis of Antihypertensive Intervention Trial, found a reduction of risk for stroke and major cardiovascular events in women. The effectiveness of various antihypertensive drugs appears to be comparable in women and men; however, women may experience more side effects, such as cough with angiotensin-converting enzyme inhibitors.

AUTOIMMUNE DISORDERS

(See also Chap. 355.) Most autoimmune disorders occur more commonly in women than in men; they include autoimmune thyroid and liver diseases, SLE, RA, scleroderma, multiple sclerosis (MS), and idiopathic thrombocytopenic purpura. However, there is no sex difference in the incidence of type 1 DM, and ankylosing spondylitis occurs more commonly in men. Sex differences in both immune responses and adverse reactions to vaccines have been reported. For example, there is a female preponderance of postvaccination arthritis.

Adaptive immune responses are more robust in women than in men; this may be explained by the stimulatory actions of estrogens and the inhibitory actions of androgens on the cellular mediators of immunity. Consistent with an important role for sex hormones, there is variation in immune responses during the menstrual cycle, and the activity of certain autoimmune disorders is altered by castration or pregnancy (e.g., RA and MS may remit during pregnancy). Nevertheless, the majority of studies show that exogenous estrogens and progestins in the form of HT or oral contraceptives do not alter autoimmune disease incidence or activity. Exposure to fetal antigens, including circulating fetal cells that persist in certain tissues, has been speculated to increase the risk of autoimmune responses. There is clearly an important genetic component to autoimmunity, as indicated by the familial clustering and HLA association of many such disorders.

X chromosome genes also contribute to sex differences in immunity. Indeed, nonrandom X chromosome inactivation may be a risk factor for autoimmune diseases.

HIV INFECTION

(See also Chap. 202.) Women accounted for almost 18% of the ~36,400 new HIV diagnoses in the United States in 2018. Annual HIV diagnoses remained stable among women from 2014 to 2018. In 2018, the infectivity rate for black/African-American females was 13 times the rate for white females and 4 times higher than Hispanic/Latino females. Nevertheless, AIDS remains an important cause of death in younger women, particularly African-American women aged 25–44 years. Heterosexual contact with an at-risk partner is the fastest-growing transmission category, and women are more susceptible to HIV infection during vaginal sex than men. This increased susceptibility is accounted for in part by an increased prevalence of sexually transmitted diseases, i.e., gonorrhea and syphilis, in women.

Some studies have suggested that hormonal contraceptives may increase the risk of HIV transmission. Progesterone has been shown to increase susceptibility to infection in nonhuman primate models of HIV. Women are also more likely to be infected by multiple variants of the virus than men. Women with HIV have more rapid decreases in their CD4 cell counts than do men. Compared with men, HIV-infected women more frequently develop candidiasis, but Kaposi's sarcoma is less common than it is in men. Women have more adverse reactions, such as lipodystrophy, dyslipidemia, and rash, with antiretroviral therapy than do men. This observation is explained in part by sex differences in the pharmacokinetics of certain antiretroviral drugs, resulting in higher plasma concentrations in women.

OBESITY

(See also Chap. 402.) The prevalence of both obesity (BMI ≥30 kg/m^2) and abdominal obesity (waist circumference ≥88 cm in women) are similar in U.S. women and men. In 2018, the age-adjusted prevalence of obesity in U.S. adults was 42.4%, and there were no significant differences between women and men, even across different age groups. In 2018, the prevalence of obesity was 41.9% for women and 43.0% for men. The prevalence of obesity was highest among non-Hispanic black women (56.9%) as compared with non-Hispanic white (39.8%), Hispanic (43.7%), and non-Hispanic Asian women (17.2%). Non-Hispanic black women had a higher prevalence of obesity compared to non-Hispanic black men. There were no significant differences in prevalence between men and women among non-Hispanic white, non-Hispanic Asian, or Hispanic adults. More than 80% of patients who undergo bariatric surgery are women. Pregnancy and menopause are risk factors for obesity.

There are major sex differences in body fat distribution. Women characteristically have a gluteal and femoral or gynoid pattern of fat distribution, whereas men typically have a central or android pattern. Women have more subcutaneous fat than men. In women, endogenous androgen levels are positively associated with abdominal obesity, and androgen administration increases visceral fat. In contrast, there is an inverse relationship between endogenous androgen levels and abdominal obesity in men. Further, androgen administration decreases visceral fat in these obese men. The reasons for these sex differences in the relationship between visceral fat and androgens are unknown; however, emerging evidence suggests that there is a contribution of genetic variation. Studies in humans also suggest that sex steroids play a role in modulating food intake and energy expenditure.

In men and women, abdominal obesity characterized by increased visceral fat is associated with an increased risk for CVD and DM. Obesity increases a woman's risk for certain cancers, in particular postmenopausal breast and endometrial cancer, in part because adipose tissue provides an extragonadal source of estrogen through aromatization of circulating adrenal and ovarian androgens, especially the conversion of androstenedione to estrone. Obesity increases the risk of infertility, miscarriage, and complications of pregnancy.

OSTEOPOROSIS

(See also Chap. 411.) Osteoporosis is about five times more common in postmenopausal women than in age-matched men, and osteoporotic hip fractures are a major cause of morbidity in elderly women. Men accumulate more bone mass and lose bone more slowly than do women. Sex differences in bone mass are found as early as infancy. Calcium intake, vitamin D, and estrogen all play important roles in bone formation and bone loss. Particularly during adolescence, calcium intake is an important determinant of peak bone mass. Vitamin D deficiency is surprisingly common in elderly women, occurring in >40% of women living in northern latitudes. Receptors for estrogens and androgens have been identified in bone. Estrogen deficiency is associated with increased osteoclast activity and a decreased number of bone-forming units, leading to net bone loss. The aromatase enzyme, which converts androgens to estrogens, is also present in bone. Estrogen is an important determinant of bone mass in men (derived from the aromatization of androgens) as well as in women.

PHARMACOLOGY

On average, women have lower body weights, smaller organs, a higher percentage of body fat, and lower total-body water than men. There are also important sex differences in drug action and metabolism that are not accounted for by these differences in body size and composition. Sex steroids alter the binding and metabolism of a number of drugs. Further, menstrual cycle phase and pregnancy can alter drug action. Women also take more medications than men, including over-the-counter formulations and supplements. The greater use of medications combined with these biologic differences may account for the reported higher frequency of adverse drug reactions in women than in men.

Two-thirds of cases of drug-induced torsades des pointes, a rare, life-threatening ventricular arrhythmia, occur in women because they have a longer, more vulnerable QT interval. These drugs, which include certain antihistamines, antibiotics, antiarrhythmics, and antipsychotics, can prolong cardiac repolarization by blocking cardiac voltage-gated potassium channels.

PSYCHOLOGICAL DISORDERS

(See also Chap. 452.) Depression, anxiety, and affective and eating disorders (bulimia and anorexia nervosa) are more common in women than in men. Epidemiologic studies from both developed and developing nations consistently find major depression to be twice as common in women as in men, with the sex difference becoming evident in early adolescence. Depression occurs in 10% of women during pregnancy and in 10–15% of women during the postpartum period. There is a high likelihood of recurrence of postpartum depression with subsequent pregnancies. The incidence of major depression diminishes after the age of 45 years and does not increase with the onset of menopause. Depression in women appears to have a worse prognosis than does depression in men; episodes last longer, and there is a lower rate of spontaneous remission. Schizophrenia and bipolar disorders occur at equal rates in men and women, although there may be sex differences in symptoms.

Both biologic and social factors account for the greater prevalence of depressive disorders in women. Men have higher levels of the neurotransmitter serotonin. Sex steroids also affect mood, and fluctuations during the menstrual cycle have been linked to symptoms of premenstrual syndrome. Sex hormones differentially affect the hypothalamic-pituitary-adrenal responses to stress. Testosterone appears to blunt cortisol responses to corticotropin-releasing hormone. Both low and high levels of estrogen can activate the hypothalamic-pituitary-adrenal axis.

COVID-19 INFECTION

(See also Chap. 199.) Soon after the discovery of COVID-19, which was identified in November 2019 in Wuhan, China, as being caused by the novel coronavirus SARS-CoV-2, it was evident that there were appreciable sex differences in severity and outcomes. Indeed, initial observational data from the winter of 2019 and spring of 2020 demonstrated a higher overall incidence of infectious cases, hospitalizations, intensive care unit admissions, and case-fatality rates among men as compared to women. More pronounced sex differences were observed with advanced age, with a higher overall incidence in older male age groups. These sex differences have persisted among different racial, ethnic, and socioeconomic groups and across all continents, as SARS-CoV-2 became a global pandemic.

There are several potential mechanisms for these sex-specific effects of SARS-CoV-2 infection. The virus's entry point into cells is the membrane-bound angiotensin-converting enzyme 2 (ACE2) receptor, and it also harnesses the primer TMPRSS2, a cellular serine protease (Fig. 398-3). Circulating levels of ACE2, which is expressed in a variety of tissues including the lung, heart, and kidneys, have been reported to be relatively higher in men who have diabetes and/or kidney disease, as well as in healthy men; however, not all studies have reported similar sex differences. One hypothesis is that upregulation of the ACE2 receptor in men may provide greater opportunity for cellular entry, viral replication, and development of symptoms and deleterious sequelae.

ACE2 plays a critical role in bronchial transient secretory cells/type II alveolar cells as well as the renin-angiotensin-aldosterone system (RAAS). In the RAAS, ACE2 opposes angiotensin II's vasoconstrictive actions by converting angiotensin II to the vasodilatory angiotensin 1-7 in critical tissues, including cardiac myocytes, cardiac fibroblasts, and coronary endothelial cells. Importantly, recent evidence has shown the impact of sex and sex hormones on the RAAS and ACE2: estrogen downregulates angiotensin II receptor type 1 and regulates renin activity, as well as modulates local RAAS in the atrial myocardium. Furthermore, it has been shown that ovariectomized females have increased ACE2 activity and expression in their kidney and adipose tissue and that estradiol replacement reduces ACE2 expression. On the contrary, orchiectomized males have decreased ACE2 activity. Estrogen appears to reduce ACE2 expression in the heart and kidney in both rodent and human studies.

TMPRSS2, a vital contributor to SARS-CoV-2 cellular invasion, is a protein that is most abundantly expressed in prostate epithelial tissue, including high-grade prostate cancers and metastases. Accordingly, the protein's involvement in viral priming is thought to be an important reason for the higher case-fatality rate observed in men; however, the association has not yet been proven. TMPRSS2 is also expressed in airway epithelia, where its physiologic function is not entirely clear. Transcription of the cellular protein is regulated by androgenic ligands and androgen receptor binding element; it is unknown whether estrogen plays a role in its regulation. Emerging in vitro studies have demonstrated that a TMPRSS2 inhibitor blocks viral entry into cells. These data may serve as an important foundation for sex-specific and personalized therapeutic approaches in the future.

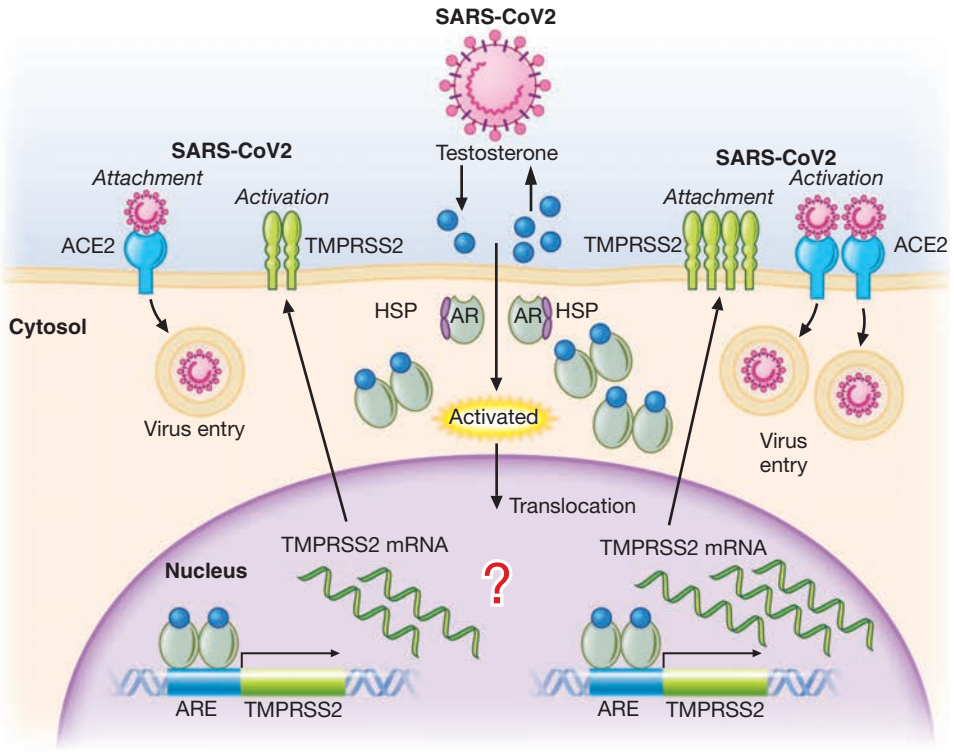

FIGURE 398-3 Proposed sex hormone differences in TMPRSS2-mediated SARS-CoV-2 host cell entry. The virus entry point into cells is the membrane-bound angiotensin-converting enzyme 2 (ACE2) receptor. The cell-membrane protease, TMPRSS2, is also vital for host cell entry. Circulating levels of ACE2, expressed abundantly in the lung, heart, and kidney tissues, have been reported to be relatively higher in men. Upregulation of the ACE2 receptor in men may provide greater opportunity for cellular entry, viral replication, symptom development, and multiorgan involvement. *(Reproduced with permission from C Gebhard et al: Impact of sex and gender on COVID-19 outcomes in Europe. Biol Sex Differ 11:29, 2020.)*

SUBSTANCE ABUSE AND TOBACCO

(See also Chaps. 453 and 454.) Substance abuse is more common in men than in women. However, one-third of Americans who suffer from alcoholism are women. Women are less likely to be diagnosed with alcoholism than men. A greater proportion of men than women seek help for alcohol and drug abuse. Men are more likely to go to an alcohol or drug treatment facility, whereas women tend to approach a primary care physician or mental health professional for help under the guise of a psychosocial problem. Blood alcohol levels are higher in women than in men after drinking equivalent amounts of alcohol, adjusted for body weight. This greater bioavailability of alcohol in women is due to both the smaller volume of distribution and the slower gastric metabolism of alcohol secondary to lower activity of gastric alcohol dehydrogenase than is the case in men. Women with alcoholism have a higher mortality rate than do women and men without alcoholism. Women also appear to develop alcoholic liver disease and other alcohol-related diseases with shorter drinking histories and lower levels of alcohol consumption. Alcohol abuse also poses special risks to a woman, adversely affecting fertility and the health of the baby (fetal alcohol syndrome). Even moderate alcohol use increases the risk of breast cancer, hypertension, and stroke in women.

More men than women smoke tobacco, but this sex difference continues to decrease. Women have a much larger burden of smoking-related disease. Smoking markedly increases the risk of CVD in premenopausal women and is also associated with a decrease in the age of menopause. Women who smoke are more likely to develop chronic obstructive pulmonary disease and lung cancer than men and at lower levels of tobacco exposure. Postmenopausal women who smoke have lower bone density than women who never smoked. Smoking during pregnancy increases the risk of preterm deliveries and low birth weight infants.

VIOLENCE AGAINST WOMEN

More than one in four women in the United States have experienced rape, physical violence, and/or stalking by an intimate partner. Adult women are much more likely to be raped by a spouse, ex-spouse, or acquaintance than by a stranger. Intimate partner violence (IPV) is a leading cause of death among young women. Rates of reported IPV in the United States increased dramatically amid stay-at-home orders during the COVID-19 pandemic. IPV is an important risk factor for depression, substance abuse, and suicide in women. Screening instruments can accurately identify women experiencing IPV and should be administered in settings that ensure adequate privacy and safety.

SUMMARY

Women's health is now a mature discipline, and the importance of sex differences in biologic processes is well recognized. Nevertheless, ongoing misperceptions about disease risk, not only among women but

also among their health care providers, result in inadequate attention to modifiable risk factors. Research into the fundamental mechanisms of sex differences will provide important biologic insights. Furthermore, those insights will have an impact on both women's and men's health.

399 Men's Health

Shalender Bhasin

The emergence of men's health as a distinct discipline within internal medicine is founded on the wide consensus that men and women differ across their life span in their susceptibility to disease, in the clinical manifestations of the disease, and in their response to treatment. Furthermore, men and women weigh the health consequences of illness differently and have different motivation for seeking care. Men and women experience different types of disparities in access to health care services and in the manner in which health care is delivered to them because of a complex array of socioeconomic and cultural factors. Attitudinal and institutional barriers to accessing care, fear and embarrassment due to the perception that it is not manly to seek medical help, and reticence on the part of patients and physicians in discussing issues related to sexuality, drug use, and aging have heightened the need for programs tailored to address the specific health needs of men.

The sex differences in disease prevalence, susceptibility, and clinical manifestations of the disease were discussed in **Chap. 398** (Women's Health) and will not be discussed here. It is notable that the two leading causes of death in both men and women—heart disease and cancer—are the same. However, men have higher prevalence of neurodevelopmental and degenerative disorders, substance use disorders, including the use of performance-enhancing drugs and alcohol dependence, diabetes, and cardiovascular disease, and women have a higher prevalence of autoimmune disorders, depression, rheumatologic disorders, and osteoporosis. Men are substantially more likely to die from accidents, suicides, and homicides than women. Among men 15–34 years of age, unintentional injuries, homicides, and suicides account for over three-fourths of all deaths. Among men 35–64 years of age, heart disease, cancer, and unintentional injuries are the leading causes of death. Among men ≥65 years of age, heart disease, cancer, lower respiratory tract infections, and stroke are the major causes of death.

From 1999 to 2010, the mortality rates in the United States decreased for men and women of all age groups, largely due to reduced death rates from heart attacks, cancer, motor vehicle injuries, and HIV infection. However, during the past decade, troubling disparities in sex-specific mortality rates have emerged among middle-aged men in the United States. From 2010 to 2017, the death rates have risen and life expectancy has decreased for young and middle-aged men. The increase in mortality rates among people aged 25–64 was the highest in the Ohio Valley and Appalachia, and in the New England states of New Hampshire, Maine, and Vermont. The rising mortality rates in young and middle-aged men have been attributed to an increase in deaths due to drug overdose, alcohol-related liver disease, and suicide. The rising rates of "deaths of despair" among young and middle-aged men, especially white non-Hispanics, have been associated with deterioration in economic and social well-being, reduced rates of marriage and labor force participation, and poor physical and mental health.

The biologic bases of sex differences in disease susceptibility, progression, and manifestation remain incompletely understood and are likely multifactorial. Undoubtedly, sex-specific differences in the genetic architecture and circulating sex hormones influence disease phenotype; additionally, epigenetic effects of sex hormones during fetal life, early childhood, and pubertal development may epigenetically imprint sexual and nonsexual behaviors, body composition, and disease susceptibility. The circulating and tissue concentrations of sex hormones differ substantially in men and women, and these hormonal differences may affect gene expression in cells of males and females in all parts of the body. The presence of only one X chromosome in men renders them more susceptible to X-linked disorders than women. Due to the X inactivation of one randomly chosen X chromosome, women's bodies contain two epigenetically different cell populations. The genes that do not undergo X inactivation exhibit dosage differences between male and female cells. Expression of the Y chromosome genes in men may affect the function of somatic cells containing the Y chromosome. The differences in the imprinting of maternally and paternally derived genes may also contribute to sex differences in the expression of disease. Reproductive load and physiologic changes during pregnancy, including profound hormonal and metabolic shifts and microchimerism (transfer of cells from the mother to the fetus and from the fetus to the mother), may affect disease susceptibility and disease severity in women. Sociocultural norms of child-rearing practices, societal expectations of gender roles, and the long-term economic impact of these practices and gender roles influence health behaviors and disease risk. Furthermore, the trajectories of age-related changes in sex hormones during the reproductive and postreproductive years vary substantially between men and women and influence the sex-specific patterns of the temporal evolution of age-related conditions such as osteoporosis, breast cancer, and autoimmune disease.

In a reflection of the growing attention on issues related to men's health, men's health clinics have mushroomed all over the country. Although the major threats to men's health have not changed—heart disease, cancer, and unintentional injury continue to dominate the list of major medical causes of morbidity and mortality in men—the men who attend men's health clinics do so largely for sexual, reproductive, and urologic health concerns involving common conditions, such as androgen deficiency syndromes, age-related decline in testosterone levels, sexual dysfunction, muscle dysmorphia and anabolic-androgenic steroid (AAS) use, lower urinary tract symptoms (LUTS), and medical complications of prostate cancer therapy, which are the subjects of this chapter. Additionally, we are witnessing the emergence of new categories of body image disorders in men that had not been recognized until the 1980s, such as the body dysmorphia syndrome and the use of performance-enhancing drugs to increase muscularity and lean appearance. Although menopause has been the subject of intense investigation for more than five decades, these issues that are specific to men's health are just beginning to gain the attention that they deserve because of their high prevalence and impact on overall health, well-being, and quality of life.

AGING-RELATED CHANGES IN MALE REPRODUCTIVE FUNCTION

A number of cross-sectional and longitudinal studies (e.g., the Baltimore Longitudinal Study of Aging, the Framingham Heart Study [FHS], the Massachusetts Male Aging Study, and the European Male Aging Study [EMAS]) have established that testosterone concentrations decrease with advancing age. This age-related decline starts in the third decade of life and progresses slowly **(Fig. 399-1)**; the rate

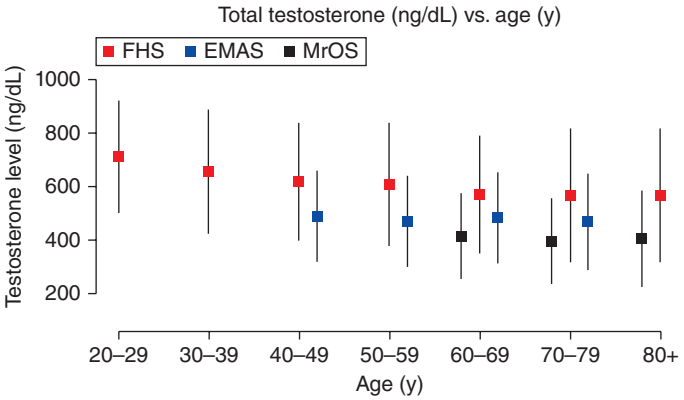

FIGURE 399-1 Age-related decline in total testosterone levels. Total testosterone levels measured using liquid chromatography–tandem mass spectrometry in men of the Framingham Heart Study (FHS), the European Male Aging Study (EMAS), and the Osteoporotic Fractures in Men Study (MrOS). *(Reproduced with permission from S Bhasin et al: Reference ranges for testosterone in men generated using liquid chromatography tandem mass spectrometry in a community-based sample of healthy nonobese young men in the Framingham Heart Study and applied to three geographically distinct cohorts. J Clin Endocrinol Metab 96:2430, 2011.)*

TABLE 399-1 Association of Testosterone Levels with Outcomes in Older Men

1. Positively associated with:
   - Muscle mass and muscle strength
   - Self-reported and performance-based measures of physical function
   - Sexual desire
   - Bone mineral density, bone geometry and quality, and volumetric bone mineral density
2. Negatively associated with risk of:
   - Coronary artery disease
   - Type 2 diabetes mellitus
   - Metabolic syndrome
   - All-cause mortality
   - Falls and fracture risk
   - Dementia and Alzheimer's disease
   - Frailty
   - Late-onset low-grade persistent depressive disorder (dysthymia)
3. Not associated with:
   - Lower urinary tract symptoms
   - Erectile dysfunction
   - Major depressive disorder

of decline in testosterone concentrations is greater in obese men, in men with chronic illness, and in those taking medications than in healthy older men. Because sex hormone–binding globulin (SHBG) concentrations are higher in older men than in younger men, free or bioavailable testosterone concentrations decline with aging to a greater extent than total testosterone concentrations. The age-related decline in testosterone is due to defects at all levels of the hypothalamic-pituitary-testicular (HPT) axis: pulsatile gonadotropin-releasing hormone (GnRH) secretion is attenuated, luteinizing hormone (LH) response to GnRH is reduced, and testicular response to LH is impaired. However, the gradual rise of LH with aging suggests that testis dysfunction is the main cause of declining androgen levels. The magnitude and trajectory of age-related decline in testosterone levels are affected by adiposity and weight change, comorbid conditions, and genetic factors. In the EMAS, 2.1% of community-dwelling men aged 40–70 years had total testosterone levels <317 ng/dL and a free testosterone level of <64 pg/mL, as well as sexual symptoms.

In epidemiologic surveys, low total and bioavailable testosterone concentrations in middle-aged and older men have been associated with decreased sexual desire, poor erections, and diminished early morning erections; lower appendicular skeletal muscle mass, muscle strength, and self-reported physical function; increased risk of mobility limitation and falls; higher visceral fat mass, insulin resistance, and type 2 diabetes; reduced telomere length and increased all-cause and cardiovascular mortality; lower areal and volumetric bone mineral density and bone quality; and higher rates of bone fractures (Table 399-1). Hypogonadal men often report low mood. However, testosterone levels have not been consistently associated with major depressive disorder; rather, low testosterone levels are more robustly associated with late-onset, low-grade, persistent depressive disorder previously referred to as dysthymia. An analysis of signs and symptoms in older men in the EMAS revealed a syndromic association of sexual symptoms with total testosterone levels <320 ng/dL and free testosterone levels <64 pg/mL in community-dwelling older men. Neither testosterone nor dihydrotesterone levels are associated with the risk of prostate cancer or LUTS.

Mendelian randomization studies using data from the United Kingdom Biobank Study found a sexual dimorphic relation between genetically determined testosterone levels and the risk of type 2 diabetes; in men, lower genetically determined testosterone levels were associated with higher risk of type 2 diabetes, but in women, higher genetically determined testosterone levels were associated with higher risk of type 2 diabetes. Higher genetically determined testosterone levels were also associated with increased risk of prostate cancer in men in this study.

Among the small number of randomized trials that have evaluated the efficacy of testosterone treatment in older men, the Testosterone Trials (TTrials)—a set of seven coordinated placebo-controlled trials of testosterone replacement conducted in 788 community-dwelling older men aged 65 years or older, who had an average of two morning, fasting total testosterone levels, measured using liquid chromatography–tandem mass spectrometry (LC-MS/MS), <275 ng/dL—have provided the most comprehensive data on the efficacy of testosterone treatment. The eligible men in the TTrials were required to have one or more of the following: low sexual desire, mobility limitation, and/or fatigue, and they were allocated using minimization to receive either placebo gel or testosterone gel for 1 year. Testosterone treatment was associated with greater improvement in overall sexual activity, sexual desire, erectile function, and satisfaction with sexual experience than placebo (Table 399-2). Testosterone treatment improved volumetric as well as areal bone density and estimated bone strength more than placebo; the improvements in volumetric bone density in the spine were greater than in the hip and greater in the trabecular than the peripheral bone. Testosterone treatment also corrected anemia in a greater proportion of older men with unexplained anemia of aging than placebo. No trials have been large enough or long enough to determine the long-term benefits of testosterone treatment in older men on clinically important outcomes such as disability, fractures, progression from prediabetes to diabetes, remission of dysthymia, and progression to Alzheimer's disease (AD) in men at risk of AD.

Testosterone therapy of healthy older men with low or low-normal testosterone levels is associated with greater increments in lean body mass, grip strength, and some measures of physical function than those associated with placebo (Fig. 399-2). In the TTrials, testosterone therapy of older hypogonadal men with self-reported mobility limitation consistently improved self-reported walking ability and modestly improved 6-min walking distance across all TTtrials participants but did not affect falls. Testosterone treatment of hypogonadal men without a depressive disorder has been associated with a small but significantly greater improvement in depressive symptoms compared to placebo; however, testosterone treatment alone or as an adjunct to antidepressant pharmacologic therapy has not been found to be efficacious in major depressive disorder. Two small, randomized trials in men with late-onset, low-grade persistent depressive disorder (dysthymia) have reported improvements in depressive symptoms in dysthymic men with low testosterone levels. In a large randomized trial (T4DM Trial) in men aged 50–74 years without hypogonadism, who had a waist circumference of ≥95 cm and impaired glucose tolerance or newly diagnosed type 2 diabetes, testosterone treatment in conjunction with

TABLE 399-2 The Main Findings of the Testosterone Trials (TTrials)

TRIAL	PRIMARY OUTCOME(S)	MAIN FINDINGS
Sexual Function Trial	Sexual activity	Testosterone treatment improved sexual activity, sexual desire, and erectile function.
Physical Function Trial	Distance walked over 6 min and self-reported physical function	Testosterone treatment consistently improved self-reported walking ability and modestly improved 6-min walk test distance across all TTtrials participants but did not affect falls.
Vitality Trial	Energy measured using the Functional Assessment of Chronic Illness Therapy (FACIT-F)	Testosterone did not improve energy but modestly improved mood and depressive symptoms.
Anemia Trial	The proportion of men with unexplained anemia who increased their hemoglobin ≥1.0 g/dL and experienced correction of anemia	Testosterone treatment, compared to placebo, was associated with a greater proportion of men with unexplained anemia increasing their hemoglobin by ≥1.0 g/dL and correcting their anemia.
Cognitive Function Trial	Delayed paragraph recall (Wechsler-Memory scale, a measure of memory)	Testosterone treatment did not improve delayed paragraph recall, visual memory, spatial ability, subjective memory complaints, or global cognitive function.
Bone Trial	Volumetric bone mineral density (vBMD) assessed using quantitative computed tomography	Testosterone treatment increased vBMD of the trabecular as well as peripheral bone in the spine and hip and increased estimated bone strength in the spine and hip more than placebo.
Cardiovascular Trial	Noncalcified coronary artery plaque volume determined by computed tomographic angiography	Testosterone treatment was associated with greater increase in the volume of noncalcified plaque in the coronary arteries than placebo.

Note: The TTrials were a set of seven coordinated placebo-controlled trials whose primary goal was to determine whether testosterone treatment for 1 year of men aged 65 years or older with an average of two morning, fasting total testosterone levels <275 ng/dL plus one or more of three conditions (low sexual desire, mobility limitation, and/or low vitality) was more efficacious than placebo in improving sexual function, mobility, and/ or vitality. The other four linked trials evaluated the effects of testosterone treatment on volumetric bone mineral density, anemia, cognitive function, and coronary artery plaque volume.

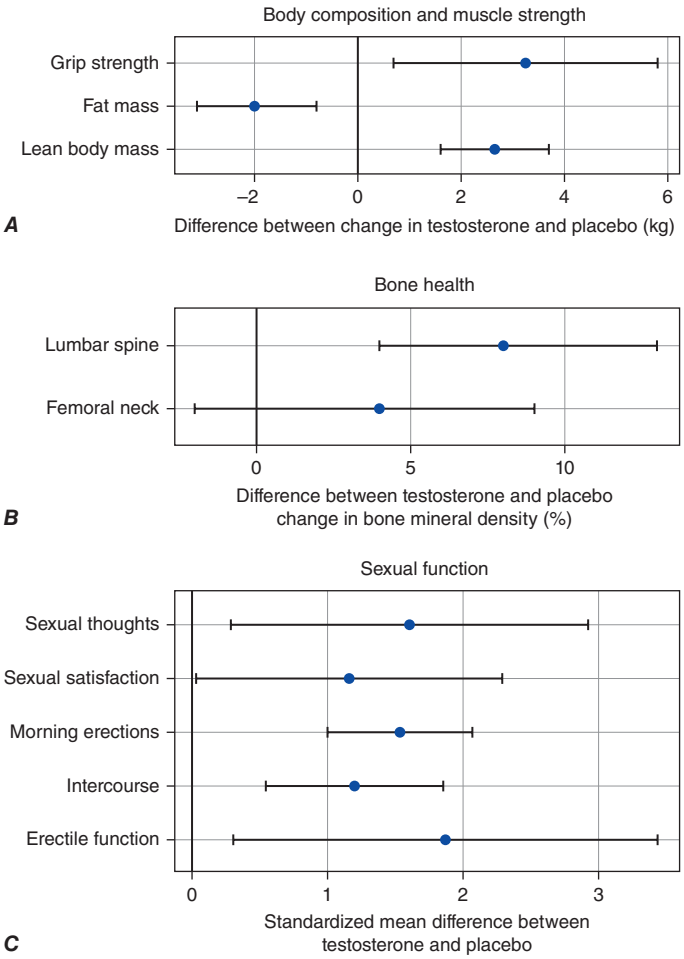

FIGURE 399-2 The effects of testosterone therapy on body composition, muscle strength, bone mineral density (BMD), and sexual function in intervention trials. The point estimates and the associated 95% confidence intervals are shown. ***A.*** The effects of testosterone therapy on lean body mass, grip strength, and fat mass in a meta-analysis of randomized trials. ***B.*** The effects of testosterone therapy on lumbar and femoral BMD in a meta-analysis of randomized trials. ***C.*** The effects of testosterone therapy on measures of sexual function in men with baseline testosterone <10 nmol/L (290 ng/dL). *(**A.** Data from S Bhasin et al: Drug insight: Testosterone and selective androgen receptor modulators as anabolic therapies for chronic illness and aging. Nat Clin Pract Endocrinol Metab 2:146, 2006; **B.** Data from MJ Tracz et al: Testosterone use in men and its effects on bone health. A systematic review and meta-analysis of randomized placebo-controlled trials. J Clin Endocrinol Metab 91:2011, 2006. **C.** Data from AM Isidori et al: Effects of testosterone on sexual function in men: results of a meta-analysis. Clin Endocrinol (Oxf) 63:381, 2005.)*

a lifestyle program for 2 years reduced the proportion of participants with type 2 diabetes more than placebo plus lifestyle program. Testosterone therapy has not been shown to improve fracture risk, cognitive function, or response to phosphodiesterase inhibitors in older men.

Neither the long-term risks nor the clinical benefits of testosterone therapy in older men have been demonstrated in adequately powered trials. Erythrocytosis is the most frequent adverse event associated with testosterone treatment. While there is no evidence that testosterone causes prostate cancer, there is concern that testosterone therapy might cause subclinical prostate cancers to grow. Testosterone therapy is associated with increased risk of detection of prostate events. Testosterone does not worsen LUTS in older men who do not have severe LUTS prior to treatment.

There is no clear evidence that testosterone treatment increases the risk of major adverse cardiovascular events (MACE). No randomized trial to date has been long enough or large enough to determine whether testosterone increases the risk of MACE. In two placebo-controlled trials, the rates of atherosclerosis progression did not differ significantly between the testosterone and placebo groups. In the Cardiovascular Trial of the TTrials, testosterone treatment was associated with a greater increase in the volume of the noncalcified plaque, compared to placebo. A large randomized trial to determine the effects of testosterone replacement therapy on MACE in middle-aged and older hypogonadal men aged 45–85 years (TRAVERSE Trial, ClincalTrials.gov identifier: NCT03518034) is in progress. The number of venous thromboembolic events in randomized testosterone trials has been too small to draw meaningful inferences. The risk for venous thromboembolic events may be increased in men with hypercoagulable states.

APPROACH TO THE PATIENT

Older Men with Age-Related Decline in Testosterone

Population screening of all older men for low testosterone levels is not recommended; testing should be restricted to men who have symptoms or physical features attributable to androgen deficiency. Testosterone treatment of older men with symptomatic testosterone deficiency offers some clinical benefits (e.g., improvement of sexual symptoms in men with low libido, correction of anemia), but because of the lack of evidence of long-term safety and limited evidence of long-term efficacy, an expert panel of the Endocrine Society recommended against testosterone treatment of *all* older men with low testosterone levels. Instead, the expert panel recommended that "testosterone therapy should be offered on an

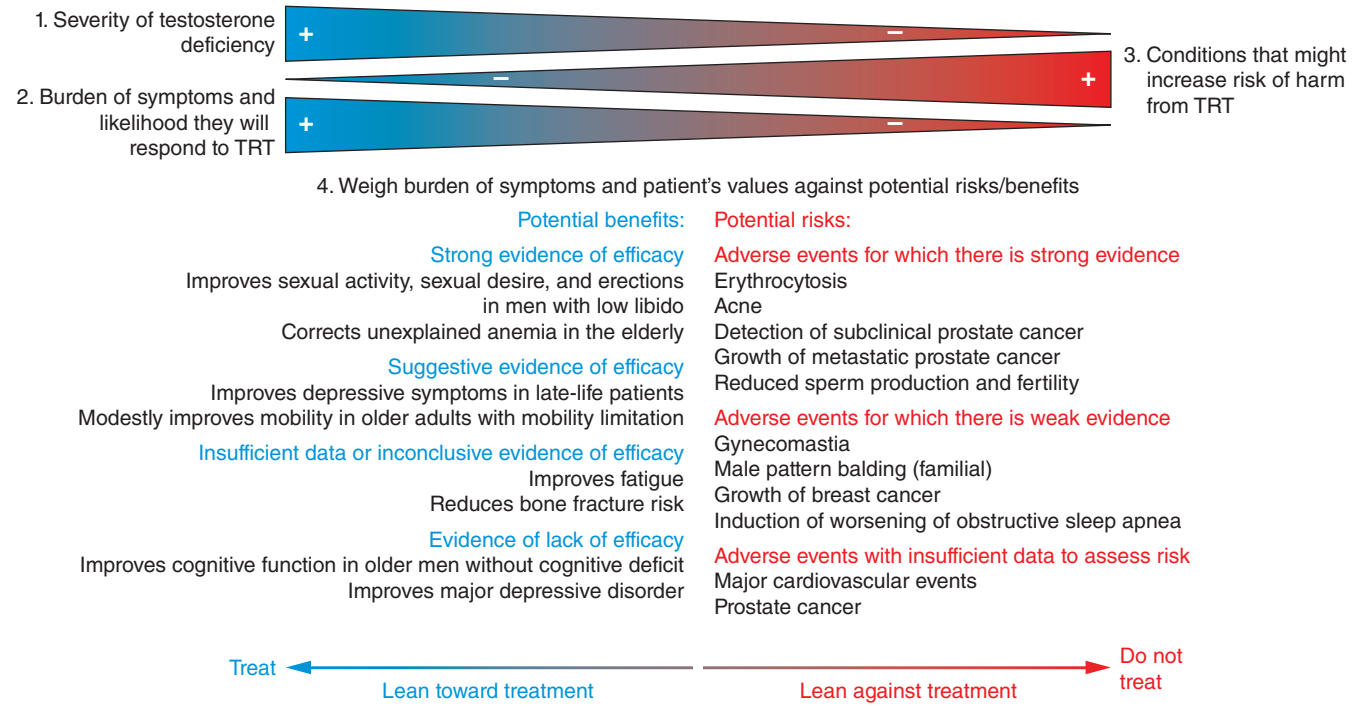

FIGURE 399-3 An individualized, patient-centric approach to shared treatment decision-making in older men with testosterone deficiency. Testosterone treatment is not indicated in all older men with low testosterone levels. The decision to treat should be individualized based on considerations of the severity of testosterone deficiency, the burden of symptoms and conditions associated with testosterone deficiency, the presence of conditions that might increase the patient's risk of harm from testosterone treatment, and the patient's values and willingness to accept the uncertainty of the long-term benefits and risks and the burden of treatment and monitoring. TRT, testosterone replacement therapy. *(Reproduced with permission from S Bhasin. Testosterone replacement in aging men: an evidence-based patient-centric perspective. J Clin Invest 131:e146607, 2021.)*

individualized basis . . . in men >65 years who have symptoms or conditions suggestive of testosterone deficiency (e.g., low libido or unexplained anemia) and consistently low testosterone." The decision to offer testosterone treatment to older men with low testosterone levels should be a shared decision, guided by an individualized assessment of potential benefits and risks, and careful weighing of the burden of symptoms/conditions against the potential benefits and risks **(Fig. 399-3)**. Evaluate whether the patient has clear evidence of testosterone deficiency. The diagnosis of testosterone deficiency should be made on the basis of two or more early morning, fasting testosterone levels below the lower limit of normal for healthy young men plus the presence of symptoms. Weigh the burden of symptoms/conditions against the known benefits and the uncertainty of long-term harm. Ascertain whether the patient has any conditions that might increase the risk of harm, such as prostate cancer, severe LUTS, erythrocytosis, or deep-venous thrombosis. Older men considering testosterone supplementation should undergo baseline evaluation of risk factors for prostate cancer. The initiation of prostate screening and monitoring should be a shared decision because prostate cancer screening has some risks. A shared decision to treat should be accompanied by a standardized monitoring plan to optimize the benefit-to-risk ratio.

AGE-RELATED CHANGES IN FECUNDITY

Although testicular morphology, semen production, and fertility are maintained up to a very old age in men, advanced paternal age is a risk factor for reduced fertility. Compared to men aged 21–25 years, men >50 years old have lower sperm motility and sperm morphology, a higher frequency of sperm tail defects, and lower fecundity. The fecundity is reduced when both parents are >40 years old. Increased workforce participation and changing career expectations of women, a higher age at reproductive union, and the availability of contraceptives that enable couples to separate their sexual and procreative lives have underpinned powerful secular trends toward postponement of childbearing to an older age. The median age at first childbirth has been increasing steadily across the world; postponement of childbirth to an older age increases the risk of involuntary childlessness because of the adverse effects of advanced maternal and paternal age on fecundity, increased risk of comorbidities that may indirectly affect fecundity, and the age-related changes in reproductive behaviors. Increased paternal age is associated with increased risk of germline mutations in the *FGFR2*, *FGFR3*, and *RET* genes and the associated autosomal dominant diseases, such as achondroplasia, Pfeiffer's syndrome, Crouzon's syndrome, Apert's syndrome, multiple endocrine neoplasia (MEN) 2A, and MEN 2B. Advanced paternal age also increases the risk of Klinefelter's syndrome, trisomy 13 and 18, neurodevelopmental disorders such as schizophrenia, autism, bipolar disorders, and cardiac malformations such as ventricular septal defects, atrial septal defects, and patent ductus arteriosus.

Sexual Dysfunction Various forms of sexual dysfunction are a major motivating factor for men seeking care at men's health clinics. The landmark descriptions of the human sexual response cycle by Masters and Johnson demonstrating that men and women display predictable physiologic responses after sexual stimulation provided the basis for rational classification of human sexual disorders. Accordingly, sexual disorders have been classified into four categories depending on phase of sexual response cycle in which the abnormality exists:

1. Hypoactive sexual desire disorder
2. Erectile dysfunction
3. Ejaculatory and orgasmic disorders
4. Disorders of pain

Classification of the patient's disorder into these categories is important as the etiologic factors, diagnostic tests, and therapeutic strategies vary for each class of sexual disorder. Historically, the classification and nomenclature for sexual disorders were based on the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), based on the erroneous belief that sexual disorders in men are largely psychogenic in origin. However, the recognition of erectile dysfunction as a manifestation of systemic disease and the availability of easy-to-use oral selective phosphodiesterase-5 (PDE5) inhibitors have placed sexual disorders in men

within the purview of the primary care provider. These disorders have been discussed in Chap. 397 (Sexual Dysfunction).

MUSCLE DYSMORPHIA SYNDROME IN MEN—A FORM OF BODY IMAGE DISORDER

Muscle dysmorphia is a form of body image disorder characterized by a pathologic preoccupation with muscularity and leanness. The men with muscle dysmorphia express a strong desire to be more muscular and lean. These men describe shame and embarrassment about their body size and shape and often report aversive symptoms such as dissatisfaction with appearance, preoccupation with bodybuilding and muscularity, and functional impairment. Patients with muscle dysmorphia also report higher rates of mood and anxiety disorders and obsessive and compulsive behaviors than individuals with no history of muscle dysmorphia. These men often experience impairment of social and occupational functioning.

Patients with muscle dysmorphia syndrome—nearly all men—are almost always engaged in weightlifting and body building and are more likely to use performance-enhancing drugs, especially AASs, than men in the general population or even weightlifters without body dysmorphia. Muscle dysmorphia disorder exposes men to an increased risk of disease due to the combined interactive effects of the intensity of physical exercise, the use of performance-enhancing drugs, and other lifestyle factors associated with weightlifting and the use of performance-enhancing drugs. These patients are also at increased risk of functioning poorly in their occupation and social life than men without this disorder. No randomized trials of any treatment modalities have been conducted; anecdotally, behavioral and cognitive therapies have been tried with varying degrees of success.

AAS Abuse by Athletes and Recreational Bodybuilders The illicit use of AASs to enhance athletic performance first surfaced in the 1950s among powerlifters and spread rapidly to other sports, professional as well as high school athletes, and recreational bodybuilders. In the early 1980s, the use of AAS spread beyond the athletic community into the general population. As many as 3 million Americans—most of them men—have likely used these compounds. Most AAS users are not athletes, but rather recreational weightlifters who use these drugs to look lean and more muscular.

The most commonly used AASs include testosterone esters, nandrolone, stanozolol, methandienone, and methenolol. AAS users generally use increasing doses of multiple steroids in a practice known as stacking.

The adverse effects of long-term AAS abuse remain poorly understood. Most of the information about the adverse effects of AAS has emerged from case reports, uncontrolled studies, or clinical trials that used replacement doses of testosterone (Table 399-3). The adverse event data from clinical trials using physiologic replacement doses of testosterone have been extrapolated unjustifiably to AAS users who may administer 10–100 times the replacement doses of testosterone over many years and to support the claim that AAS use is safe. A substantial fraction of AAS users also use other drugs that are perceived to be muscle-building or performance-enhancing, such as growth hormone; erythropoiesis-stimulating agents; insulin; stimulants such as amphetamine, clenbuterol, cocaine, ephedrine, and thyroxine; and drugs perceived to reduce adverse effects such as human chorionic gonadotropin (hCG), aromatase inhibitors, or estrogen antagonists. Men who abuse AAS are more likely to engage in other high-risk behaviors than nonusers. The adverse events associated with AAS use may be due to AAS themselves, concomitant use of other drugs, high-risk behaviors, and host characteristics that may render these individuals more susceptible to AAS use or to other high-risk behaviors.

The high rates of mortality and morbidities observed in AAS users are alarming. One Finnish study reported 4.6 times the risk of death among elite power lifters than in age-matched men from the general population. The causes of death among power lifters included suicides, myocardial infarction, hepatic coma, and non-Hodgkin's lymphoma. A retrospective review of patient records in Sweden also reported higher standardized mortality ratios for AAS users than for nonusers.

TABLE 399-3 Potential Adverse Effects Associated with the Use of Anabolic-Androgenic Steroids

ORGAN SYSTEM	EFFECT
Cardiovascular	Dyslipidemia Atherosclerotic disease Sudden death Myocardial fibrosis, cardiomyopathy Cardiac conduction abnormalities Hypertension
Neuroendocrine	HPT suppression; hypogonadism on AAS withdrawal Gynecomastia
Females	Virilizing effects
Neuropsychiatric	Major mood disorders (mania, hypomania, depression) Aggression, violence AAS dependence Neuronal apoptosis; cognitive deficits
Hematologic	Polycythemia Hypercoagulability and thrombosis
Hepatic	Inflammatory and cholestatic effects Peliosis hepatis (rare) Neoplasms (rare)
Musculoskeletal	Premature epiphyseal closure (in adolescents) Tendon rupture
Kidney	Renal failure secondary to rhabdomyolysis Focal segmental glomerulosclerosis
Dermatologic	Acne Striae

Abbreviations: AAS, anabolic-androgenic steroids; HPT axis, hypothalamic-pituitary-testicular axis.

Source: Data from HG Pope Jr et al: Adverse health consequences of performance-enhancing drugs: an Endocrine Society scientific statement. Endocr Rev 35:341, 2014.

Studies indicate that 32% of deaths among AAS users were suicidal, 26% homicidal, and 35% accidental. The median age of death among AAS users—24 years—is even lower than that for heroin or amphetamine users.

Numerous reports of cardiac death among young AAS users raise concerns about the adverse cardiovascular effects of AAS. High doses of AAS may induce proatherogenic dyslipidemia, increase thrombosis risk via effects on clotting factors and platelets, induce vasospasm through their effects on vascular nitric oxide, and induce myocardial hypertrophy and fibrosis.

Replacement doses of testosterone, when administered parenterally, are associated with only a small decrease in high-density lipoprotein (HDL) cholesterol and little or no effect on total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels. In contrast, supraphysiologic doses of testosterone and orally administered, 17-α-alkylated, nonaromatizable AAS are associated with marked reductions in HDL cholesterol and increases in LDL cholesterol.

Recent studies of AAS users using tissue Doppler and strain imaging and magnetic resonance imaging (MRI) have reported diastolic and systolic dysfunction, including significantly lower early and late diastolic tissue velocities, reduced E/A ratio, and reduced peak systolic strain in AAS users than in nonusers. Power athletes using AAS often have short QT intervals but increased QT dispersion, which may predispose them to ventricular arrhythmias. Long-term AAS use may be associated with myocardial hypertrophy and fibrosis. Myocardial tissue of power lifters using AAS has been shown to be infiltrated with fibrous tissue and fat droplets. AAS users demonstrate higher coronary artery plaque volume than nonusers, and lifetime AAS dose is associated with coronary atherosclerotic burden.

Long-term AAS use suppresses LH and follicle-stimulating hormone (FSH) secretion and inhibits endogenous testosterone production and spermatogenesis. Men who have used AAS for more than a few months experience marked suppression of the HPT axis after stopping AAS

that may be associated with sexual dysfunction, fatigue, infertility, and depressive symptoms. In some AAS users, HPT suppression may last more than a year, and in a few individuals, complete recovery may not occur. The symptoms of androgen deficiency during AAS withdrawal may cause some men to revert back to using AAS, leading to continued use and AAS dependence. As many as 30% of AAS users develop a syndrome of AAS dependence, characterized by long-term AAS use despite adverse medical and psychiatric effects. In some men's health clinics, as many as 25% of young men receiving testosterone replacement therapy have anabolic steroid withdrawal hypogonadism.

Supraphysiologic doses of testosterone may also impair insulin sensitivity. Orally administered androgens have been associated with insulin resistance and diabetes.

Unsafe injection practices, high-risk behaviors, and increased rates of incarceration render AAS users at increased risk of HIV and hepatitis B and C. In one survey, nearly 1 in 10 gay men had injected AAS or other substances, and AAS users were more likely to report high-risk unprotected anal sex than other men.

Some AAS users develop hypomanic and manic symptoms during AAS exposure (irritability, aggressiveness, reckless behavior, and occasional psychotic symptoms, sometimes associated with violence) and major depression (sometimes associated with suicidality) during AAS withdrawal. Users may also develop other forms of illicit drug use, which may be potentiated or exacerbated by AAS.

AAS use has been associated with difficulties with spatial as well as working memory, problem solving, and attention, and structural and functional changes in many brain regions involved in inhibitory control and emotional regulation. A structural MRI study of users of high doses of AAS reported smaller cortical, gray matter, putamen, and corpus callosum volumes. Both low and high androgen levels have been associated with increased Aβ and tau-P levels and Aβ toxicity. These data have raised concern that long-term AAS use may increase the risk of Alzheimer's disease and related dementias.

Elevated liver enzymes, cholestatic jaundice, hepatic neoplasms, and peliosis hepatis have been reported with oral, 17-α-alkylated AAS. AAS use may cause muscle hypertrophy without compensatory adaptations in tendons, ligaments, and joints, thus increasing the risk of tendon and joint injuries. AAS use is associated with acne, baldness, and increased body hair.

APPROACH TO THE PATIENT

Detection of AAS Use

AAS users generally mistrust physicians and seek medical help infrequently; when they do seek medical help, it is often for the treatment of AAS withdrawal syndrome, infertility, gynecomastia, or other medical or psychiatric complications of AAS use. The suspicion of AAS use should be raised by the increased hemoglobin and hematocrit levels; suppressed LH, FSH, and testosterone levels; low HDL cholesterol; and low testicular volume and sperm density in a person who looks highly muscular **(Table 399-4)**. A combination of these findings along with self-report of their use by the patient—which usually can be elicited by a tactful interview—are often sufficient to establish a diagnosis in clinical practice.

Accredited laboratories use gas chromatography and mass spectrometry or liquid chromatography and mass spectrometry to detect AAS abuse. In recent years, the availability of high-resolution mass spectrometry and tandem mass spectrometry has further improved the sensitivity of detecting AAS abuse. Illicit testosterone use is detected generally by the application of the measurement of the urinary testosterone-to-epitestosterone ratio and further confirmed by the use of the ^{13}C:^{12}C ratio in testosterone by the use of isotope ratio combustion mass spectrometry. Exogenous testosterone administration increases urinary testosterone glucuronide excretion and consequently the testosterone-to-epitestosterone ratio. Ratios >4 suggest exogenous testosterone use but can also reflect genetic variation. Genetic variations in the uridine diphospho-glucuronyl transferase 2B17 (*UGT2B17*), the major enzyme for testosterone glucuronidation, affect the testosterone-to-epitestosterone ratio. Synthetic testosterone has a lower ^{13}C:^{12}C ratio than endogenously produced testosterone, and these differences in the ^{13}C:^{12}C ratio can be detected by isotope ratio combustion mass spectrometry and used to confirm exogenous testosterone use in individuals with a high testosterone-to-epitestosterone ratio.

TABLE 399-4 Detection of the Use of Anabolic-Androgenic Steroids

Clinical indicators that should raise suspicion of anabolic-androgenic steroid use
1. Very muscular phenotype
2. Reduced testicular volume (<15 mL)
Laboratory indicators
1. Suppressed LH and FSH levels
2. Increased hematocrit
Detection of anabolic-androgenic steroids
1. LC-MS/MS analysis of urine
Detection of exogenous testosterone use
1. Urinary testosterone-to-epitestosterone ratio
2. Isotope ratio mass spectrometry analysis to detect differences in ^{13}C:^{12}C ratio in exogenous and endogenous testosterone

Note: In clinical settings, the use of anabolic-androgenic steroids can often be ascertained simply by direct questioning. Reduced testicular volume, suppressed LH and FSH, and increased hematocrit in an unusually muscular man should raise suspicion of anabolic-androgenic steroid use. Although rarely needed in clinical practice, recent use of anabolic-androgenic steroids can be confirmed by LC-MS/MS analysis of urine. Exogenous testosterone use can be detected using the urinary testosterone-to-epitestosterone ratio and isotope ratio mass spectrometry analysis to detect differences in ^{13}C:^{12}C ratio in exogenous and endogenous testosterone.

Abbreviations: FSH, follicle-stimulating hormone; LC-MS/MS, liquid chromatography–tandem mass spectrometry; LH, luteinizing hormone.

TREATMENT

Integrated Management of Patients with AAS Use

The nonathlete weightlifters who abuse AAS frequently do not seek medical treatment and often mistrust physicians. They also do not view these drugs and the associated lifestyle as deleterious to their health. In turn, many internists erroneously view AAS abuse as largely a problem of cheating in competitive sports, while, in fact, most AAS users are not athletes at all. Also, physicians often have a poor understanding of the factors motivating the use of these performance-enhancing drugs, the long-term health effects of AAS, and the associated psychopathologies that may affect treatment choices.

In addition to treating the underlying body dysmorphia disorder that motivates the use of these drugs, the treatment should be directed at the symptoms or the condition for which the patient seeks therapy, such as infertility, sexual dysfunction, gynecomastia, or depressive symptoms. Accordingly, therapy may include some combination of cognitive and behavioral therapy for muscle dysmorphia syndrome, antidepressant therapy for depression, selective PDE5 inhibitors for erectile dysfunction, and/or use of selective estrogen receptor modulators or aromatase inhibitors to reactivate HPT axis or hCG to restore testosterone levels.

As discussed above, AASs suppress the male hypothalamic-pituitary-gonadal axis, and men with long-term AAS use may experience symptoms of profound androgen deficiency such as sexual dysfunction, fatigue, and depressive symptoms during AAS withdrawal. Some of these patients may resume AAS use or start using other drugs to combat the distressing withdrawal symptoms. There are no randomized trials of any therapies for AAS withdrawal. Case reports and clinical experience suggest that administration of selective estrogen receptor modulators, CYP19 aromatase inhibitors, or hCG may restore circulating testosterone levels. Clomiphene citrate, a partial estrogen receptor agonist, administered in a dose

of 25–50 mg on alternate days, can increase LH and FSH levels and restore testosterone levels in a vast majority of men with AAS withdrawal syndrome. However, the recovery of sexual function during clomiphene administration is variable despite improvements in testosterone levels. Anecdotally, other aromatase inhibitors such as anastrozole have also been used. hCG, administered by intramuscular injections of 750–1500 IU three times each week, can raise testosterone levels into the normal range. Some patients may not respond to either clomiphene or hCG therapy, raising the possibility of irreversible long-term toxic effects of AAS on Leydig cell function.

Adjunctive cognitive and behavioral therapy or antidepressants to treat depression inadequately responsive to endocrine therapies alone may be needed. Emerging human and animal evidence suggests AAS and opioids likely promote dependence via common mechanisms. The opioid antagonist naltrexone blocks AAS dependence in animals. Therefore, treatments for human opioid dependence might also benefit AAS dependence. Many patients who abuse AAS suffer from body-image disorder and require psychiatric treatment for this underlying disorder.

LUTS IN MEN

LUTS in men include storage symptoms (urgency, daytime as well as nighttime frequency, and urgency incontinence), voiding disturbances (slow or intermittent stream, difficulty in initiating micturition, straining to void, pain or discomfort during the passage of urine, and terminal dribbling), or postmicturition symptoms (a sense of incomplete voiding after passing urine and postmicturition dribble). The overactive bladder syndrome refers to urgency with or without urgency incontinence, usually with urinary frequency and nocturia, and is often due to detrusor muscle overactivity. A presumptive diagnosis of benign prostatic hyperplasia should be made only in men with LUTS, who have demonstrable evidence of prostate enlargement and obstruction based on the size of the prostate. LUTS have historically been attributed to benign prostatic hyperplasia, although it has become apparent that the pathophysiologic mechanisms of LUTS are complex and multifactorial and may include structural or functional abnormalities of the bladder, bladder neck, prostate, distal sphincter mechanism, and urethra, as well as abnormalities in the neural control of the lower urinary tract. Diuretics, antihistamines, antidepressants, and other medications that have anticholinergic properties can cause or exacerbate LUTS in older men. The intensity of LUTS tends to fluctuate over time.

LUTS is highly prevalent in older men, affecting nearly 50% of men >65 and 70% of men >80 years old. The LUTS adversely affects quality of life because of its impact on sleep, ability to perform activities of daily living, and depressive symptoms. LUTS is often associated with erectile dysfunction.

APPROACH TO THE PATIENT

Lower Urinary Tract Symptoms

Medical evaluation should include assessment of potential causes of symptoms; medications including herbal and over-the-counter products that might contribute to symptoms; the symptom severity and bother using an International Prostate Symptom Score; and in some patients, a frequency-volume chart. The impact of LUTS on sleep, activities of daily living, and quality of life should be evaluated. Evaluation should also include digital prostate examination, neurologic examination focused on perineum and lower extremities, urinalysis, fasting blood glucose, electrolytes, creatinine, and prostate-specific antigen (PSA). Urodynamic studies are not required in most patients but are recommended when invasive surgical therapies are being considered. A urologic referral may be appropriate if the patient has hydronephrosis, renal insufficiency, recurrent urinary tract infections, hematuria, or history of acute urinary retention.

TREATMENT

Patients with LUTS

Considerations of the severity of symptoms; the impact of symptoms on sleep, activities of daily living, and quality of life; the natural history of the disease; and potential adverse effects of the intervention should guide the decision to intervene. In men with mild to moderately severe LUTS, the symptoms typically progress slowly over many years and may remain stable or even improve in some men. The men who have mild symptoms can usually be reassured and followed. Several simple steps such as reducing caffeine and alcohol intake, especially late in the day, taking the diuretic medication early in the day, avoiding excessive water intake close to bedtime, bladder training, pelvic floor exercises including biofeedback to promote pelvic floor relaxation, and timed voiding regimens or double voiding to ensure complete emptying of the bladder may be helpful in reducing the severity of symptoms. Men with mild to moderate bothersome LUTS can be treated effectively using α-adrenergic antagonists, steroid 5α-reductase inhibitors, PDE5 inhibitors, or anticholinergic agents alone or in combination. Selective α-adrenergic antagonists are typically the first line of therapy; their side effects include hypotension, dizziness, nasal congestion, retrograde or delayed ejaculation, and rarely floppy iris syndrome. In men with probable benign prostate obstruction with gland enlargement and LUTS, therapy with steroid 5α-reductase inhibitors, finasteride, or dutasteride for 1 or more years improves urinary symptoms and flow rate and reduces prostatic volume. Long-term treatment with 5α-reductase inhibitors can reduce the risk of acute urinary retention and need for prostate surgery. Combined administration of a steroid 5α-reductase inhibitor and an α_1-adrenergic blocker can rapidly improve urinary symptoms and reduce the relative risk of acute urinary retention and surgery. PDE5 inhibitors, when administered chronically alone or in combination with α-adrenergic blockers, are effective in improving LUTS and erectile dysfunction through their effects on nitric oxide–cyclic guanosine monophosphate (cGMP) in the bladder, urethra, and prostate. PDE5 inhibitors do not improve uroflow parameters, and their hypotensive effect may be potentiated by α_1-adrenergic blockers. Anticholinergic drugs are used for the treatment of overactive bladder in men with prominent irritative symptoms, such as frequency, urgency, and incontinence, and no evidence of elevated postvoid residual urine. Containment products, such as pads, can help improve social life in men who have severe storage symptoms, including incontinence. Surgery is indicated when medical therapy fails, symptoms progress in spite of medical therapy, or the patient develops acute urinary retention, hydronephrosis, renal insufficiency, or recurrent urinary tract infections, or if the patient has postvoid residual urine volume >25% of the urinary bladder volume.

MEDICAL COMPLICATIONS OF PROSTATE CANCER THERAPY

Prostate cancer is the most common malignancy in American men, accounting for 19% of all diagnosed cancers and ~8% of all cancer deaths; its incidence is on the rise, partly due to increased screening with PSA. The American Cancer Society estimates that, in 2021, 248,530 new cases of prostate cancer will be diagnosed in the United States and 34,130 men will die from this disease. The majority of these men have low-grade, organ-confined prostate cancer and excellent prospects of long-term survival. Substantial improvement in survival in men with prostate cancer has focused attention on the high prevalence of sexual dysfunction, physical dysfunction, and low vitality in the men, which are important contributors to poor quality of life among patients treated for prostate cancer. The pathophysiology of these symptoms after radical prostatectomy is multifactorial, but denervation and androgen deficiency are important contributors to these symptoms.

Androgen deficiency is common in men with prostate cancer. Testosterone levels decline with age, and men with prostate cancer are at risk of having low testosterone levels simply by virtue of their age.

However, total and free testosterone levels are even lower in men with prostate cancer who have undergone prostatectomy, when compared to noncancer age-matched controls. This age-related androgen deficiency in men with prostate cancer is associated with fatigue, sexual dysfunction, mobility limitation, and decreased physical function. Even with bilateral nerve-sparing procedure, >50% of men develop sexual dysfunction after surgery. Although there is some recovery of sexual function with passage of time, 40–50% of men undergoing radical prostatectomy find their sexual performance to be a moderate to large problem 18 months after surgery. Sexual problems are a source of psychosocial distress in men with localized prostate cancer. The men with locally advanced or metastatic prostate cancer who undergo androgen deprivation therapy (ADT) encounter even more distressing symptoms because of the profound androgen deficiency. In addition to fatigue, sexual dysfunction, and hot flushes, these men are at increased risk for diabetes, metabolic syndrome, coronary heart disease, and frailty.

Testosterone Therapy in Men with a History of Prostate Cancer A history of prostate cancer has historically been considered a contraindication for testosterone therapy. This guidance is based on observations that testosterone promotes the growth of metastatic prostate cancer. Metastatic prostate cancer generally regresses after orchidectomy and ADT. Androgen receptor signaling plays a central role in maintaining growth of normal prostate and prostate cancer. PSA levels are lower in hypogonadal men and increase after testosterone therapy. Prostate volume is lower in hypogonadal men and increases after testosterone therapy to levels seen in age-matched controls.

However, the role of testosterone in prostate cancer is complex. Epidemiologic studies and their meta-analyses have not revealed a consistent relationship between serum testosterone and prostate cancer. Others have reported that low testosterone levels are associated with high-grade cancers. In a landmark randomized trial, testosterone therapy of older men with low testosterone did not affect intraprostatic androgen levels or the expression of androgen-dependent prostatic genes. The suppression of circulating testosterone levels by a GnRH antagonist also does not affect intraprostatic androgen concentrations. Open-label trials and retrospective analyses of testosterone therapy in men with prostate cancer, who have undergone radical prostatectomy and have undetectable PSA levels after radical prostatectomy, have found very low rates of PSA recurrence. Even in men with high-grade prostatic intraepithelial neoplasia (HGPIN)—a group at high risk of developing prostate cancer—testosterone therapy for 1 year did not increase PSA or rates of prostate cancer.

A majority of men diagnosed with prostate cancer today have localized disease that can be potentially cured by radical prostatectomy. The men with organ-confined prostate cancer (pT2, N0, M0) and Gleason score <6 are at a very low risk of disease recurrence after radical prostatectomy with 0.5% biochemical recurrence rate and 0.2% local recurrence rate at >10–15 years. Similarly, preoperative PSA <10 ng/mL is associated with lower risk of disease recurrence than PSA >10 ng/mL. After radical prostatectomy, in the absence of residual cancer, PSA becomes undetectable within a month. An undetectable PSA after radical prostatectomy is a good indicator of biochemical recurrence-free survival at 5 years. Therefore, men with organ-confined prostate cancer (pT2), Gleason score <6, and a preoperative PSA of <10 ng/mL, who have had undetectable PSA levels (<0.1 ng/mL) for >2 years after radical prostatectomy, have very low risk of disease recurrence (<0.5% at 10 years) and may be considered for testosterone therapy on an individualized basis. If testosterone therapy is instituted, it should be associated with careful monitoring of PSA levels and close consultation with a urologist.

MEDICAL COMPLICATIONS OF ADT

In patients with prostate cancer and distant metastases, ADT improves survival. In patients with locally advanced disease, ADT in combination with external beam radiation or as an adjuvant therapy (post-prostatectomy and pelvic lymphadenectomy) also has been shown to improve survival. However, ADT is being increasingly used as primary therapy in men with localized disease and in men encountering biochemical recurrence without clear evidence of survival advantage. The overall use of ADT in men with prostate cancer has increased in the past two decades, and its use in men with localized disease and biochemical recurrence accounts for a substantial fraction of this increase. Since most men with prostate cancer die of conditions other than their primary malignancy, recognition and management of these adverse effects is paramount.

Profound hypogonadism resulting from ADT is associated with sexual dysfunction, vasomotor symptoms, gynecomastia, decreased muscle mass and strength, frailty, increased fat mass, anemia, fatigue, bone loss, loss of body hair, depressive symptoms, and reduced quality of life. Diabetes and cardiovascular disease have recently been added to the list of these complications **(Fig. 399-4)**. Treatment with GnRH agonists in men with prostate cancer is associated with rapid induction of insulin resistance, hyperinsulinemia, and a significant increase in the risk of incident diabetes. Metabolic syndrome is prevalent in >50% of men undergoing long-term ADT when compared to age-matched men with prostate cancer not undergoing ADT (22%) and their age-matched eugonadal counterparts (20%). Some but not all studies have reported an increased risk of cardiovascular events, death due to cardiovascular events, and peripheral vascular disease in men undergoing ADT. Some reports suggest that men receiving ADT are at an increased risk of thromboembolic events and cognitive dysfunction. The rates of acute kidney injury are higher in men currently receiving ADT than in men not receiving ADT; the increased risk appears to be particularly associated with the use of combined regimens of a GnRH agonist plus an antiandrogen. ADT also is associated with substantially increased risk of osteoporosis and bone fractures.

APPROACH TO THE PATIENT

Men Receiving ADT

The benefits of ADT in treating nonmetastatic prostate cancer should be carefully weighed against the risks of ADT-induced adverse events **(Table 399-5)**. If ADT is medically indicated, consider whether intermittent ADT is a feasible option. Men being considered for ADT should undergo assessment of cardiovascular, diabetes, and fracture risk; this assessment may include measurement of blood glucose, plasma lipids, and bone mineral density by dual energy x-ray absorptiometry. Institute measures to prevent bone loss, including physical activity, adequate calcium and vitamin D intake, and pharmacologic therapy in men with a previous minimal trauma fracture and those with 10-year risk of a major osteoporotic fracture >20%, unless contraindicated. Bisphosphonates and denosumab have been shown to reduce fracture risk in men undergoing ADT, and zoledronic acid and denosumab have been approved by the U.S. Food and Drug Administration for the prevention of metastasis-related skeletal-related events in this population. Men with prostate cancer who are receiving ADT should be monitored for weight gain and diabetes. Encourage lifestyle interventions, including physical activity and exercise, and attention to weight, blood pressure, lipid profile, blood glucose, and smoking cessation to reduce the risk of cardiometabolic complications. In randomized trials, medroxyprogesterone, cyproterone acetate, and the serotonin reuptake inhibitor venlafaxine have been shown to be more efficacious than placebo in alleviating hot flushes. The side effects of these medications—increased appetite and weight gain with medroxyprogesterone, gynecomastia with estrogenic compounds, and dry mouth with venlafaxine—should be weighed against their relative efficacy. Acupuncture, soy products, vitamin E, herbal medicines, and transdermal estradiol have been used empirically for the treatment of vasomotor symptoms without clear evidence of efficacy. Gynecomastia can be prevented by the use of an antiestrogen, an aromatase inhibitor, or local radiation therapy; these therapies are effective in alleviating pain and tenderness but are less effective in reducing established gynecomastia. For long-standing gynecomastia that persists after cessation of ADT and is bothersome, mammoplasty is an effective treatment option.

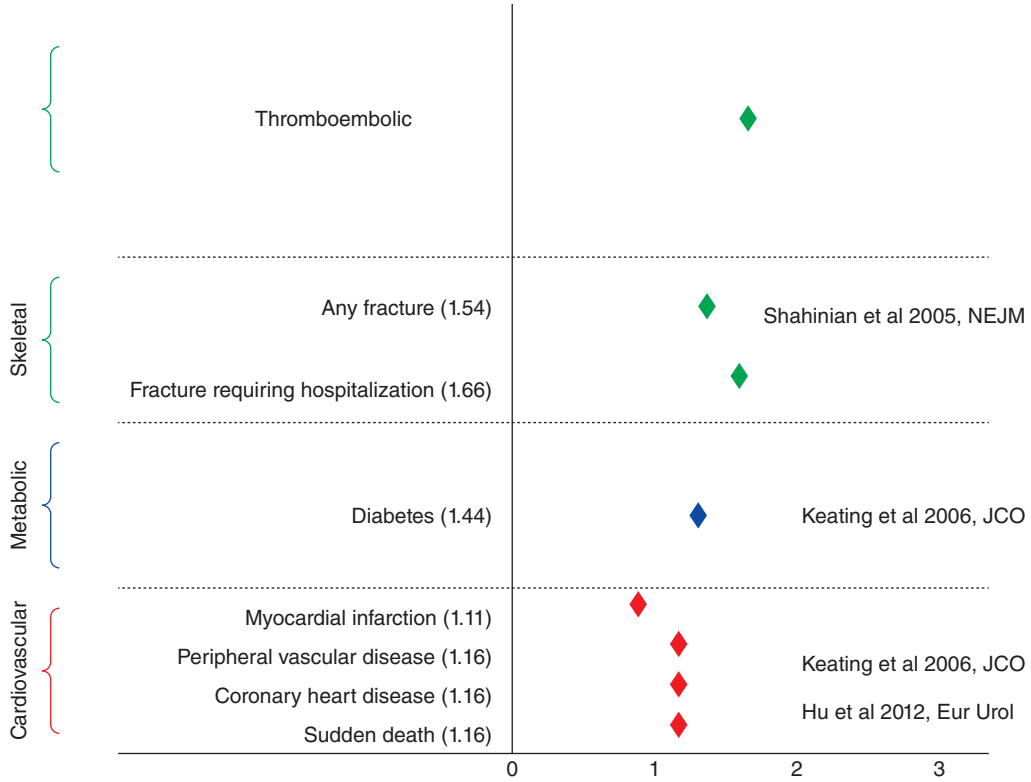

FIGURE 399-4 Adverse cardiometabolic and skeletal effects of androgen deprivation therapy (ADT) in men receiving ADT for prostate cancer. Administration of ADT has been associated with increased risk of thromboembolic events, fractures, and diabetes. Some, but not all, studies have reported increased risk of cardiovascular events in men receiving ADT. *(Data from VB Shahinian et al: N Engl J Med 352:154, 2005; NL Keating et al: J Clin Oncol 24:4448, 2006; JC Hu et al: Eur Urol 61:1119, 2012.)*

PREVENTION OF SEXUALLY TRANSMITTED DISEASES

Adolescent boys and young men aged 15–24 years; men who have sex with men, have multiple sex partners, have unprotected sex without condom, or have sex with sex workers; men who use illicit drugs; men who have a history of previous sexually transmitted infection (STI); and transgender men are at increased risk for STIs. STIs increase the risk of oropharyngeal and anogenital cancers, liver disease, pelvic pain, infertility, inadvertent transmission of infection to others, and emergency department visits and are a preventable cause of excess morbidity and mortality. HIV, hepatitis B and C infections, and syphilis can have additional disease-specific complications. The prevention and treatment of STIs are discussed in **Chap. 136**. Additionally, the Centers for Disease Control and Prevention (CDC) and U.S. Preventive Services Task Force (USPSTF) have published guidelines on the prevention, treatment, and pre- and postexposure prophylaxis of STIs. The approach to the prevention of STIs includes a structured risk assessment; counseling about safe sex practices including condom use; immunization of individuals at risk; diagnosis and treatment of infected individuals whether or not they are symptomatic; detection and treatment of sexual partners; and targeted sex education of adolescents and young men who are at high risk for STIs. The USPSTF recommends screening for HIV in all men aged 15–65 years, regardless of risk, and for hepatitis B virus and syphilis in men at increased risk. Because more than half of STIs occur in persons aged 15–24 years, the USPSTF also recommends behavioral counseling for all sexually active adolescents and adult men at increased risk of STIs to encourage condom use and other protective behaviors, including consideration of abstinence, reducing the number of sex partners, and avoidance of unsafe sex practices. Consistent and correct condom use is the most important method of preventing STIs. Effective immunizations are available against hepatitis B, human papillomavirus (HPV), and *Neisseria meningitides*. The CDC's Advisory Committee on Immunization Practices (ACIP) recommends universal hepatitis B immunization for all unvaccinated adults presenting to an STI clinic, all HIV-infected adults, and health workers. Although ACIP recommends HPV vaccination in males aged 9–21 years and in men aged 9–26 if they have sex with men or have an immunocompromising condition, recent data suggest that the prevalence of HPV and its complications continue to increase until middle age, and some experts recommend extending the age limit for HPV vaccination. Meningococcal vaccination is indicated for men who have sex with men from an area of outbreak and for all HIV-infected men.

Because men seeking care in men's health clinics often do so for sexual and urogenital problems, these visits offer opportunities for counseling, screening, and treatment of STIs and institution of immunization and other preventive measures for STIs.

TABLE 399-5 Checklist for Men Undergoing Androgen Deprivation Therapy (ADT)

1. Weigh the risks and benefits of ADT and whether intermittent ADT is a feasible and safe option.
2. Perform a baseline assessment including fasting glucose, plasma lipids, blood pressure, bone mineral density, and FRAX score.
3. Optimize calcium and vitamin D intake, encourage structured physical activity and exercise, and consider pharmacologic therapy in men with a previous minimal trauma fracture and those with a 10-year risk of a major osteoporotic fracture >20%, unless contraindicated.
4. Monitor body weight, fasting glucose, plasma lipids, blood pressure, and bone mineral density, and encourage smoking cessation and physical activity.
5. In men who are receiving ADT and who experience bothersome hot flushes, as indicated by sleep disturbance or interference with work or activities of daily living, consider initial therapy with venlafaxine. If ineffective, add medroxyprogesterone acetate.
6. In men who experience painful breast enlargement, consider therapy with an estrogen receptor antagonist, such as tamoxifen.

SEX DIFFERENCES IN COVID-19 DISEASE OUTCOMES

The COVID-19 pandemic has highlighted sex differences in the susceptibility to respiratory viral infections. Men infected with SARS-CoV-2

virus are more likely to have a more severe disease, require mechanical ventilation, have disease complications, and die of the disease than women. Somewhat similar sex differences in morbidity and mortality have been reported for influenza infection. In the United States, the incidence and rates of hospitalization for influenza are higher in men than in women across all age groups. However, the sex-specific mortality rates associated with influenza vary substantially across countries and age groups. The sex differences in susceptibility to SARS-CoV-2 infection and morbidity have been attributed to behavioral factors, such as higher rates of smoking and alcohol use in men; biologic factors, such as higher rates of comorbid conditions in men than in women; sex differences in immune responses, including a poor T lymphocyte response to SARS-CoV-2 infection; and lower expression levels in men of X-linked genes that are involved in the innate detection of RNA viruses and that escape X inactivation in women, resulting in higher expression levels in women. Additionally, the expression of angiotensin-converting enzyme 2 (ACE2) and the cell surface transmembrane protease serine 2 (TMPRSS2), the two host proteins that facilitate the entry of SARS-CoV-2 into the alveolar cells, is regulated by androgens in subsets of lung epithelial cells, and it is possible that higher testosterone levels in men may contribute to increased susceptibility to the infection.

400 Lesbian, Gay, Bisexual, and Transgender (LGBT) Health

Baligh R. Yehia, Zachary B. R. McClain

UNDERSTANDING LGBT HEALTH DISPARITIES

The acceptance of the lesbian, gay, bisexual, and transgender (LGBT) community has greatly increased over the past decade in certain communities and parts of the world. However, numerous studies highlight health disparities involving the care of LGBT people. Lesbian and bisexual women are less likely to receive recommended preventive screenings such as breast, cervical, and colorectal cancer screenings. Among men who have sex with men, rates of human papillomavirus–associated anal cancers are 17 times higher than those of heterosexual men. In addition, gay and bisexual men accounted for 70% of all new HIV diagnoses in the United States in 2018, and they disproportionately contract sexually transmitted infections. In 2018, men who have sex with men accounted for 64% of primary and secondary syphilis infections in the United States where the sex of the sexual partner was known. Transgender individuals have a higher prevalence of HIV infection and suicide compared with other groups.

Research has found that LGBT individuals are more likely to experience depression, anxiety, and alcohol and drug use than their counterparts. Most concerning are the rates of suicide attempts and ideation among the LGBT community, particularly youth. Lesbian, gay, and bisexual (LGB) youth are four times more likely to attempt suicide than their heterosexual peers, and 61% of gender variant youth reported suicidal ideation at some point in their life. Additionally, the recent U.S. Transgender Survey found that 40% of transgender young adults and adults reported attempting suicide at some point in their lives.

In addition, U.S. studies indicate that substance abuse is twice as common in LGBT youth compared with their counterparts. These findings are mirrored among LGBT adults: the prevalence of substance abuse disorders is 20–30% compared with ~9% in the general population.

These health issues are compounded by structural barriers to health care, including decreased access to medical care, lack of awareness to the unique health needs of LGBT individuals, and stigma and discrimination toward the LGBT community. Many LGB individuals perceive the health care setting and providers as threatening, which may lead to avoiding needed medical care or withholding important medical information. A large U.S. survey identified that 8% of LGB and 27% of transgender individuals were refused needed health care, and almost 11% of LGB and 21% of transgender people reported being subjected to harsh or abusive language by health care professionals. Apart from health care settings, more than two-thirds of LGB people report discrimination in their personal lives, and 90% of transgender individuals report harassment, mistreatment, or discrimination at work. Chronic exposure to high levels of stress from real or anticipated discrimination, referred to as "minority stress," may be an important factor contributing to the poor health outcomes experienced by LGBT populations.

While some research on LGBT health has been conducted, there remains a great opportunity to better understand the needs and experiences of LGBT individuals. Moreover, many LGBT individuals experience health disparities across their life cycle (e.g., LGBT youth

are at greater risk of suicide and homelessness, whereas elderly LGBT individuals face barriers to health because of isolation and fewer family supports), necessitating a longitudinal approach to examining LGBT health issues. There are more limited data on the health of LGBT individuals outside the United States and Europe. However, studies demonstrate that problems are greatest when people cannot be open about their sexual orientation and gender identity. Encouraging greater LGBT acceptance and access to health care will be critical to improving outcomes and experiences for LGBT communities.

CREATING POSITIVE HEALTH EXPERIENCES FOR LGBT PATIENTS

Understanding Gender Identity and Sexual Orientation

Addressing health disparities and creating positive health care experiences require an understanding of the diversity of cultural expression and lives of LGBT persons. First, providers must be able to distinguish *gender identity* from *sexual orientation*. Gender identity is a person's internal sense of their gender. It should not be confused with sex assigned at birth, which is based on anatomy and biology. Gender identity expands beyond the binary male and female and includes persons who think of their gender as containing elements of both or neither. Many individuals who do not identify with the gender that correlates with their sex assigned at birth often use the terms *transgender* or *trans-male* or *trans-female* to identify themselves. Sexual orientation refers to how one thinks of their physical or emotional attraction to others. Sexual orientation has three dimensions: attraction, behavior, and identity. *Attraction* refers to one's desire to be with someone, regardless of one's behavior or stated identity. For example, a woman may be attracted to another woman, but this attraction may never be acted upon and may not form part of her sexual identity. *Behavior* refers to a person's sexual and romantic partners. Although sexual identity often aligns with behavior, some individuals who identify as heterosexual may have same-gender partners and some individuals who identify as lesbian or gay may have different-gender partners. Lastly, *identity* refers to how a person defines their own sexuality. Common terms for sexual identity include *gay*, *lesbian*, *bisexual*, *straight*, *heterosexual*, *homosexual*, and *asexual* (Table 400-1). As individuals go through the process of understanding their sexuality and self-identity over time, they may change how they define their sexual identity.

TABLE 400-1 Common LGBT Terminology and Definitions

TERM	DEFINITION
Agender	Identifying as having no gender.
Asexual	Experiencing little or no sexual attraction to others.
Assigned sex at birth	The sex (male or female) assigned to a child at birth, most often based on the child's external anatomy. Also referred to as birth sex, natal sex, biological sex, or sex.
Bisexual	A sexual orientation that describes a person who is emotionally and sexually attracted to people of their own gender and people of other genders.
Cisgender	A person whose gender identity and assigned sex at birth correspond (i.e., a person who is not transgender).
Gay	A sexual orientation that describes a person who is emotionally and sexually attracted to people of their own gender. It can be used regardless of gender identity, but it is more commonly used to describe men.
Gender dysphoria	Distress experienced by some individuals whose gender identity does not correspond with their assigned sex at birth. Manifests as clinically significant distress or impairment in social, occupational, or other important areas of functioning.
Gender expression	The way a person acts, dresses, speaks, and behaves (i.e., feminine, masculine, androgynous). Gender expression does not necessarily correspond to assigned sex at birth or gender identity.
Gender identity	A person's internal sense of being a man/male, woman/female, both, neither, or another gender.
Gender nonconforming	Expressing a gender that differs from a given society's norms for males and females.
Heterosexual	A sexual orientation that describes women who are emotionally and sexually attracted to men, and men who are emotionally and sexually attracted to women.
Intersex (disorders of sexual development)	A group of rare conditions where the reproductive organs and genitals do not develop as expected.
Lesbian	A sexual orientation that describes a woman who is emotionally and sexually attracted to other women.
Men who have sex with men (MSM)/women who have sex with women (WSW)	Categories used in research and public health to describe those who engage in same-sex sexual behavior, regardless of their sexual orientation. Individuals rarely use the terms MSM or WSW to describe themselves.
Pangender	Describes a person whose gender identity comprises many genders.
Pansexual	A sexual orientation that describes a person who is emotionally and sexually attracted to people regardless of gender.
Queer	An umbrella term used by some to describe people who think of their sexual orientation or gender identity as outside of societal norms. Some people view the term as more fluid and inclusive than traditional categories for sexual orientation and gender identity. Due to its history as a derogatory term, it is not embraced or used by all members of the LGBT community.
Questioning	Describes an individual who is unsure about or is exploring their own sexual orientation and/or gender identity.
Same-sex attraction	Describes the experience of a person who is emotionally and/or sexually attracted to people of the same gender. Use of this term is not indicative of a person's sexual behavior.
Sexual orientation	Describes how a person characterizes their physical and emotional attraction to others. Sexual orientation is distinct from sex, gender identity, and gender expression.
Trans man/transgender man/female-to-male (FTM)	A transgender person whose gender identity is male may use these terms to describe themselves. Some will just use the term *man*.
Trans woman/transgender woman/male-to-female (MTF)	A transgender person whose gender identity is female may use these terms to describe themselves. Some will just use the term *woman*.
Transgender	Describes a person whose gender identity and assigned sex at birth do not correspond. Also used as an umbrella term to include gender identities outside of male and female.
Transition/affirmation	For transgender persons, the process of coming to recognize, accept, and express one's gender identity. Most often, this refers to the period when a person makes social, legal, and/or medical changes, such as changing their clothing, name, and sex designation, as well as using medical interventions.

Note: It is important to note that definitions vary across communities, that they change over time, and that not all LGBT people agree with all these definitions.

The creation of a welcoming environment requires not making any assumptions about an individual's gender identity or sexual orientation. Both front-line staff and clinicians should be cognizant of patient communication. For example:

- *Instead of saying* "How may I help you, sir?", *say* "How may I help you?"
- *Instead of saying* "She is here for her appointment," *say* "The patient is here in the waiting room."
- *Instead of saying* "Do you have a wife?", *say* "Are you in a relationship?
- *Instead of saying* "What are your mother's and father's names?", *say* "What are your parents' names?"

Developing Comfort and Competency in Sexual Health
Developing comfort discussing sexual health and intimacy is critical to providing appropriate care. After inquiring about healthy relationships and relationship status, a good starting place is to ask if a patient is sexually active and, if so, with whom, how often, and what types of physical interactions and types of sex they have with their partner(s). These discussions can allow clinicians to focus subsequent conversations on issues most relevant to a patient's health. For example, a gay man with multiple sexual partners who engages in receptive anal sex without condoms is at high risk for HIV and sexually transmitted infections (STIs). It will be important to recommend more frequent screenings for STIs and discuss use of preexposure prophylaxis (PrEP) and condoms to prevent HIV and STIs. Additionally, if you are seeing a transgender man, it will be important to know if he still has natal female genitalia to ensure appropriate cancer screening, desire for having biologic children, and contraceptive needs. Notably, many if not most transgender people have not had gender affirmation surgery and retain their natal sex organs.

Creating a Welcoming and Safe Health Care Environment
Hospitals and clinics can take a number of steps to create a welcoming and safe space for LGBT patients. This starts by establishing and communicating a nondiscrimination policy that clearly includes gender identity, gender expression, and sexual orientation protections. Additionally, hospitals and clinics can develop and implement an equal visitation policy to ensure equal visitation for LGBT patients from same-sex partners, parents, and other family and friends. Staff training in LGBT patient-centered care also is a key component of creating inclusive health environments. This includes covering LGBT cultural competency, caring for LGBT patients, creating an inclusive environment for LGBT patients and staff, and other topics important for LGBT health.

As hospitals and clinics continue to adopt electronic health records, collecting sexual orientation and gender identity information becomes increasingly important to delivering personalized care to LGBT individuals. It allows providers to monitor quality of care and track population-based outcomes. This information can be captured by three questions:

- *How do you think of yourself?* As straight or heterosexual; lesbian, gay, or homosexual; bisexual; something else; don't know; choose not to disclose.
- *What is your current gender identity?* Male; female; transgender male/trans man/female-to-male (FTM); transgender female/trans woman/male-to-female (MTF); genderqueer, neither exclusively male nor female; additional category, please specify; choose not to disclose.
- *What sex were you assigned at birth on your original birth certificate?* Male; female; choose not to disclose.

The physical environment of a hospital or clinic is important, but the majority of clinical spaces do not signal that they are safe spaces for LGBT patients. Most health care posters, pamphlets, and materials feature heterosexual individuals or couples; adding LGBT-friendly images and text can help signal that the hospital or clinic is a safe space for sexual and gender minorities. In addition, easily identifying LGBT-competent providers by using websites, buttons, and pins can help patients select providers and feel at ease when attending appointments. Lastly, designating all-gender bathrooms is important to creating welcoming spaces, particularly for transgender and gender-nonconforming individuals.

FUTURE DIRECTION IN LGBT HEALTH

While social and cultural acceptance of the LGBT community has improved in certain parts of the world, many LGBT individuals continue to experience discrimination, stigmatization, and violence. Inequitable health care policies and practices, lack of awareness of LGBT health issues, and limited understanding of the unique health needs of LGBT individuals contribute to decreased access to care and disparities in health outcomes for LGBT individuals. Addressing these barriers will require improved data collection on the LGBT population; understanding of the intersectionality of gender identity, sexual orientation, race/ethnicity, and other sociocultural determinants of health; and outcomes-focused research across the life course. In striving to deliver high-quality care experiences for all patients, hospitals, clinics, and providers need to focus on meeting the needs of the LGBT community.

Section 3 Obesity, Diabetes Mellitus, and Metabolic Syndrome

401 Pathobiology of Obesity

Stephen O'Rahilly, I. Sadaf Farooqi

Adipose tissue evolved as a solution to the challenge of the intermittent availability of food. At times when food is plentiful, excess calories are converted to triglycerides and efficiently stored in the unilocular lipid droplets that occupy most of the volume of fat cells. When needed, the triglyceride is rapidly broken down to free fatty acids and glycerol, which provide an energy source to other sites throughout the body.

However, in environments where food is abundant and when individuals tend to be sedentary, the chronic excess of energy intake over expenditure leads to obesity. The risks of becoming obese under those circumstances and of developing the illnesses associated with obesity vary greatly between individuals, with that variation having a strong genetic basis.

DEFINITION OF OBESITY AND OVERWEIGHT

Obesity is defined as a state of excess adipose tissue mass that adversely affects health. The direct measurement of fat mass is not something that is readily undertaken in routine clinical practice, so a proxy measure, the body mass index (BMI), is generally used. This is calculated as weight/height^2 (in kg/m^2) **(Fig. 401-1)**. BMI-based definitions of obesity and overweight have been established based on associations with certain morbidities and excess mortality. These definitions have been based largely on studies of predominantly white, Western populations, and there is growing evidence that the relationship between BMI and adverse outcomes may be different in people from other ethnic groups, usually in the direction of worse health outcomes being seen at lower levels of BMI. The World Health Organization (WHO) defines a BMI of 30 kg/m^2 as the cutoff point for obesity, while individuals with values between 25 and 30 kg/m^2 are classified as overweight. For individuals with a very muscular body habitus, the BMI may overestimate the amount of body fat. For any given BMI, women will generally have a higher percentage of body fat than men.

The extent to which different adipose depots expand in response to chronic overnutrition varies markedly between people. In general, females store more fat in subcutaneous tissues, especially on buttocks, thighs, and upper arms, whereas men are more prone to store fat in intraabdominal and truncal subcutaneous sites. A simple measure of fat distribution is provided by a measurement of the waist-to-hip ratio. Independent of how obese a person is, a waist-to-hip ratio >0.9 in women and >1.0 in men is associated with adverse health outcomes such as type 2 diabetes and dyslipidemia.

EPIDEMIOLOGY

The annual National Health and Nutrition Examination Survey (NHANES) provides an ongoing record of the prevalence of obesity in the United States. In 2017–2018, 42.4% of U.S. adults aged ≥20 years old were obese with no significant differences in prevalence by age group. Non-Hispanic black people had the highest prevalence of obesity at 49.6%, followed by Hispanic (44.8%), non-Hispanic white (42.2%), and non-Hispanic Asian (17.4%) people. In the United States, Asians represent a highly heterogeneous group encompassing both East and South Asia as well as a substantial Filipino community. The risks of obesity and its complications may differ greatly between people from different parts of Asia; in general, the prevalence of obesity is somewhat higher in women than in men, with black women having the highest prevalence at 56.9%. There has been a marked increase in the prevalence of obesity over time. For example, between 1976 and 1980, the NHANES survey reported a prevalence of 14.5%, indicating a near threefold increase over the past 40 years.

This trend is seen globally. According to the WHO, obesity has nearly tripled worldwide since 1975. In 2016, >1.9 billion adults aged ≥18 years old were overweight. Of these, >650 million were obese; 39% of adults aged ≥18 years old were overweight in 2016, and 13% were obese. Most of the world's population lives in countries where overweight and obesity kills more people than underweight.

During this time, one of the most striking changes has been in the prevalence of obesity in children. In children, the relationship between BMI and body fat varies considerably with age and with pubertal maturation; however, when adjusted for age and sex, BMI is a reasonable proxy for fat mass. Using age- and sex-specific BMI cutoffs (overweight ≥91st percentile; obesity ≥99th percentile), in 2019, the WHO estimated that 38 million children under the age of 5 were overweight or obese, and in 2016, they reported that 340 million children and adolescents aged 5–19 were overweight or obese.

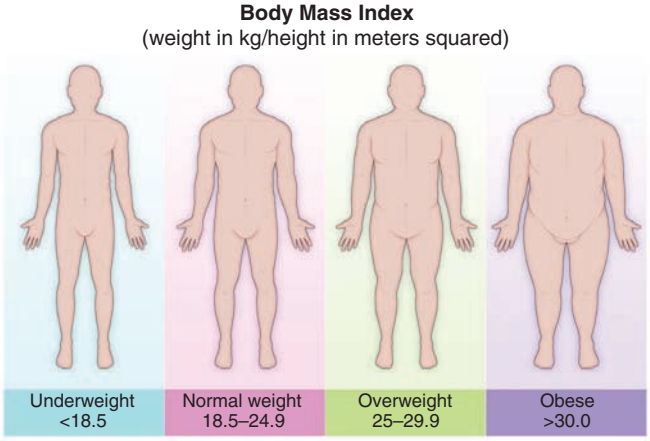

FIGURE 401-1 Definitions of overweight and obesity. The World Health Organization defines obesity based on body mass index (BMI), which is calculated as weight in kilograms divided by the height in meters squared.

PHYSIOLOGIC REGULATION OF ENERGY BALANCE

Discussions about obesity so frequently focus on the issues of personal choice or the obesogenic environment that it can be easy to forget that the amount of stored energy in our bodies is subject to homeostatic control by fundamental physiologic processes essential to our survival. In the 1940s, it was demonstrated that rodents defend their level of body fat; once returned to ad libitum diets after a short period of enforced caloric restriction or excess, animals either overconsumed or underconsumed calories until they returned to their previous status. Since that time, research has progressively dissected the signals that sense nutrient stores and the contents of our diets and how this information is integrated to control hunger, satiety, and the expenditure of energy. The key locus for the integration of these signals is the hypothalamus, an area of the brain at least partially outside the blood-brain barrier that facilitates its ability to receive hormonal signals and combine these with sensory, cognitive, and other neural inputs.

The hypothalamus receives two broad types of hormonal signals relevant to energy balance **(Fig. 401-2)**. The circulating concentration of leptin, a peptide hormone produced by fat cells, increases as fat stores increase and declines as fat stores are depleted. Importantly, under conditions of caloric restriction, circulating leptin levels fall faster than the disappearance of fat. Humans born without functional leptin or leptin receptors, although normal weight at birth, become severely obese from an early age, largely as a result of an intense insatiable appetite. Clearly, a reduction of leptin below normal level is a powerful stimulus to food intake and largely explains the rebound overeating and weight regain that occurs after a period of starvation or dieting. The hypothalamus also receives hormonal signals that are more immediately related to the amount and type of food that has been ingested. Peripheral hormones such as cholecystokinin (CCK) from the stomach, glucagon-like peptide 1 (GLP-1) and gastric inhibitory polypeptide (GIP) from enteroendocrine cells of the small intestine, and peptide YY (PYY) and oxyntomodulin from the large intestine are secreted in response to eating a meal and/or the presence of nutrients in the intestinal lumen. Their release together with neural signals from the vagus nerve and the enteric nervous system contributes to satiety, often indirectly acting on the hypothalamus via projections from the brainstem. Insulin, produced by the pancreas in response to carbohydrate and protein-rich meals, also has effects on the hypothalamic neurons controlling energy balance.

The propeptide pro-opiomelanocortin (POMC) is expressed in a highly restricted population of hypothalamic neurons that project widely throughout the brain **(Fig. 401-3)**. These neurons are responsive to the endocrine signals described above and are critical to the regulation of energy balance. The POMC-derived peptides α- and β-melanocyte-stimulating hormone (MSH) act on the melanocortin 4 receptor (MC4R) to regulate both food intake and aspects of energy expenditure that are influenced by the sympathetic nervous system.

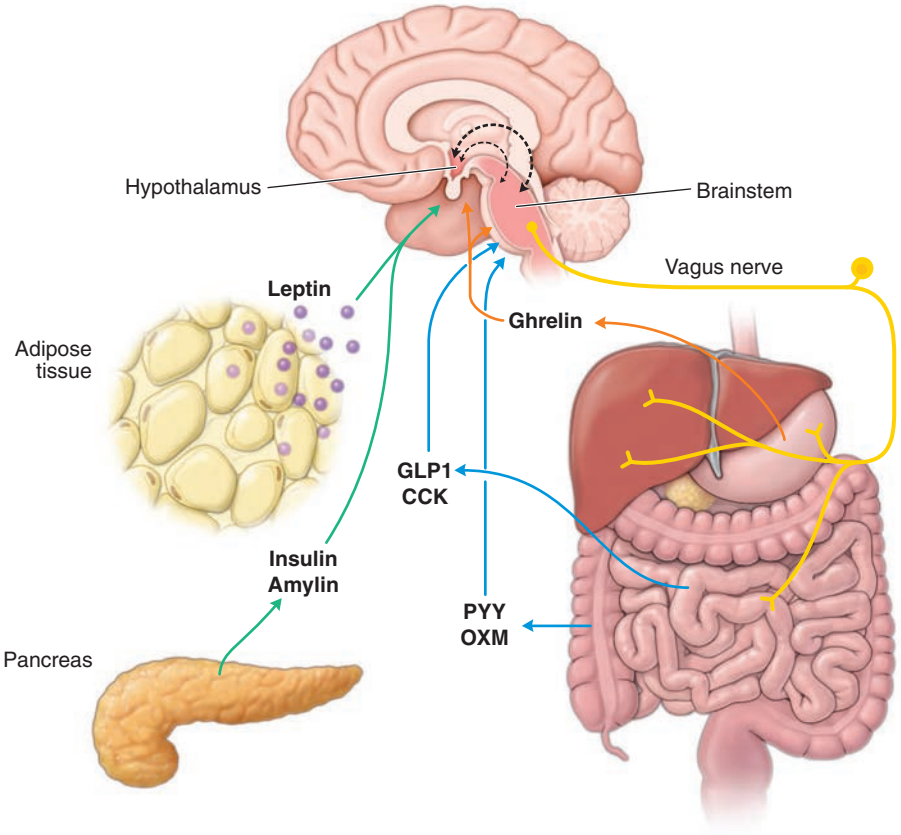

FIGURE 401-2 The homeostatic regulation of body weight. In most people, body weight remains stable over long periods of time despite fluctuations in the amount of food we eat and the amount of activity we undertake. This homeostatic regulation of body weight is controlled by the neurons in the hypothalamus, which receive hormonal signals from adipose tissue such as leptin and neural and hormonal signals from the gut in response to meals. Glucagon-like peptide 1 (GLP1) and cholecystokinin (CCK) from enteroendocrine cells of the small intestine and peptide YY (PYY) and oxyntomodulin (OXM) from the large intestine are secreted in response to eating a meal and/or the presence of nutrients in the intestinal lumen. Their release, together with neural signals from the vagus nerve and the enteric nervous system, contributes to satiety, acting on the hypothalamus via projections from the brainstem. Insulin, produced by the pancreas in response to carbohydrate- and protein-rich meals and potentiated by the action of some of the gut hormones, also has effects on the hypothalamic neurons controlling energy balance. The release of the hormone ghrelin from the stomach increases in the unfed state and induces appetite by acting on hypothalamic neurons as well as on receptors in the brainstem.

γ-MSH, acting mostly through the MC3 receptor, appears to play more of a role in controlling linear growth and the disposition of nutrients into lean versus fat tissues. Signaling through both these melanocortin receptors is also subject to negative control by a different population of neurons, which make and release agouti-related peptide (AGRP), neuropeptide Y (NPY), and the inhibitory neurotransmitter γ-aminobutyric acid (GABA). AGRP actively switches off melanocortin receptors. Leptin, which suppress food intake, simultaneously stimulates POMC neurons and inhibits NPY/AGRP neurons. Human energy balance is highly sensitive to signaling through this system as people who have a genetic defect in just one of the two copies of the *MC4R* gene are very prone to overeat (hyperphagia) and to gain weight.

THE PHYSIOLOGY OF NUTRIENT STORAGE IN ADIPOSE TISSUE

When energy intake exceeds energy expenditure, a small amount of that excess energy is stored as glycogen in liver and skeletal muscle. But if the imbalance is greater, then our bodies are designed to store that excess energy in a more efficient way as triacylglycerol (triglyceride). This fat is more efficient because, unlike glycogen, it does not need accompanying water, and when metabolized, it generates almost three times more energy per gram than does carbohydrate. Adipocytes (fat cells) have evolved to contain a highly specialized organelle, the unilocular fat droplet, which holds the triglyceride within a single-layer of phospholipid that contains all the components needed for enzymes that make and breakdown triglycerides in a manner that is rapidly responsive to metabolic requirements. No other type of cell is specifically designed to store fat safely in this manner, and many of the adverse consequences of obesity are likely caused not by having too much fat in adipocytes but by "nonprofessional" cells being forced to take up and store fat. Some new fat cells can be made in adulthood when ~10% of our fat cell population turns over every year.

THE CAUSES OF OBESITY: AN INTERACTION OF GENES AND ENVIRONMENT

For a person to become obese, energy intake must exceed energy expenditure in a manner that is sufficiently sustained to result in the accumulation of a large excess of triglyceride in adipose tissue. As obesity is a cumulative pathology, if energy intake exceeds energy expenditure by even a small amount (as little as 7 kcal/d), this is sufficient to develop obesity over a matter of years or decades. Even where obesity is common, there are many people who are not overweight. Economic and social factors are likely to play a role as there are more normal-weight people in wealthier and more socially advantaged groups, at least in Western societies. It is also true, however, that because of discrimination, obese people may become socially and economically disadvantaged, which complicates interpretation of that data. We can, however, state with considerable certainty that genetic factors play a major role in predisposing people to a range of adiposity. We know this from a large number of studies comparing identical and nonidentical twins. It is particularly tellingly that the degree of adiposity in adult life of identical twins brought up in different families is very similar between the twins but is not at all correlated with that of the adoptive siblings with whom they were raised.

THE RELATIVE ROLES OF EXCESS INTAKE AND LOWER ENERGY EXPENDITURE IN CONFERRING BIOLOGIC PREDISPOSITION

Do these heritable factors influence energy intake, energy expenditure, or both? It is clear that by the time a person is obese the amount of energy they expend in the resting state is more, not less, than a nonobese person. However, if an obese person loses weight by dieting, there is some evidence that they tend to be more "energy efficient" than a person who has never been obese, particularly in terms of how many calories they burn during a defined bout of muscular activity. However, the effects are subtle. It seems very likely that there are some individuals who are predominantly predisposed to develop obesity by virtue of a lower metabolic rate, but thus far, apart from severe hypothyroidism, concrete examples are scarce. In contrast, a much more consistent and compelling body of evidence supports the idea that the genetic predisposition to obesity is largely mediated through the brain's control of food intake. When studied in controlled settings, individuals who carry genetic variants that predispose to obesity tend to eat more and be less readily satiated. This is very readily demonstrable when the mutation has a major effect on obesity predisposition, but similar data are now emerging in the case of common genetic variants with smaller effects.

ENVIRONMENTAL FACTORS PREDISPOSING TO OBESITY

Obesity cannot exist in the absence of sufficient food to lay down and maintain excess fat stores. That fact not infrequently leads to the belief

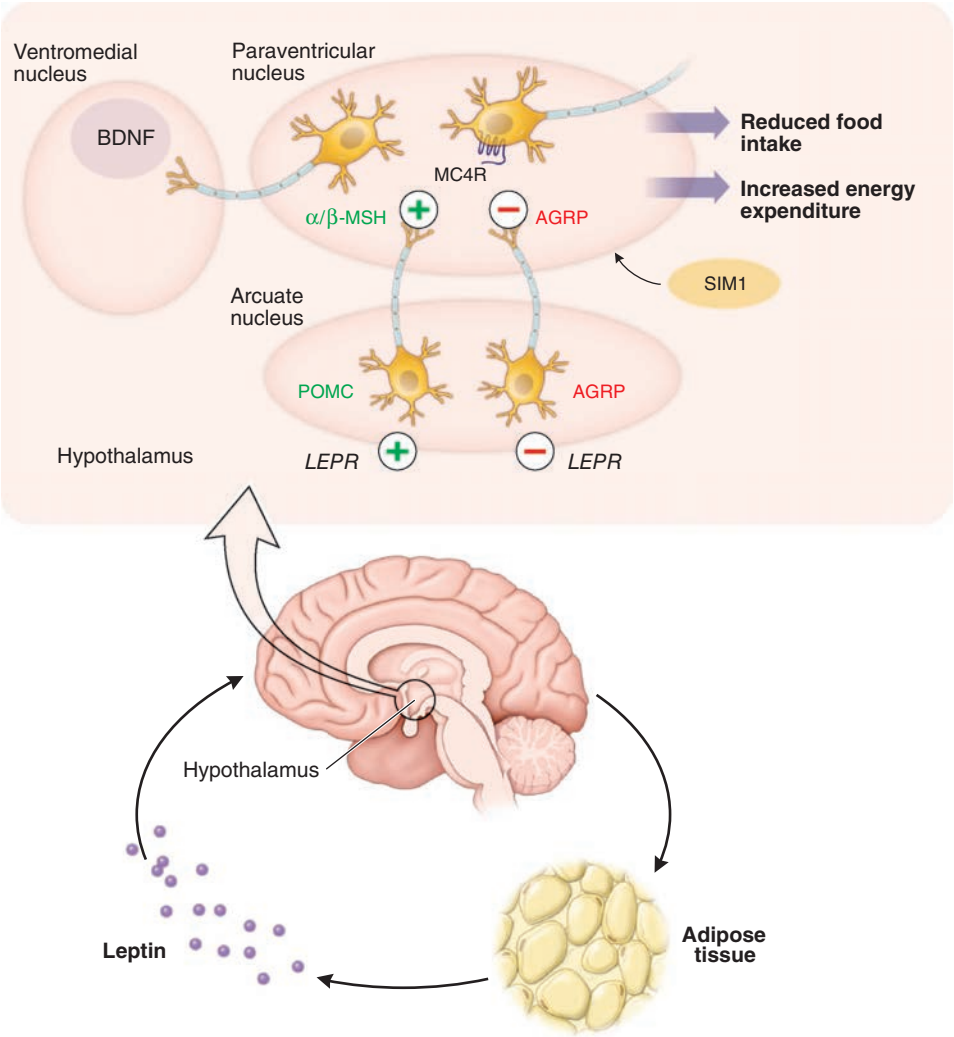

FIGURE 401-3 Hypothalamic pathways regulating body weight. Neurons in the hypothalamus regulate energy intake and expenditure in response to leptin and other hormones. In the fed state, leptin stimulates primary neurons in the arcuate nucleus of the hypothalamus that express pro-opiomelanocortin (POMC). The POMC-derived peptides α- and β-melanocyte-stimulating hormone (MSH) act on the melanocortin 4 receptor (MC4R) expressed on neurons in the paraventricular nucleus to reduce energy intake and increase energy expenditure. At the same time, leptin inhibits neurons expressing agouti-related peptide (AGRP), which switches off melanocortin receptors. When these and other key molecules, such as brain-derived neurotrophic factor (BDNF) and single minded-1 (SIM1), are disrupted by inherited mutations, affected individuals have hyperphagia and severe obesity.

that the principal cause of obesity must be either the obese person's ignorance of the role of excess caloric intake or their conscious choice to prioritize the immediate pleasures of eating over the long-term health harms associated with obesity. Taken to extremes, these views can engender serious social, economic, and medical discrimination against obese people. It is clear that genetic factors, however important they are in an individual's predisposition to obesity, cannot explain the marked increase in obesity prevalence that has occurred in the past few decades. We have to look to an environment that has become increasingly obesogenic to explain that phenomenon. In most developed and developing countries, energy-dense and highly palatable food and beverages have been aggressively marketed, made cheaper than ever before, provided in larger portions, and made available ubiquitously and continuously. This has been combined with the reduction in physical activity in work and domestic life due to mechanization and the change in the nature of employment. Even the control of our external temperature by artificial heating and cooling has meant less energy expended on thermoregulation. Taken together, these are likely to be the major factors driving the recent increase in obesity. It is important to remember, however, that a substantial proportion of the populace remains normal weight under these circumstances and a large part of that is attributable to their genetic good fortune.

There is much current investigation into other environmental factors that might influence the development of obesity. Heated debates continue about the optimal balance of macronutrients in the diet to maintain normal weight and good health. Much of this revolves around the potential benefits of reducing the relative proportion of carbohydrates in the diet (Chap. 402). There seems to be reasonable consensus that, in the short term, diets that are rich in protein and fat and lower in carbohydrates more readily result in quick weight loss. This may be because the appetite-suppressing gut hormones discussed above increase more in response to protein than to carbohydrate, thus inducing earlier satiation. However, longer-term studies to date are less compelling, and the long-term increases in protein and fat intake are not without at least theoretical risks. A growing body of evidence suggests that exposures early in life, either in utero or in early postnatal life, might "program" individuals to develop obesity and/or cardiometabolic disease through effects that are often attributed to "epigenetics" (Chap. 483). This is an attractive idea, and if true, it would mean that time-limited and affordable interventions early in life might have lifelong benefits. Inevitably, it will take time to see if the promise of such interventions will be fulfilled. Much excitement has been generated by the increasing recognition of the diversity of our intestinal microbiome, which clearly has relevance to gastrointestinal health (Chap. 471). At present, it is premature to ascribe any significant role to the human microbiome in obesity or its adverse consequences.

WHY DOESN'T LEPTIN PREVENT OBESITY?

Leptin is known to suppress food intake, and its levels rise as fat stores expand. So why does this not prevent us from becoming obese? The most plausible explanation lies in the evolutionary history of leptin and the fact that it appears to defend strongly against the loss of body fat stores, with a fall in circulating leptin below a person's habitual level being a powerful stimulus to food intake, whereas the response to rises in leptin above the normal level is less pronounced. At higher levels of leptin, administering extra amounts of the hormone may have no discernible effect at all—a phenomenon that has come to be called leptin resistance. It is important to remember that even though a person appears to be leptin resistant, some leptin action is occurring; otherwise, the person would become as insatiably hungry and progressively obese as someone with congenital leptin deficiency (see below). It also seems likely that a subgroup of people may have relatively low leptin levels, which plays a role in the etiology of their obesity. There are likely other hormonal signals produced in severe obesity that, unlike leptin, continue to exert a suppressive effect on food intake and help to ensure that the expansion of adipose tissue does not become indefinitely cumulative.

SINGLE-GENE DISORDERS LEADING TO OBESITY

The assessment of severely obese children and, indeed, adults should be directed at screening for potentially treatable endocrine and neurologic conditions and identifying genetic conditions so that appropriate

TABLE 401-1 Classical Genetic Obesity Syndromes

SYNDROME	INHERITANCE	ADDITIONAL CLINICAL FEATURES
Prader-Willi	Autosomal dominant	Hypotonia, failure to thrive in infancy, developmental delay, short stature, hypogonadotropic hypogonadism, sleep disturbance, obsessive behavior
Albright's hereditary osteodystrophy	Autosomal dominant	Short stature in some, skeletal defects, developmental delay, shortened metacarpals; hormone resistance when mutation on maternally inherited allele
Bardet-Biedl	Autosomal recessive	Syndactyly/brachydactyly/polydactyly, developmental delay, retinal dystrophy or pigmentary retinopathy, hypogonadism, renal abnormalities
Cohen's	Autosomal recessive	Facial dysmorphism, microcephaly, hypotonia, developmental delay, retinopathy
Carpenter's	Autosomal recessive	Acrocephaly, brachydactyly, developmental delay, congenital heart defects; growth retardation, hypogonadism
Alström's	Autosomal recessive	Progressive cone-rod dystrophy, sensorineural hearing loss, hyperinsulinemia, early type 2 diabetes mellitus, dilated cardiomyopathy, pulmonary, hepatic and renal fibrosis
Tubby	Autosomal recessive	Progressive cone-rod dystrophy, hearing loss

TABLE 401-2 Obesity Syndromes due to Mutations in Genes Controlling Energy Homeostasis Pathways

GENE AFFECTED	INHERITANCE	ADDITIONAL CLINICAL FEATURES
Leptin	Autosomal recessive	Severe hyperphagia, frequent infections, hypogonadotropic hypogonadism, mild hypothyroidism
Leptin receptor	Autosomal recessive	Severe hyperphagia, frequent infections, hypogonadotropic hypogonadism, mild hypothyroidism
Proopiomelanocortin	Autosomal recessive	Hyperphagia, cholestatic jaundice or adrenal crisis due to ACTH deficiency, pale skin and red hair
Prohormone convertase 1	Autosomal recessive	Small-bowel enteropathy, postprandial hypoglycemia, hypothyroidism, ACTH deficiency, hypogonadism, central diabetes insipidus
Carboxypeptidase E	Autosomal recessive	
Melanocortin 4 receptor	Autosomal dominant	Hyperphagia, accelerated linear growth
Single-minded 1	Autosomal dominant	Hyperphagia, accelerated linear growth, speech and language delay, autistic traits
BDNF	Autosomal dominant	Hyperphagia, developmental delay, hyperactivity, behavioral problems including aggression
TrkB	Autosomal dominant	Hyperphagia, speech and language delay, variable developmental delay, hyperactivity, behavioral problems including aggression
SH2B1	Autosomal dominant	Hyperphagia, disproportionate hyperinsulinemia, early type 2 diabetes mellitus, behavioral problems including aggression

Abbreviations: ACTH, adrenocorticotropic hormone; BDNF, brain-derived neurotrophic factor; SH2B1, Src-homology-2 (SH2) B-adaptor protein-1 (SH2B1); TrkB, tropomyosin receptor kinase B.

genetic counseling and, in some cases, treatment can be started. Clinically, it remains useful to categorize the genetic obesity syndromes as those with dysmorphism and/or developmental delay and those without these features (Tables 401-1 and 401-2). Although individually these monogenic disorders are rare, cumulatively, up to 20% of children with severe obesity have rare chromosomal abnormalities and/or highly penetrant genetic mutations that drive their obesity. This figure is likely to increase with wider accessibility to genetic testing and as new genes are identified. A genetic diagnosis can inform management (many such patients find it very difficult to lose weight through diet and exercise) and can inform clinical decision-making regarding the use of bariatric surgery (feasible in some; high risk in others) (Chap. 402). There are a number of drugs in clinical trials targeted specifically at patients with genetic obesity syndromes. Specifically, setmelanotide, a MC4R agonist, has been used effectively in phase 2/3 clinical trials in children who are genetically deficient in POMC or the leptin receptor. It is also being explored for the treatment of other genetic obesity syndromes affecting the melanocortin pathway.

CLASSICAL SYNDROMIC DISORDERS

A number of syndromes were identified by clinicians long before their exact genetic cause was known. In these syndromes, obesity is associated with a stereotyped set of other anomalies, often neurodevelopmental in type. The precise genetic basis for the majority of these syndromes is now known. Prader-Willi syndrome (PWS) is the most common syndromic cause of obesity, with an estimated prevalence of ~1 in 25,000. It is an autosomal dominant disorder caused by deletion of an imprinted region on the paternal chromosome 15 (Chap. 466). The characteristic clinical features are hypotonia, feeding difficulties in infancy, developmental delay, hypogonadotropic hypogonadism, hyperphagia (increased food intake), and obesity. Children with PWS are short with reduced lean body mass and increased fat mass, features resembling those seen in growth hormone (GH) deficiency; GH treatment decreases body fat and increases linear growth and muscle mass and is now standard of care in this condition. Low levels of brain expression of the neuropeptide oxytocin and the nerve growth factor Brain-derived neurotrophic factor (BDNF) in PWS patients have suggested new therapeutic opportunities for these patients.

Inherited or de novo (not found in either parent) mutations in another imprinted gene, *GNAS1*, which encodes Gsα protein, cause a syndrome known as Albright's hereditary osteodystrophy (AHO) (Chap. 412). Maternal transmission of *GNAS1* mutations leads to AHO (characterized by short stature, obesity, and skeletal defects) plus resistance to several hormones (e.g., parathyroid hormone), whereas paternal transmission leads only to the AHO phenotype. The clinical spectrum is very broad, and some patients may present with obesity alone.

Bardet-Biedl syndrome is a rare autosomal recessive disease characterized by obesity, developmental delay, polydactyly, retinal dystrophy or pigmentary retinopathy, hypogonadism, and renal abnormalities. The same clinical features can arise from mutations in >20 genes, which disrupt signaling in primary cilia. Overlapping clinical features are seen in a number of other genetic obesity syndromes (Table 401-1).

DISORDERS OF LEPTIN-MELANOCORTIN SIGNALING

Homozygous mutations that disrupt the production or action of leptin are rare but result in a disorder that is treatable. Children with homozygous loss-of-function leptin mutations have rapid weight gain in the first few months of life, resulting in severe obesity due to an intense drive to eat (hyperphagia) and impaired satiety with food-seeking behavior soon after the end of a meal. Congenital leptin deficiency can be treated with subcutaneous injections of recombinant leptin, which reduce hunger, increase satiety, and lead to weight loss. Similar clinical features are seen in patients with homozygous mutations in the leptin receptor gene, but they are not responsive to leptin treatment (Table 401-2). Normal pubertal development rarely occurs in adults with leptin or leptin receptor deficiency, with biochemical evidence of hypogonadotropic hypogonadism. However, there is some evidence

for the delayed but spontaneous onset of menses in a small number of leptin- and leptin receptor–deficient adults. Leptin treatment permits progression of pubertal development, suggesting that leptin is a permissive factor for the development of puberty.

Homozygous or compound heterozygous mutations in POMC lead to hyperphagia and early-onset obesity. As adrenocorticotropic hormone (ACTH) is produced in the pituitary gland by cleavage from POMC, patients also present with isolated ACTH deficiency (neonatal hypoglycemia and cholestatic jaundice). In the skin, POMC-derived melanocortin peptides act on melanocortin 1 receptors to induce pigmentation. For this reason, the lack of POMC-derived peptides in obese patients with POMC deficiency results in hypopigmentation of skin and hair, which is more noticeable in people of Caucasian ancestry who often have red hair. Prohormone convertase 1 (PCSK1) is an enzyme involved in the cleavage of POMC into ACTH, which is then further cleaved to make α-MSH by carboxypeptidase E. Impaired processing of POMC contributes to the hyperphagic severe early-onset obesity and ACTH deficiency in people lacking PCSK1 who also have hypogonadotropic hypogonadism, postprandial hypoglycemia (due to impaired processing of proinsulin to insulin), and a neonatal enteropathy in early childhood. Heterozygous mutations that impair the function of MC4R are found in 5–6% of patients with severe early-onset obesity and at a frequency of ~1 in 300 in the general population, making this the most common gene in which variants contribute to obesity. MC4R mutations are inherited in a co-dominant manner, with variable penetrance and expression in heterozygous carriers; homozygous carriers are severely obese. Patients are often hyperphagic from early childhood and hyperinsulinemic and have increased lean mass and increased linear growth.

GENETIC SUBTYPES OF OBESITY ASSOCIATED WITH NEUROBEHAVIORAL ABNORMALITIES

Both PWS patients and patients with mutations in *SIM1* (a gene that acts downstream of MC4R) exhibit a spectrum of behavioral abnormalities that overlap with autism-like features that could be related to reduced oxytocin signaling (Table 401-2). Mutations affecting BDNF and its receptor tropomyosin receptor kinase B (TrkB) cause speech and language delay, hyperphagia, and severe obesity, as well as hyperactivity, autistic traits, and impaired short-term memory. Interestingly, a common variant in BDNF (V66M), found in heterozygous form in ~20% of the population, is associated with a number of traits and neuropsychiatric disorders including anxiety and depression. Chromosomal deletion and mutations affecting Src-homology-2 (SH2) B-adaptor protein-1 (*SH2B1*) are associated with dominantly inherited, severe, early-onset obesity, disproportionate insulin resistance, early-onset type 2 diabetes, and behavioral problems including aggressive behavior.

OBESITY SECONDARY TO OTHER DISORDERS

Endocrine Disorders Patients with hypothyroidism may gain weight and become obese, although it is rarely the sole cause of severe obesity. It is nonetheless prudent always to measure thyroid function in a patient presenting with obesity. Measurement of thyroid-stimulating hormone (TSH) will detect significant primary disease of the thyroid, but for rare secondary hypothyroidism, additional measurement of free thyroxine levels is needed (Chap. 383). Weight gain can also be a presenting feature of Cushing's syndrome. Clinically, the presence of spontaneous bruising, livid striae, myopathy, and marked centripetal distribution of body fat help to distinguish true endogenous hypercortisolism from common obesity. This condition is usually reasonably straightforward to diagnose based on tests that approximate cortisol production rates (24-h urine free cortisol) or the suppression of serum cortisol by dexamethasone (Chap. 386). Occasionally, in severely obese patients, effects of adiposity on glucocorticoid metabolism can make it difficult to interpret results, and more sophisticated tests, including those measuring diurnal rhythm of cortisol, may be necessary to establish or exclude the diagnosis with confidence. Weight gain can also be a presenting feature of patients with insulinoma, driven largely by the need to eat more frequently than normal to avoid hypoglycemia.

Hypothalamic Damage The hypothalamic regions that control energy balance can be disrupted by tumors (such as craniopharyngiomas), inflammatory masses, or after a severe head injury (Chap. 379). In such cases, there is often some accompanying evidence of disruption of the hormonal functions of the anterior or posterior pituitary, although it may be subtle and the history of hyperphagia and weight gain is often short. It is worth noting that in common obesity, GH levels in response to provocative testing may be somewhat lower than normal, but this does not necessarily suggest the presence of a structural lesion.

ADVERSE CONSEQUENCES OF OBESITY

Mechanistic Considerations Obesity is associated with a wide range of pathologies that can adversely impact morbidity and mortality (Chap. 408). Some of these consequences are related, at least in part, to the direct mechanical or gravitational effects of the expanded fat mass itself (Fig. 401-4). However, the principal mechanisms behind many of the complications of obesity are less likely to be due to the expanded fat mass itself but more closely related to the chronic state of overnutrition itself and its effects on tissues throughout the body.

As people become obese, one of the first and most prominent biochemical abnormalities that develops is the need for increased circulating concentrations of insulin to maintain glucose homeostasis. This state of insulin resistance generally worsens with a greater degree of obesity, but there is a high degree of interindividual variability. It is more prominent when fat is distributed more centrally. Insulin resistance/hyperinsulinemia is likely to play a major role in the predisposition to metabolic endocrine and cardiovascular diseases seen more frequently in obesity and may even play a role in the predisposition of obese people to develop certain cancers.

The main sites of insulin action in the body are the liver and skeletal muscle. Thus, for insulin resistance to be discernible at the level of the whole body, the action of insulin must be disturbed in one or both of these tissues. It seems unlikely that an expanded fat cell mass would do that directly. How then does obesity lead to a state of insulin resistance?

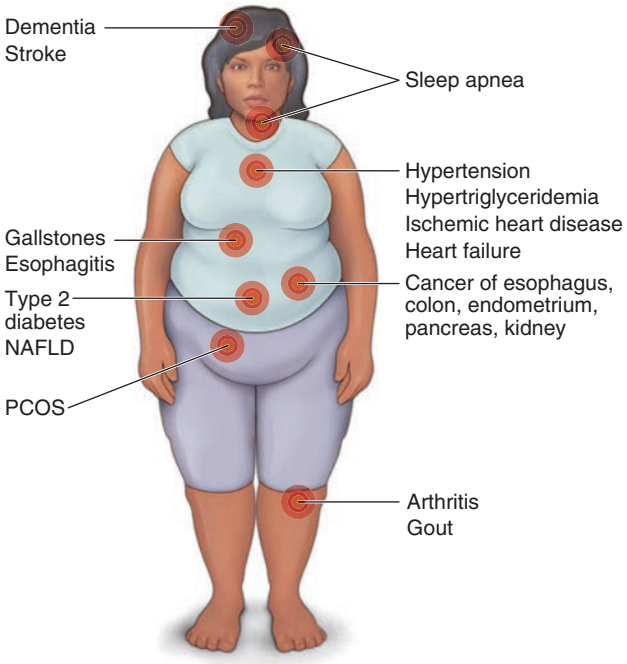

FIGURE 401-4 Obesity-related complications. The expanded fat mass that characterizes obesity predisposes to certain obesity-related complications (e.g., osteoarthritis of knees, reflux esophagitis, and obstructive sleep apnea) directly through its mass and/or volume. However, in the case of the metabolic, endocrine, and cardiovascular complications, the link is less clear. Further research is needed to establish whether some features of the expanded fat mass influence the development of these complications or whether other aspects of the chronically overnourished state, such as excess fat outside the fat depot, are more relevant. NAFLD, nonalcoholic fatty liver disease; PCOS, polycystic ovarian syndrome.

One hypothesis suggests a leading role for the inflammation that occurs in the adipose tissue in obesity (Fig. 401-5). This undoubtedly happens, as there are more macrophages in obese than nonobese adipose tissues, and this is associated with higher levels of inflammatory markers in the circulation of obese people. The majority of macrophages in obese adipose tissue are found in clusters around dead or dying adipocytes, so it appears that these cells are clearing debris after cell death. Studies in animal models provide strong support for the notion that this inflammatory state is mechanistically linked to insulin resistance, but evidence from humans for this is not as strong.

An alternative hypothesis is that as individuals becomes more obese they become less able to safely store nutrients in their adipose tissue and begin to redirect macronutrients to other tissues that are not designed for fat storage and may be damaged by the nutrient excess. This certainly happens to people who are born with a lack of adipose tissue (lipodystrophy) who, early in life, develop severe versions all the metabolic complications that are seen in obesity as they have no safe depot in which to store excess nutrients. There are stronger human data from both genetic and pharmacologic studies for the existence of the latter mechanism. How ectopic fat leads to insulin resistance and other damaging effects is still a puzzle, but it is very likely a major driver of pathology associated with obesity.

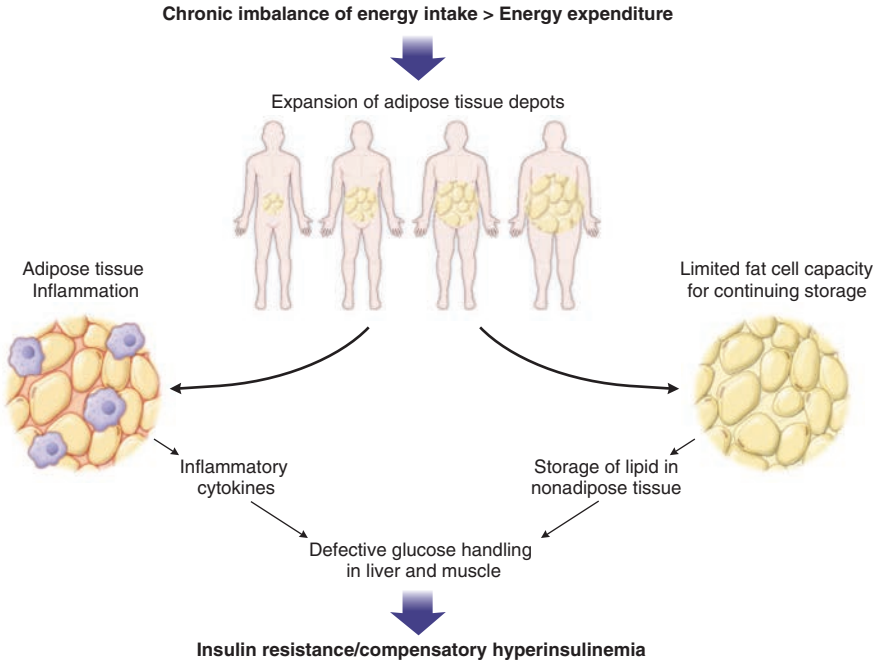

FIGURE 401-5 How does obesity cause metabolic disease? Insulin resistance is one of the earliest complications of obesity and underlies and precedes many of its adverse health consequences. The disposal and production of glucose by the most important tissues, muscle and liver, respectively, become less sensitive to insulin, and this results in a compensatory increase in insulin secretion from the pancreas. There are two main theories for the association of obesity with insulin resistance. In the first, products of macrophages and other inflammatory cells that are more abundant in obese adipose tissue can, through paracrine or endocrine routes, disturb insulin's action in muscle and liver cells. In the second, as adipose storage deposits fill up, they become less able to take on excessive calories, which end up being stored as ectopic lipid in tissues such as muscle and liver, which are not primarily designed to store nutrients of this type. The evidence in humans is stronger for the latter hypothesis.

Metabolic Complications • DYSLIPIDEMIA The insulin resistance of obesity is frequently associated with dyslipidemia characterized by high circulating triglycerides and low high-density lipoprotein cholesterol (Chap. 407). Occasionally, the hypertriglyceridemia may be severe enough to put the patient at risk of pancreatitis. Although there is a relationship between obesity and raised circulating levels of low-density lipoprotein cholesterol (which is the major risk factor for coronary artery disease), genetic factors independent of obesity and the type of dietary fat consumed probably have an even greater impact.

FATTY LIVER DISEASE Obesity is strongly associated with the presence of ectopic fat in hepatocytes. This can progress to nonalcoholic steatohepatitis (NASH), which can progress to the fibrosis, which is a precursor to cirrhosis (Chap. 343). The reported incidence of NASH-related cirrhosis and of hepatocellular carcinoma has increased markedly in step with the increase in the prevalence of obesity in adolescents and adults.

TYPE 2 DIABETES The insulin resistance characteristic of the overnourished state strongly predisposes to the development of type 2 diabetes in people who, largely for genetic reasons, are less able to maintain the high levels of insulin secretion over many decades. Impaired glucose tolerance and type 2 diabetes are among the most common complications of obesity (Chap. 403).

Endocrine Complications In females, the insulin resistance/hyperinsulinemia frequently found in obesity strongly predisposes to the development of polycystic ovaries, characterized by irregular menstruation, anovulatory infertility, and hirsutism due to hyperandrogenism. In males, obesity is more often associated with a degree of central hypogonadism, where low circulating testosterone is associated with levels of luteinizing hormone and follicle-stimulating hormone that do not rise appropriately to compensate for the testosterone-deficient state

Dermatologic Complications Obesity can result in problems with excessive skin folds that can cause discomfort through mechanical irritation and can also become infected with fungi. Insulin resistance/hyperinsulinemia is associated with acanthosis nigricans, where areas such as axilla, groin, and the back of neck develop velvety hyperpigmentation. Hidradenitis suppurativa is a potentially disabling skin condition strongly associated with obesity. It is characterized by recurrent boils often with chronically draining sinus tracts affecting skin areas containing apocrine sweat glands.

Cardiovascular Complications Obese people, even if they do not have diabetes, have increased morbidity and mortality from atherothrombotic vascular disease, including coronary artery disease and stroke. The factors that result in this are complex and involve increased prevalence of hypertension, dyslipidemia, and insulin resistance/hyperinsulinemia. The rare condition of thrombotic thrombocytopenic purpura, which causes microvascular platelet thrombosis, thrombocytopenia, and hemolytic anemia due to the presence of abnormally large von Willebrand factor multimers, is strongly associated with obesity.

Independent of occlusive arterial disease, obese people are also at increased risk of heart failure, particularly characterized primarily by diastolic dysfunction, and of atrial fibrillation, the most common arrhythmia.

Respiratory Complications Exertional dyspnea is common in obesity, contributed to by the increased work required to move a greater mass as well as impacts of pressure on the diaphragm and thoracic cage on chest wall compliance. Enlargement of soft tissue of the mouth and throat and adipose depots around the airways contribute to the high prevalence of sleep apnea, although other factors may contribute to some forms, where central nocturnal hypoventilation also occurs.

Gastrointestinal Disorders Reflux esophagitis is the most common gastrointestinal complication of obesity, particularly occurring in those with high intraabdominal pressure. Gallstones are also more common in obese people, bringing increased risks of biliary colic, cholecystitis, pancreatitis, and gallbladder cancer.

Rheumatologic Disorders Osteoarthritis of the knee and gout are the two most common rheumatologic conditions clearly associated with obesity. Interestingly, despite obesity being described as a proinflammatory state, there is no evidence for an increase in rheumatoid arthritis or the seronegative arthritides among people who are obese.

Cancers Obesity is a risk factor for a number of common cancers. Indeed, it has recently been calculated that, at least in some countries, obesity has overtaken smoking as the greatest risk factor for developing cancer. Recent research has found that as the BMI increases by 5 kg/m^2, cancer mortality increases by 10%. The largest effects are on colorectal, kidney, and pancreatic cancer, adenocarcinoma of the esophagus, and, in women, endometrial carcinoma. The recent rapid increase in the prevalence of esophageal adenocarcinoma is likely related to the marked recent increase in reflux esophagitis due to the raised intraabdominal pressure (with or without hiatus hernia) characteristic of central obesity.

Response to Infection The fact that obesity can influence the outcome of some infections has become very apparent with the COVID-19 pandemic. Obese patients have a substantially worse outcome if infected by SARS-CoV-2 through mechanisms that are as yet unclear. Obese patients also appear to be more susceptible to bacterial wound infections and postoperative sepsis.

Disorders of the Central Nervous System There is increasing evidence that obesity is a risk factor for dementia in later life, although how that risk is mediated is not clear. Idiopathic intracranial hypertension is a rare disorder that is strongly associated with obesity.

CONCLUSION

Obesity is a medical disorder that has been greatly increasing in prevalence due to environmental factors that are ubiquitous in developed and developing countries. However, it is important to bear in mind that it is a highly heterogeneous condition, which in some people is attributable entirely to genetic causes, and that underlying genetic variation strongly influences the risk of obesity in all people. It is a serious condition leading to multiple adverse health outcomes and considerable human suffering. As our understanding of its pathogenesis increases, our duty to treat obese patients with understanding and compassion and to develop new and better options for its treatment and prevention is worthy of emphasis.

402 Evaluation and Management of Obesity

Robert F. Kushner

More than 70% of U.S. adults are considered to be overweight or have obesity, and the prevalence of obesity is increasing rapidly in most of the industrialized world. Children and adolescents also are becoming more obese, indicating that the current trends will accelerate over time. Obesity is associated with an increased risk of multiple health problems, including hypertension, type 2 diabetes, dyslipidemia, obstructive sleep apnea, nonalcoholic fatty liver disease, degenerative joint disease, and some malignancies. Thus, it is important for health care providers to identify, evaluate, and treat patients for obesity and associated comorbid conditions.

EVALUATION

Health care providers should screen all adult patients for obesity and offer intensive counseling and behavioral interventions to promote sustained weight loss. The four main steps in the evaluation of obesity, as described below, are (1) a focused obesity-related history that includes lifestyle questions about diet, physical activity, sleep, and stress; (2) a physical examination to determine the degree and type of obesity; (3) assessment of comorbid conditions; and (4) assessment of the patient's readiness to adopt lifestyle changes.

The Obesity-Focused History The first step in taking an obesity-focused history is to approach the topic in a sensitive manner. The reason for this concern is that the word *obesity* is a highly charged, emotive term. It has a significant pejorative meaning for many patients, leaving them feeling judged and blamed when labeled as such. This is not the case when patients are told that they have other chronic diseases such as diabetes or hypertension. Patients prefer that clinicians use more neutral words or terms such as *weight*, *excess weight*, *body mass index (BMI)*, or *unhealthy weight*, versus more stigmatizing terms such as *obesity*, *morbid obesity*, or *fatness*.

Information from the history should address the following seven questions:

- What factors contribute to the patient's obesity?
- How is the obesity affecting the patient's health?
- What is the patient's level of risk from obesity?
- What does the patient find difficult about managing weight?
- What are the patient's goals and expectations?
- Is the patient motivated to begin a weight management program?
- What kind of help does the patient need?

Although the vast majority of cases of obesity are promoted by behavioral factors that affect diet and physical activity patterns, the history may suggest secondary causes that merit further evaluation. Disorders to consider include polycystic ovarian syndrome, hypothyroidism, Cushing's syndrome, and hypothalamic disease. Drug-induced weight gain also should be considered. Common causes include medications for diabetes (insulin, sulfonylureas, thiazolidinediones), steroid hormones, antipsychotic agents (clozapine, olanzapine, risperidone), mood stabilizers (lithium), antidepressants (tricyclics, monoamine oxidase inhibitors, paroxetine, mirtazapine), and antiepileptic drugs (valproate, gabapentin, carbamazepine). Other medications, such as nonsteroidal anti-inflammatory drugs and calcium channel blockers, may cause peripheral edema but do not increase body fat.

The patient's current diet and physical activity patterns may reveal factors that contribute to the development of obesity and may identify behaviors to target for treatment. Physical fitness, in particular, is an important predictor of all-cause mortality rate independent of BMI and body composition and highlights the importance of taking a physical activity and exercise history during examination as well as emphasizing physical activity as a treatment approach.

TABLE 402-1 Classification of Weight Status and Disease Risk

CLASSIFICATION	BODY MASS INDEX (kg/m²)	OBESITY CLASS	DISEASE RISK
Underweight	<18.5	—	—
Healthy weight	18.5–24.9	—	—
Overweight	25.0–29.9	—	Increased
Obesity	30.0–34.9	I	High
Obesity	35.0–39.9	II	Very high
Extreme obesity	≥40	III	Extremely high

World Health Organization. *https://apps.who.int/iris/bitstream/handle/10665/63854/WHO_NUT_NCD_98.1_%28p159-276%29.pdf?sequence=2&isAllowed=y*

Inquiring about sleep health that addresses regularity, duration, efficiency, and satisfaction is also important. Although the mechanisms are uncertain, sleep deprivation is associated with metabolic alterations in appetite regulation, sympathetic nervous system overactivity, insulin sensitivity, and changes in circadian rhythm. Stress may also contribute to obesity, in part due to activation of the adrenal cortical axis and elevated cortisol levels and its impact on emotional health and behaviors. This historic information is best obtained by the combination of a questionnaire and an interview.

BMI and Waist Circumference Three key anthropometric measurements are important in evaluating the degree of obesity: weight, height, and waist circumference. The BMI, calculated as weight (kg)/height (m)^2 or as weight (lb)/height (in)^2 × 703, is used to classify weight status and risk of disease (Table 402-1). BMI is highly correlated with body fat and is related to disease risk. Lower BMI thresholds for overweight and obesity have been proposed for the Asia-Pacific region since this population appears to be at risk for glucose and lipid abnormalities at lower body weights.

Excess abdominal fat, assessed by measurement of waist circumference, is independently associated with a higher risk for metabolic syndrome, diabetes mellitus, and cardiovascular disease. Measurement of the waist circumference is a surrogate for visceral adipose tissue and should be performed in the horizontal plane above the iliac crest (Table 402-2).

Obesity-Associated Comorbid Conditions The evaluation of comorbid conditions should be based on presentation of symptoms, risk factors, and index of suspicion. For all patients, a fasting lipid profile (total, low-density lipoprotein, and high-density lipoprotein cholesterol and triglyceride levels), chemistry panel, and glycated hemoglobin should be performed, and blood pressure determined. Symptoms and diseases that are directly or indirectly related to obesity are listed in Table 402-3. Although individuals vary, the number and severity of organ-specific comorbid conditions usually rise with increasing levels of obesity.

TABLE 402-2 Ethnic-Specific Cutpoint Values for Waist Circumference

ETHNIC GROUP	WAIST CIRCUMFERENCE
Europeans	
Men	>94 cm (>37 in)
Women	>80 cm (>31.5 in)
South Asians and Chinese	
Men	>90 cm (>35 in)
Women	>80 cm (>31.5 in)
Japanese	
Men	>85 cm (>33.5 in)
Women	>90 cm (>35 in)
Ethnic South and Central Americans	Use South Asian recommendations until more specific data are available.
Sub-Saharan Africans	Use European data until more specific data are available.

- Acanthosis nigricans
- Acrochordons (skin tags)
- Hidradenitis suppurativa

Respiratory
- Dyspnea
- Obstructive sleep apnea
- Hypoventilation syndrome
- Pickwickian syndrome
- Asthma

Gastrointestinal
- Gastroesophageal reflux disease
- Nonalcoholic fatty liver disease
- Cholelithiasis
- Hernias
- Colon cancer

Genitourinary
- Urinary stress incontinence
- Obesity-related glomerulopathy
- Hypogonadism (male)
- Breast and uterine cancer
- Pregnancy complications

Neurologic
- Stroke
- Idiopathic intracranial hypertension
- Meralgia paresthetica
- Dementia

Identifying the High-Risk Patient Efforts are under way to develop more practical and useful assessments to identify patients who are at high risk in addition to using BMI alone. Analogous to other staging systems commonly used for congestive heart failure or chronic kidney disease, the American Association of Clinical Endocrinology (AACE) and the American College of Endocrinology (ACE) guidelines advocate a simple and clinically useful obesity disease staging system that is based on ethnic-specific BMI cutoffs in conjunction with assessment for adiposity-related complications (Fig. 402-1). Stage 0 is assigned to individuals who are overweight or obese by BMI classification but have no complications, whereas stages 1 and 2 are defined as individuals who are overweight or obese by BMI classification and have one or more mild-moderate complications (stage 1) or at least one severe complication (stage 2). A different functional staging system for obesity, called the Edmonton Obesity Staging System (EOSS), classifies individuals with obesity into five graded categories (0–4), based on their morbidity and health-risk profile along three domains—medical, functional, and mental. In this system, staging occurs independent of BMI.

Assessing the Patient's Readiness to Change An attempt to initiate lifestyle changes when the patient is not ready usually leads

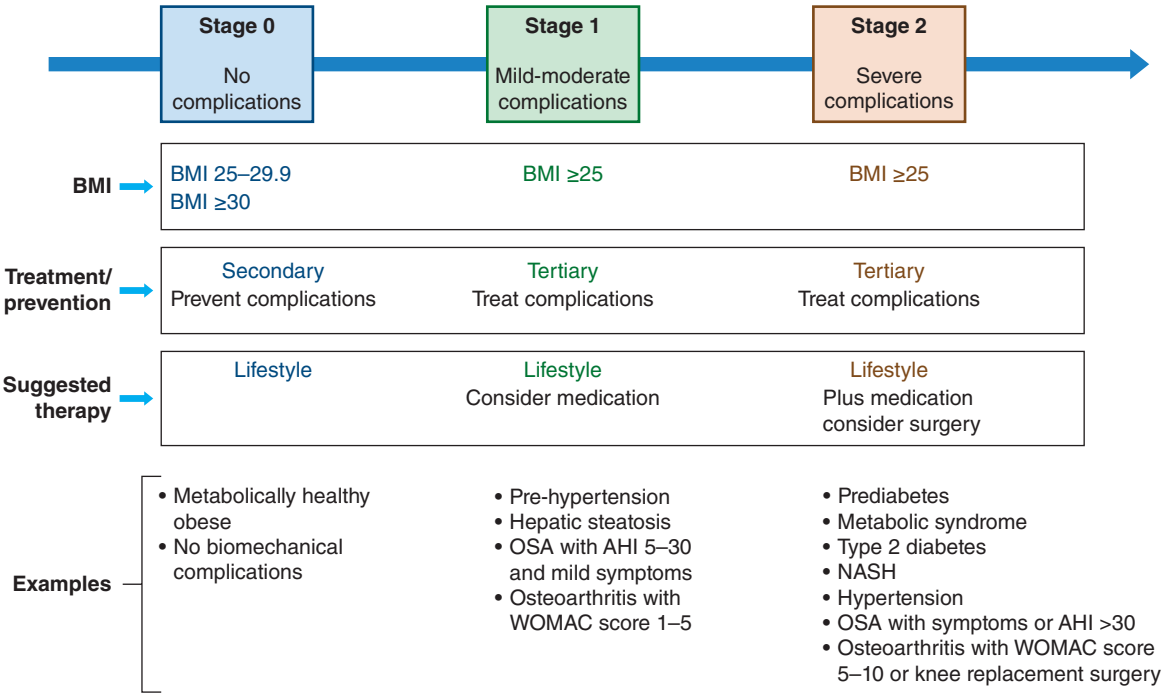

FIGURE 402-1 Staging the severity of obesity using the American Association of Clinical Endocrinology clinical practice guidelines. AHI, apnea-hypopnea index; BMI, body mass index; NASH, nonalcoholic steatohepatitis; OSA, obstructive sleep apnea; WOMAC, Western Ontario and McMaster Universities Osteoarthritis Index (a patient-reported outcome measure for osteoarthritis registering pain, stiffness, and function). *(Data from WT Garvey et al: American Association of Clinical Endocrinologists and American College of Endocrinology comprehensive clinical practice guidelines for medical care of patients with obesity. Endocr Pract 22 (Suppl 3):1, 2016.)*

to frustration and may hamper future weight-loss efforts. Assessment includes patient motivation and support, stressful life events, psychiatric status, time availability and constraints, and appropriateness of goals and expectations. Readiness can be viewed as the balance of two opposing forces: (1) motivation, or the patient's desire to change; and (2) resistance, or the patient's resistance to change.

A helpful method to begin a readiness assessment is to use the motivational interviewing technique of "anchoring" the patient's interest and confidence to change on a numerical scale. With this technique, the patient is asked to rate—on a scale from 0 to 10, with 0 being not so important (or confident) and 10 being very important (or confident)—his or her level of interest in and confidence about losing weight at this time. This exercise helps establish readiness to change and also serves as a basis for further dialogue.

TREATMENT

Obesity

THE GOAL OF THERAPY

The primary goals of treatment are to improve obesity-related comorbid conditions and quality of life and reduce the risk of developing future obesity-related complications. Information obtained from the history, physical examination, and diagnostic tests is used to determine risk and develop a treatment plan **(Fig. 402-2)**. The decision of how aggressively to treat the patient and which modalities to use is determined by the patient's risk status, expectations, and available resources. Not all patients who are deemed obese by BMI screening need to be treated, since BMI alone does not directly measure body fat, distinguish body fat distribution, or assess an individuals' health status. However, patients who present with obesity-related comorbidities and who would benefit from weight-loss intervention should be managed proactively. Therapy for obesity always begins with lifestyle management and may include pharmacotherapy or bariatric surgery, depending on BMI risk category **(Table 402-4)**. Setting an initial weight-loss goal of 8–10% over 6 months is a realistic target.

LIFESTYLE MANAGEMENT

Obesity care involves attention to three essential elements of lifestyle: dietary habits, physical activity, and behavior modification. Because obesity is fundamentally a disease of energy imbalance, all patients must learn how and when energy is consumed (diet), how and when energy is expended (physical activity), and how to incorporate this information into their daily lives (behavioral therapy). Lifestyle management has been shown to result in a modest (typically 3–5 kg) weight loss when compared with no treatment or usual care.

Diet Therapy The primary focus of diet therapy is to reduce overall calorie consumption. Guidelines from the American Heart Association/American College of Cardiology/The Obesity Society (AHA/ACC/TOS) recommend initiating treatment with a calorie deficit of 500–750 kcal/d compared with the patient's habitual diet. Alternatively, a diet of 1200–1500 kcal/d for women and 1500–1800 kcal/d for men (adjusted for the individual's body weight) can be prescribed. This reduction is consistent with a goal of losing ~1–2 lb/week. The calorie deficit can be instituted through dietary substitutions or alternatives. Examples include choosing smaller portion sizes, eating more fruits and vegetables, consuming more whole-grain cereals, selecting leaner cuts of meat and skimmed dairy products, reducing consumption of fried foods and other foods with added fats and oils, and drinking water instead of sugar-sweetened beverages. It is important that dietary counseling remains patient centered and that the selected goals are SMART (specific, measurable, agreed upon, realistic, timely).

The macronutrient composition of the diet will vary with the patient's preference and medical condition. The 2020 U.S. Department of Agriculture Dietary Guidelines for Americans **(Chap. 332)**, which focus on health promotion and risk reduction, can be applied to treatment of patients who are overweight or obese. The recommendations include maintaining a diet rich in whole grains, fruits, vegetables, and dietary fiber; decreasing sodium intake to <2300 mg/d; consuming fat-free or low-fat dairy products; and keeping added sugars and saturated fat intake to <10% of daily calories. Application of these guidelines to specific calorie goals can be

found on the website *www.choosemyplate.gov*. Since portion control is one of the most difficult strategies for patients to manage, the use of preprepared products such as meal replacements is a simple and convenient suggestion. Examples include frozen entrees, protein shakes, and bars. Use of meal replacements in the diet has been shown to result in a 7–8% weight loss.

Numerous randomized trials comparing diets of different macronutrient composition (e.g., low-carbohydrate, low-fat, Mediterranean) have shown that weight loss depends primarily on reduction of total caloric intake and adherence to the prescribed diet, not the specific proportions of carbohydrate, fat, and protein in the diet. The macronutrient composition will ultimately be determined by the patient's taste preferences, cooking style, and culture. However, the patient's underlying medical problems are also important in guiding the recommended dietary composition. The dietary prescription will vary according to the patient's metabolic profile and risk factors. A consultation with a registered dietitian for medical nutrition therapy is particularly useful in considering patient preference and treatment of comorbid diseases.

Another dietary approach to consider is based on the concept of *energy density*, which refers to the number of calories (i.e., amount of energy) a food contains per unit of weight. People tend to ingest a constant volume of food regardless of caloric or macronutrient content. Adding water or fiber to a food decreases its energy density by increasing weight without affecting caloric content. Examples of foods with low energy density include soups, fruits, vegetables, oatmeal, and lean meats. Dry foods and high-fat foods such as pretzels, cheese, egg yolks, potato chips, and red meat have a high energy density. Diets containing low-energy-dense foods have been shown to control hunger and thus to result in decreased caloric intake and weight loss.

Occasionally, very-low-calorie diets (VLCDs) are prescribed as a form of aggressive dietary therapy. The primary purpose of a VLCD is to promote a rapid and significant (13- to 23-kg) short-term weight loss over a 3- to 6-month period. The proprietary formulas designed for this purpose typically supply ≤800 kcal, 50–80 g of protein, and 100% of the recommended daily intake for vitamins and minerals. According to a review by the National Task Force on the Prevention and Treatment of Obesity, indications for initiating a VLCD include the involvement of well-motivated individuals who are moderately to severely obese, have failed at more conservative approaches to weight loss, and have a medical condition that would be immediately improved with rapid weight loss. These conditions include poorly controlled type 2 diabetes, hypertriglyceridemia, obstructive sleep apnea, and symptomatic peripheral edema. In the DiRECT trial of patients with type 2 diabetes and obesity, a low-energy formula diet (825–853 kcal/d) was administered for 3 months following by a structured monthly program. At 12 months, almost half of the participants achieved remission to a nondiabetic state and were not taking antidiabetic drugs. Use of formula diets should be prescribed by trained practitioners in a medical care setting where medical monitoring and high-intensity lifestyle intervention can be provided.

Physical Activity Therapy Although exercise alone is only moderately effective for weight loss, the combination of dietary modification and exercise is the most effective behavioral approach for the treatment of obesity. The most important role of exercise appears to be in the maintenance of the weight loss. The 2018 Physical Activity Guidelines for Americans (*www.health.gov/paguidelines*) recommend that adults should engage in 150 min of moderate-intensity or 75 min a week of vigorous-intensity aerobic physical activity per week, preferably spread throughout the week. Focusing on simple ways to add physical activity into the normal daily routine through leisure activities, travel, and domestic work should be suggested. Examples include brisk walking, using the stairs, doing housework and yard work, and engaging in sports. Additionally, it is important to reduce sedentary behavior, which is associated with all-cause mortality and cardiovascular disease mortality in adults. Asking the patient to wear a pedometer or accelerometer to monitor total accumulation of steps or kcal expended as part of the activities of daily living is a useful strategy. Step counts are highly correlated with activity level. Studies have demonstrated that lifestyle activities are as effective as structured exercise programs for improving cardiorespiratory fitness and weight loss. A high level of physical activity (>300 min of moderate-intensity activity per week) is often needed to lose weight and sustain weight loss. These exercise recommendations are daunting to most patients and need to be implemented gradually. Consultation with an exercise physiologist or personal trainer may be helpful.

Behavioral Therapy Cognitive behavioral therapy is used to help change and reinforce new dietary and physical activity behaviors. Strategies include self-monitoring techniques (e.g., journaling, weighing, and measuring food and activity); stress management; stimulus control (e.g., using smaller plates, not eating in front of the television or in the car); social support; problem solving; and cognitive restructuring to help patients develop more positive and realistic thoughts about themselves. When recommending any behavioral lifestyle change, the patient should be asked to identify what, when, where, and how the behavioral change will be performed. The patient should keep a record of the anticipated behavioral change so that progress can be reviewed at the next office visit. Because these techniques are time consuming to implement, their supervision is often undertaken by ancillary office staff, such as an advanced practice provider or registered dietitian.

PHARMACOTHERAPY

Adjuvant pharmacologic treatments should be considered for patients with a BMI ≥30 kg/m^2 or for patients with a BMI ≥27 kg/m^2 who have concomitant obesity-related diseases and for whom dietary and physical activity therapy has not been successful. When an antiobesity medication is prescribed, patients should be actively engaged in a lifestyle program that provides the strategies and skills needed to use the drug effectively since such support increases total weight loss.

Medications for obesity fall into two major categories: those that affect appetite and those that inhibit gastrointestinal fat absorption. Since 2012, four new appetite-controlling medications were approved by the U.S. Food and Drug Administration (FDA) with an indication for chronic weight management, although one was voluntarily withdrawn in February 2020. These medications work biologically to suppress appetite, affecting hunger, satiety, and response to highly rewarding foods, thus making it easier for patients to follow their dietary intentions to restrict caloric intake. In addition, one capsule that is considered a medical device was marketed in 2020.

Centrally Acting Medications This class of medications affects satiety (feeling of fullness after a meal), hunger (the biologic sensation that prompts eating), and craving (intense desire for a specific food). By controlling appetite, these agents help patients reduce caloric intake without a sense of deprivation. The target site for the actions of these medications is primarily the hypothalamus and reward centers in the central nervous system **(Chap. 401)**. The classic sympathomimetic adrenergic agents (benzphetamine, phendimetrazine, diethylpropion, mazindol, and phentermine) function by stimulating norepinephrine release or by blocking its reuptake. Among these agents, phentermine is the most commonly prescribed; there are limited long-term data on its effectiveness. A 2002 review of six randomized, placebo-controlled trials of phentermine for weight control found that patients lost 0.6–6.0 additional kg of weight over 2–24 weeks of treatment. The most common side effects of the amphetamine-derived agents are restlessness, insomnia, dry mouth, constipation, and increased blood pressure and heart rate.

PHEN/TPM is a combination drug that contains a catecholamine releaser (phentermine) and an anticonvulsant (topiramate). Topiramate is approved by the FDA as an anticonvulsant for the treatment

TABLE 402-5 Clinical Trials for Antiobesity Medications

	PHEN/TPM		NALTREXONE SR/BUPROPION SR			LIRAGLUTIDE	
	EQUIP	CONQUER	COR-I	COR-II	COR-BMOD	SCALE	SCALE MAINTENANCE
No. of participants (ITT-LOCF)	1230	2487	1742	1496	793	3731	422
BMI (kg/m^2)	≥35	27–45	30–45	30–45	30–45	≥27	≥27
Age (y)	18–70	18–70	18–65	18–65	18–65	≥18	≥18
Comorbid conditions (cardiovascular and metabolic)	≥1	≥2	≥1	≥1	≥1	≥1	≥1
Mean weight loss (%) with treatment vs placebo	10.9 vs 1.6	7.8 vs 1.2	6.1 vs 1.3	6.5 vs 1.9	9.3 vs 5.1	8.0 vs 2.6	6.2 vs 0.2
Placebo-subtracted weight loss (%)	9.3	6.6	4.8	4.6	4.2	5.4	6.0
Categorical change in 5% weight loss with treatment vs placebo	66.7 vs 17.3	62 vs 21	48 vs 16	50.5 vs 17.1	66.4 vs 42.5	63.2 vs 27.1	81.4 vs 48.9
Study completion rate, treatment vs placebo (%)	66.4 vs 52.9	69 vs 57	50	54	57.9 vs 58.4	71.9 vs 64.4	75 vs 69.5

Note: EQUIP, PHEN/TPM = 15/92 mg dose; CONQUER, PHEN/TPM = 7.5/46 mg dose.

Abbreviations: BMI, body mass index; ITT-LOCF, intention to treat, last observation carried forward; PHEN/TPM, phentermine/topiramate extended release.

of epilepsy and for the prophylaxis of migraine headaches. Weight loss was identified as an unintended side effect of topiramate during clinical trials for epilepsy. The mechanism responsible for weight loss is uncertain but is thought to be mediated through the drug's modulation of γ-aminobutyric acid receptors, inhibition of carbonic anhydrase, and antagonism of glutamate. PHEN/TPM has undergone two 1-year pivotal randomized, placebo-controlled, double-blind trials of efficacy and safety: EQUIP and CONQUER. In a third study, SEQUEL, 78% of CONQUER participants continued to receive their blinded treatment for an additional year. All participants received diet and exercise counseling. Participant numbers, eligibility, characteristics, and weight-loss outcomes are displayed in **Table 402-5**. Intention-to-treat 1-year placebo-subtracted weight loss for PHEN/TPM was 9.3% (15-mg/92-mg dose) and 6.6% (7.5-mg/46-mg dose), respectively, in the EQUIP and CONQUER trials. Clinical and statistical dose-dependent improvements were seen in selected cardiovascular and metabolic outcome measurements that were related to the weight loss. The most common adverse events experienced by the drug-randomized group were paresthesias, dry mouth, constipation, dysgeusia, and insomnia. Because of an increased risk of congenital fetal oral-cleft formation from topiramate, women of childbearing age should have a negative pregnancy test before treatment and monthly thereafter and use effective contraception consistently during medication therapy.

Lorcaserin was approved by the FDA for chronic weight management in 2012 and taken off the market in 2020. Lorcaserin was developed as a selective 5-HT2$_C$ receptor agonist with a functional selectivity ~15 times that of 5-HT2$_A$ receptors and 100 times that of 5-HT2$_B$ receptors. This selectivity is important, since the drug-induced valvulopathy documented with two other serotonergic agents that were removed from the market—fenfluramine and dexfenfluramine—was due to activation of the 5-HT2$_B$ receptors expressed on cardiac valvular interstitial cells. By activating the 5-HT2$_C$ receptor, lorcaserin is thought to decrease food intake through the pro-opiomelanocortin (POMC) system of neurons.

Lorcaserin underwent two randomized, placebo-controlled, double-blind trials for efficacy and safety. Intention-to-treat 1-year placebo-subtracted weight loss was 3.6% and 3.0%, respectively, in the two pivotal trials. Modest statistical improvements consistent with the weight loss were seen in selected cardiovascular and metabolic outcome measurements. However, a postmarketing cardiovascular outcome trial found that more patients taking lorcaserin (7.7%) were diagnosed with cancer compared to those taking a placebo (7.1%). The trial was conducted in 12,000 patients over 5 years. A range of cancer types was reported, with several different types of cancers occurring more frequently in the lorcaserin group, including pancreatic, colorectal, and lung.

Naltrexone SR/bupropion SR (NB) is a combination of an opioid antagonist and a mild reuptake inhibitor of dopamine and norepinephrine, respectively. Individually, naltrexone is approved by the FDA for the treatment of alcohol dependence and for the blockade of the effects of exogenously administered opioids, whereas bupropion is approved as an antidepressant and smoking cessation aid. As a combination drug, each component works in consort: bupropion stimulates secretion of α-melanocyte-stimulating hormone (MSH) from POMC, whereas naltrexone blocks the feedback inhibitory effects of opioid receptors activated by the β-endorphin released in the hypothalamus, thus allowing the inhibitory effects of MSH to reduce food intake.

The medication has undergone three randomized, placebo-controlled, double-blind trials for efficacy and safety. Participants were randomized to receive NB (8 mg/90 mg two tablets bid) or placebo in the three COR studies. Whereas participants received standardized nutritional and exercise counseling in COR-I and COR-II, a more intensive behavior modification program was provided in COR-BMOD (Table 402-5). Intention-to-treat 1-year placebo-subtracted weight loss was 4.8%, 5.1%, and 4.2%, respectively, in the COR-I, COR-II, and COR-BMOD trials. Clinical and statistical dose-dependent improvements were seen in selected cardiovascular and metabolic outcome measurements that were related to the weight loss. However, the medication led to slight increases or smaller decreases in blood pressure and pulse than placebo. The most common adverse events experienced by the drug-randomized groups were nausea, constipation, headache, vomiting, dizziness, diarrhea, insomnia, and dry mouth.

Liraglutide, the fourth new medication, is a glucagon-like peptide-1 (GLP-1) analogue with 97% homology to human GLP-1 that was previously approved for the treatment of type 2 diabetes at doses up to 1.8 mg once daily. In addition to its effect as an incretin hormone (glucose-induced insulin secretion), liraglutide inhibits both gastric emptying and glucagon secretion and stimulates GLP-1 receptors in the arcuate nucleus of the hypothalamus to reduce feeding.

Liraglutide has undergone three randomized, placebo-controlled, double-blind trials for efficacy and safety. Participants were randomized to receive liraglutide (3.0 mg SC daily) or placebo for initial weight loss—SCALE (patients without diabetes) and SCALE Diabetes (patients with diabetes)—or for weight maintenance after initial weight loss (SCALE Maintenance) (Table 402-5). All participants received diet and exercise counseling. For SCALE and SCALE Maintenance, patients were overweight or obese and had treated or untreated hypertension or dyslipidemia. Intention-to-treat 1-year placebo-subtracted weight loss was 5.4 and 6.1%, respectively, in the SCALE and SCALE Maintenance trials. Clinical and statistical dose-dependent improvements were seen in selected

cardiovascular and metabolic outcome measurements; however, there was a small increase in heart rate. The most common adverse effects include nausea, diarrhea, constipation, and vomiting. GLP-1 agonists should not be prescribed in patients with a family or personal history of medullary thyroid cancer or multiple endocrine neoplasia.

In approving the new antiobesity medications, the FDA introduced a new provision with important clinical relevance: a prescription trial period to assess effectiveness. Response to these medications should be assessed after 12 weeks of treatment for PHEN/TPM (or 16 weeks for NB and liraglutide since these medications are uptitrated during the first month). Determining responsiveness at 3 or 4 months is based on the post hoc observed trial data that patients who did not lose a prespecified amount of weight early in treatment were less successful at 1 year. For PHEN/TPM, if the patient has not lost at least 3% of body weight at 3 months, the clinician can either escalate the dose and reassess progress at 6 months or discontinue treatment entirely. For NB, the medication should be discontinued if the patient has not lost at least 5% of body weight. The corresponding responsive target for liraglutide is a 4% weight loss.

Peripherally Acting Medications Orlistat is a synthetic hydrogenated derivative of a naturally occurring lipase inhibitor, lipostatin, that is produced by the mold *Streptomyces toxytricini*. This drug is a potent, slowly reversible inhibitor of pancreatic, gastric, and carboxylester lipases and phospholipase A_2, which are required for the hydrolysis of dietary fat into fatty acids and monoacylglycerols. Orlistat acts in the lumen of the stomach and small intestine by forming a covalent bond with the active site of these lipases. Taken at a therapeutic dose of 120 mg tid, orlistat blocks the digestion and absorption of ~30% of dietary fat. After discontinuation of the drug, fecal fat content usually returns to normal within 48–72 h.

Multiple randomized, double-blind, placebo-controlled studies have shown that, after 1 year, orlistat produces a weight loss of ~9–10%, whereas placebo recipients have a 4–6% weight loss. Because orlistat is minimally (<1%) absorbed from the gastrointestinal tract, it has no systemic side effects. The drug's tolerability is related to the malabsorption of dietary fat and the subsequent passage of fat in the feces. Adverse gastrointestinal effects, including flatus with discharge, fecal urgency, fatty/oily stool, and increased defecation, are reported in at least 10% of orlistat-treated patients. These side effects generally are experienced early, diminish as patients control their dietary fat intake, and only infrequently cause patients to withdraw from clinical trials. When taken concomitantly, psyllium mucilloid is helpful in controlling orlistat-induced gastrointestinal side effects. Because serum concentrations of the fat-soluble vitamins D and E and β-carotene may be reduced by orlistat treatment, vitamin supplements are recommended to prevent potential deficiencies. Orlistat was approved for over-the-counter use in 2007.

Oral Device Gelesis100 is a nonsystemic, water-soluble gel that was approved by the FDA in 2019. In the stomach, the capsule releases the cellulose microgel, which absorbs water and forms a matrix with the consistency of food, occupying ~25% of the stomach. In the large intestine, it is broken down by enzymes and the cellulose is excreted. Gelesis100 and placebo were evaluated over 24 weeks in patients with BMI of 27 to ≤40 kg/m^2 and fasting plasma glucose of 90–145 mg/dL. Intention-to-treat, 24-week, placebo-subtracted weight loss was 2.1% (6.4 vs 4.4%). Gelesis100 treatment had no apparent increased safety risks. The capsules are approved for patients with a BMI of ≥25 kg/m^2, with or without comorbidities.

SURGERY

Bariatric surgery **(Fig. 402-3)** can be considered for patients with severe obesity (BMI ≥40 kg/m^2) or for those with moderate obesity (BMI ≥35 kg/m^2) associated with a number of comorbid conditions.

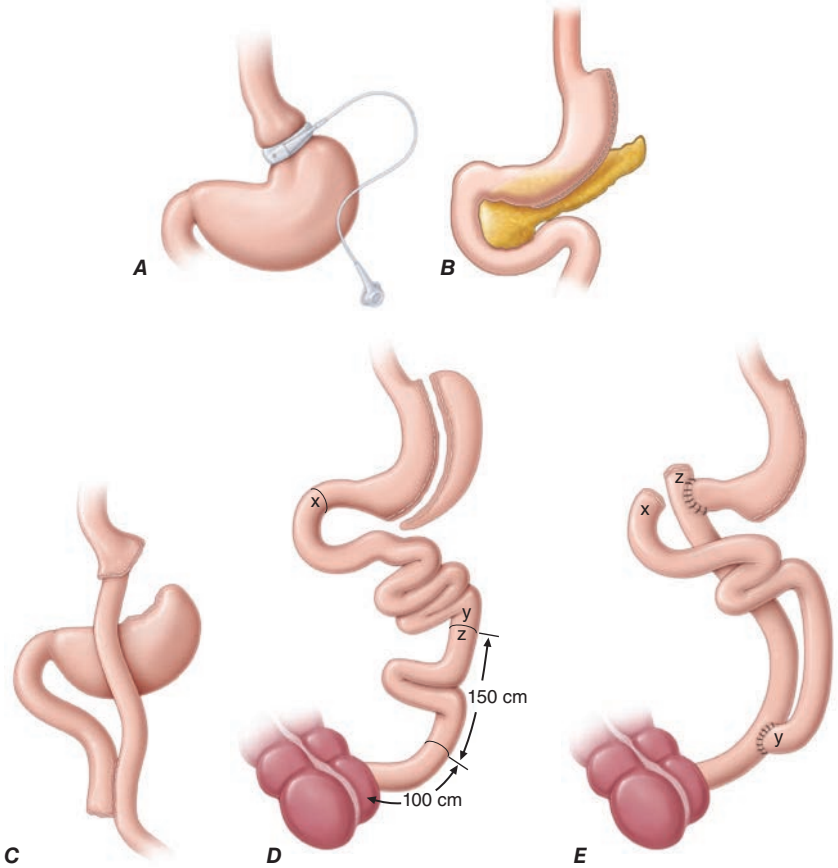

FIGURE 402-3 Bariatric surgical procedures. Examples of operative interventions used for surgical manipulation of the gastrointestinal tract. ***A.*** Laparoscopic adjustable gastric banding. ***B.*** Laparoscopic sleeve gastrectomy. ***C.*** The Roux-en-Y gastric bypass. ***D.*** Biliopancreatic diversion with duodenal switch. ***E.*** Biliopancreatic diversion.

Weight-loss surgeries have traditionally been classified into three categories on the basis of anatomic changes: restrictive, restrictive malabsorptive, and malabsorptive. More recently, however, the clinical benefits of bariatric surgery in achieving weight loss and alleviating metabolic comorbidities have been attributed largely to changes in the physiologic responses of gut hormones, bile acid metabolism, the microbiota, and adipose tissue metabolism. Metabolic effects resulting from bypassing the foregut include altered responses of ghrelin, GLP-1, peptide YY3-36, and oxyntomodulin. Additional effects on food intake and body weight control may be attributed to changes in vagal signaling. The loss of fat mass, particularly visceral fat, is associated with multiple metabolic, adipokine, and inflammatory changes that include improved insulin sensitivity and glucose disposal; reduced free fatty acid flux; increased adiponectin levels; and decreased interleukin 6, tumor necrosis factor α, and high-sensitivity C-reactive protein levels.

Restrictive surgeries limit the amount of food the stomach can hold and slow the rate of gastric emptying. *Laparoscopic adjustable gastric banding* is the prototype of this category. The first banding device, the LAP-BAND, was approved for use in the United States in 2001. In contrast to previous devices, this band has a diameter that is adjustable by way of its connection to a reservoir that is implanted under the skin. Injection of saline into the reservoir and removal of saline from the reservoir tighten and loosen the band's internal diameter, respectively, thus changing the size of the gastric opening. Although the mean percentage of total body weight lost at 5 years is estimated at 20–25%, longer-term follow-up has been more disappointing, leading to near abandonment of the procedure. In the *laparoscopic sleeve gastrectomy*, the stomach is restricted by stapling and dividing it vertically, removing ~80% of the greater curvature and leaving a slim banana-shaped remnant stomach along the lesser curvature. Weight loss after this procedure is superior to that after laparoscopic adjustable gastric banding.

The three restrictive-malabsorptive bypass procedures combine the elements of gastric restriction and selective malabsorption: Roux-en-Y gastric bypass, biliopancreatic diversion, and biliopancreatic diversion with duodenal switch (Fig. 402-3). Roux-en-Y is the most commonly undertaken and most accepted bypass procedure. These procedures are routinely performed by laparoscopy.

These procedures generally produce a 30–35% average total body weight loss at 12–18 months followed by variable weight regain thereafter. Significant improvement in multiple obesity-related comorbid conditions, including type 2 diabetes, hypertension, dyslipidemia, obstructive sleep apnea, quality of life, and long-term cardiovascular events, has been reported. A meta-analysis of controlled clinical trials comparing bariatric surgery versus no surgery showed that surgery was associated with a reduced odds ratio (OR) risk of global mortality (OR = 0.55), cardiovascular death (OR = 0.58), and all-cause mortality (OR = 0.70).

Among the observed improvements in comorbidities, the prevention and treatment of type 2 diabetes resulting from bariatric surgery have garnered the most attention. Fifteen-year data from the Swedish Obese Subjects study demonstrated a marked reduction (i.e., by 78%) in the incidence of type 2 diabetes development among obese patients who underwent bariatric surgery. Multiple randomized controlled studies have shown greater weight loss and more improved glycemic control from 1 and 5 years among surgical patients than among patients receiving conventional medical therapy. A retrospective cohort study of >4000 adults with diabetes found that, overall, 68.2% of patients experienced an initial complete remission of type 2 diabetes within 5 years after surgery. However, among these patients, one-third redeveloped type 2 diabetes within 5 years. Patients with earlier-stage type 2 diabetes (i.e., those who do not need insulin, with shorter-duration disease, and with lower hemoglobin A_{1c}) appear to have better improvement after bariatric surgery. The rapid improvement seen in diabetes after bariatric surgery is thought to be due to caloric restriction, reduced insulin resistance, and surgery-specific effects on glucose homeostasis brought about by alteration of gut hormones.

The mortality rate from bariatric surgery is generally <1% but varies with the procedure, the patient's age and comorbid conditions, and the experience of the surgical team. The most common surgical complications include stomal stenosis or marginal ulcers (occurring in 5–15% of patients) that present as prolonged nausea and vomiting after eating or inability to advance the diet to solid foods. These complications typically are treated by endoscopic balloon dilation and acid suppression therapy, respectively. For patients who undergo laparoscopic adjustable gastric banding, there are no intestinal absorptive abnormalities other than mechanical reduction in gastric size and outflow. Therefore, selective deficiencies are uncommon unless eating habits become unbalanced. In contrast, the restrictive-malabsorptive procedures carry an increased risk for micronutrient deficiencies of vitamin B_{12}, iron, folate, calcium, and vitamin D. Patients with restrictive-malabsorptive procedures require lifelong supplementation with these micronutrients.

Intraluminal Gastric Balloons Three gastric balloon devices are approved for weight loss that are either placed in the stomach endoscopically (the REHAPE and ORBERA devices) or swallowed (OBALON). Efficacy of the devices at 6 months, based on a pooled weighted-mean percent weight loss, was 9.7%, and the control-subtracted percent weight loss was 5.6%. The devices are approved only for up to 6 months of use in adults with a BMI of 30–40 kg/m^2. Adverse effects include nausea, vomiting, and abdominal pain.

403 Diabetes Mellitus: Diagnosis, Classification, and Pathophysiology

Alvin C. Powers, Kevin D. Niswender, Carmella Evans-Molina

Diabetes mellitus (DM) refers to a group of common metabolic disorders that share the phenotype of hyperglycemia. Several distinct types of DM are caused by a complex interaction of genetics and environmental factors. Depending on the etiology of the DM, factors contributing to hyperglycemia include reduced insulin secretion, decreased glucose utilization, and increased glucose production. The metabolic dysregulation associated with DM causes secondary pathophysiologic changes in multiple organ systems that impose a tremendous burden on the individual with diabetes and on the health care system. In the United States, DM is the leading cause of end-stage renal disease

(ESRD), nontraumatic lower-extremity amputations, and adult blindness. Persons with diabetes are at increased risk for cardiovascular disease, which is the main cause of morbidity and mortality in this population.

CLASSIFICATION

DM is classified on the basis of the pathogenic process leading to hyperglycemia **(Table 403-1)**. There are two broad categories of DM, designated as either type 1 or type 2 DM. However, there is increasing recognition of other forms of diabetes in which the molecular pathogenesis is better understood and may be associated with a single gene defect. These alternative forms as well as other "atypical" forms may share features of type 1 and/or type 2 DM. Type 1 DM develops as a result of autoimmunity against the insulin-producing beta cells, resulting in insulin deficiency. Type 2 DM is a heterogeneous group of disorders characterized by variable degrees of insulin resistance, impaired insulin secretion, and increased hepatic glucose production. Defects in insulin action and/or secretion give rise to the common phenotype of hyperglycemia in type 2 DM and have important therapeutic implications now that pharmacologic agents are available to target specific metabolic derangements. Both type 1 and type 2 diabetes are preceded by a period of progressive worsening of glucose homeostasis, followed by the development of hyperglycemia that exceeds the threshold for clinical diagnosis. In terms of type 2 diabetes, this phase is referred to as prediabetes and is more specifically classified as impaired fasting glucose (IFG) or impaired glucose tolerance (IGT) **(Fig. 403-1)**. Recently, three distinct stages of type 1 DM have been defined based on the development of autoantibodies against pancreatic beta cell antigens or the development of worsening dysglycemia (discussed below).

TABLE 403-1 Etiologic Classification of Diabetes Mellitus

I. Type 1 diabetes (immune-mediated beta cell destruction, usually leading to absolute insulin deficiency)

II. Type 2 diabetes (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly insulin secretory defect with insulin resistance)

III. Specific types of diabetes (monogenic or MODY)

- A. Genetic defects of beta cell development or function characterized by mutations in:
  1. Hepatocyte nuclear transcription factor (HNF) 4α
  2. Glucokinase
  3. HNF-1α
  4. Insulin promoter factor-1, HNF-1β, NeuroD1, and other pancreatic islet regulators/proteins such as *KLF11, PAX4, BLK, GATA4, GATA6, SLC2A2* (GLUT2), *RFX6, GLIS3*
  5. Insulin, leading to permanent neonatal diabetes
  6. Subunits of ATP-sensitive potassium channel, leading to permanent neonatal diabetes
  7. Mitochondrial DNA
- B. Transient neonatal diabetes
- C. Diseases of the exocrine pancreas—pancreatitis, pancreatectomy, neoplasia, cystic fibrosis, hemochromatosis, fibrocalculous pancreatopathy, mutations in carboxyl ester lipase
- D. Genetic defects in insulin action, including type A insulin resistance, Leprechaunism, Rabson-Mendenhall syndrome, lipodystrophy syndromes
- E. Endocrinopathies—acromegaly, Cushing's syndrome, glucagonoma, pheochromocytoma, hyperthyroidism, somatostatinoma, aldosteronoma
- F. Drug- or chemical-induced—glucocorticoids, calcineurin and mTOR inhibitors (after organ transplantation), vacor (a rodenticide), pentamidine, nicotinic acid, diazoxide, β-adrenergic agonists, thiazides, hydantoins, asparaginase, α-interferon, protease inhibitors, antipsychotics (atypicals and others), epinephrine
- G. Infections—congenital rubella, cytomegalovirus, coxsackievirus
- H. Uncommon forms of immune-mediated diabetes—"stiff-person" syndrome, anti-insulin receptor antibodies
- I. Other genetic syndromes sometimes associated with diabetes—Wolfram syndrome, Down's syndrome, Klinefelter's syndrome, Turner's syndrome, Friedreich's ataxia, Huntington's chorea, Laurence-Moon-Biedl syndrome, myotonic dystrophy, porphyria, Prader-Willi syndrome

IV. Gestational diabetes mellitus (GDM)

Abbreviation: MODY, maturity-onset diabetes of the young or monogenic diabetes; see text.

Source: Data from American Diabetes Association. Standards of medical care in diabetes–2014. Diabetes Care 37:S14, 2014.

	Normal glucose tolerance	Hyperglycemia		
		Pre-diabetes*	Diabetes Mellitus	
		Impaired fasting glucose or impaired glucose tolerance	Not insulin requiring	Insulin required for control / Insulin required for survival
			Symptoms of diabetes + random blood glucose concentration ≥11.1 mmol/L (200 mg/dL)[a]	
FPG	<5.6 mmol/L (100 mg/dL)	5.6–6.9 mmol/L (100–125 mg/dL)	≥7.0 mmol/L (126 mg/dL)[b]	
HbA1C	<5.6%	5.7–6.4%	≥6.5%[c]	
2-h PG	<7.8 mmol/L (140 mg/dL)	7.8–11.0 mmol/L (140–199 mg/dL)	≥11.1 mmol/L (200 mg/dL)[d]	

FIGURE 403-1 Spectrum of glucose homeostasis and diagnosis of diabetes mellitus (DM). Glucose homeostasis is a spectrum from normal glucose tolerance (*left portion of figure*) to diabetes (*right portion of figure*) including type 1 DM, type 2 DM, specific types of diabetes, and gestational DM. The diagnostic criteria for diabetes are shown in the lower right portion of the figure and include the hemoglobin A_{1c} (HbA_{1c}), the fasting plasma glucose (FPG), and the 2-h plasma glucose (PG) after a glucose challenge. In most types of DM, the individual traverses from normal glucose tolerance to impaired glucose tolerance to overt diabetes (these should be viewed not as abrupt categories but as a spectrum). Changes in glucose tolerance may be bidirectional in some types of diabetes. For example, individuals with type 2 DM may return to the impaired glucose tolerance category with weight loss; in gestational DM, diabetes may revert to impaired glucose tolerance or normal glucose tolerance after delivery. [a]Random is defined as without regard to time since the last meal. [b]Fasting is defined as no caloric intake for at least 8 h. [c]Hemoglobin A1c test should be performed in a laboratory using a method approved by the National Glycohemoglobin Standardization Program and correlated to the reference assay of the Diabetes Control and Complications Trial. Point-of-care hemoglobin A1c should not be used for diagnostic purposes. [d]The test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water, not recommended for routine clinical use. Assessment of 1-h glucose may be helpful in diabetes risk prediction in individuals with cystic fibrosis or other forms of pancreatic disease. In the absence of unequivocal hyperglycemia and acute metabolic decompensation, the blood glucose criteria should be confirmed by repeat testing on a different day. These values do not apply to the diagnosis of gestational DM. *Some use the term *increased risk for diabetes* or *intermediate hyperglycemia* (World Health Organization) rather than *prediabetes. (Data from American Diabetes Association. 2. Classification and Diagnosis of Diabetes: Standards of Medical Care in Diabetes-2021. Diabetes Care 44:S15, 2021.)*

OTHER TYPES OF DM

Other etiologies of DM include specific genetic defects in insulin secretion or action, metabolic abnormalities that impair insulin secretion, mitochondrial abnormalities, and a host of conditions that impair glucose tolerance (Table 403-1). *Maturity-onset diabetes of the young* (MODY) and *monogenic diabetes* are subtypes of DM characterized by autosomal dominant inheritance, early onset of hyperglycemia (usually <25 years; sometimes in neonatal period), and impaired insulin secretion (discussed below). Mutations in the insulin receptor cause a group of rare disorders characterized by severe insulin resistance.

DM may also develop as a result of cystic fibrosis or chronic pancreatitis, in which the islets become damaged from a primary pathologic process originating in the pancreatic exocrine tissue. Hormones that antagonize insulin action can lead to DM. Hyperglycemia is often a feature of endocrinopathies such as acromegaly and Cushing's disease. Viral infections have been implicated in pancreatic islet destruction but are an extremely rare cause of DM. A form of acute onset of type 1 diabetes, termed *fulminant diabetes*, has been noted in Japan and may be related to viral infection of the islets.

GESTATIONAL DM

Glucose intolerance developing during the second or third trimester of pregnancy is classified as gestational diabetes mellitus (GDM). Insulin resistance is related to the metabolic changes of pregnancy, during which the increased insulin demands may lead to IGT or diabetes. The American Diabetes Association (ADA) recommends that diabetes diagnosed within the first trimester be classified as preexisting pregestational diabetes rather than GDM. In 2019, the International Diabetes Federation (IDF) estimated that 16% of pregnancies worldwide were affected by either GDM or preexisting DM. Most women with GDM revert to normal glucose tolerance postpartum but have a substantial risk (35–60%) of developing DM in the next 10–20 years. In addition, children born to a mother with GDM also have an increased risk of developing metabolic syndrome and type 2 DM later in life. Currently, the ADA recommends that women with a history of GDM undergo lifelong screening for the development of diabetes or prediabetes at least every 3 years.

ATYPICAL DIABETES

It is increasingly recognized that some forms of diabetes have features of both type 1 and type 2 diabetes. These are distinct from monogenic forms (MODY) as they have not been linked to single gene defects. The development of a type 2 diabetes phenotype before puberty and a type 2 diabetes phenotype in very lean individuals are examples of atypical diabetes. An additional example is ketosis-prone diabetes, where individuals present with ketoacidosis, but do not require long-term exogenous insulin therapy. Many of these individuals are African American or Asian in heritage. Mechanisms underlying atypical forms of diabetes are being actively studied.

EPIDEMIOLOGY AND GLOBAL CONSIDERATIONS

The worldwide prevalence of DM has risen dramatically over the past two decades, from an estimated 30 million cases in 1985 to 463 million in 2019 **(Fig. 403-2)**. Based on current trends, the IDF projects that 642 million individuals will have diabetes by the year 2040 (see *http://www.idf.org/*). Although the prevalence of both type 1 and type 2 DM is increasing worldwide, the prevalence of type 2 DM is rising much more rapidly, presumably because of dietary changes and increasing obesity, reduced activity levels as countries become more industrialized, and aging of the population. The incidence of type 1 diabetes has been increasing at a rate of 3% per year worldwide, with clear geographic differences. The cause for this increase is not well understood, but type 1 DM is increasingly being diagnosed at younger ages. In 2019, the prevalence of diabetes in individuals aged 20–79 years worldwide was 9.3%, ranging from 4.7–12.2%. The countries with the greatest number of individuals with diabetes in 2019 were China (116.4 million), India (77 million), the United States (31 million), Pakistan (19.4 million), Brazil (16.8 million), and Mexico (12.8 million). In the most recent estimate for the United States (2020), the Centers for Disease Control and Prevention (CDC) estimated that 10.5% of the population had diabetes. Diabetes affected 13% of all U.S. adults, and as many as 34% or 88 million U.S. adults had prediabetes. Approximately 21.4% of U.S. adults with diabetes in the United States were undiagnosed; globally, it is estimated that as many as 50% of individuals with diabetes may be undiagnosed. The prevalence of DM increases with age. The prevalence of DM in the United States was estimated to be 0.25% in individuals age <20 years, 4.2% in persons aged 18–44 years, and 17.5% in persons 45–64 years old. In individuals aged >65 years, the prevalence of DM was 26.8%. Similar age-related trends have been observed worldwide.

There is considerable geographic variation in the incidence of both type 1 and type 2 DM. Currently, Scandinavia, followed by Sardina and Portugal, have the highest incidence of type 1 DM; the lowest incidence is in the Pacific Rim where it is twenty- to thirtyfold lower. Northern Europe and the United States have an intermediate rate. Much of the increased risk of type 1 DM is believed to reflect the frequency of high-risk human leukocyte antigen (HLA) alleles among ethnic groups in different geographic locations. However, now populations less enriched with these classic high-risk HLA alleles are experiencing more rapid increases in type 1 DM incidence, suggesting an influence of environmental factors.

The prevalence of type 2 DM and its harbinger, IGT, is highest in certain Pacific islands and the Middle East and intermediate in countries such as India and the United States. This variability is likely due to genetic, behavioral, and environmental factors. DM prevalence also varies among different ethnic populations within a given country, with indigenous populations usually having a greater incidence of diabetes than the general population of the country. For example, the CDC estimated that the age-adjusted prevalence of DM in the United States (age >20 years; 2017–2018) was 7.5% in non-Hispanic whites, 9.2% in Asian Americans, 12.5% in Hispanics, and 11.7% in non-Hispanic blacks, but it exceeds 14% in American-Indian and Alaskan native populations. The onset of type 2 DM occurs, on average, at an earlier age in ethnic groups other than non-Hispanic whites. In Asia, the prevalence of diabetes is increasing rapidly, with an onset at a lower body mass index (BMI) and younger age, greater visceral adiposity, and reduced insulin secretory capacity.

Diabetes is a major cause of mortality. In recent years, diabetes has been listed as the seventh leading cause of death in the United States, but several studies indicate that diabetes-related deaths are likely underreported. In 2019, data from the IDF suggest that diabetes was responsible for nearly 4.2 million deaths worldwide, accounting for 11.3% of global all-cause mortality in adults aged 20–79 years. Diabetes also has important economic implications. In 2019, it was estimated that $760 billion of health care expenditures worldwide were spent on diabetes (a range of 8–19% of total expenditures across regions). Up to 75% of individuals with diabetes live in low- or middle-income countries.

DIAGNOSIS

Glucose tolerance is classified into three broad categories: normal glucose homeostasis, impaired glucose homeostasis, or DM (Fig. 403-1). Glucose tolerance can be assessed using the fasting plasma glucose (FPG), the response to oral glucose challenge, or the hemoglobin A_{1c} (HbA_{1c}). An FPG <5.6 mmol/L (100 mg/dL), a plasma glucose <7.9 mmol/L (140 mg/dL) following an oral glucose challenge, and an HbA_{1c} <5.7% are considered to define normal glucose tolerance. The International Expert Committee with members appointed by

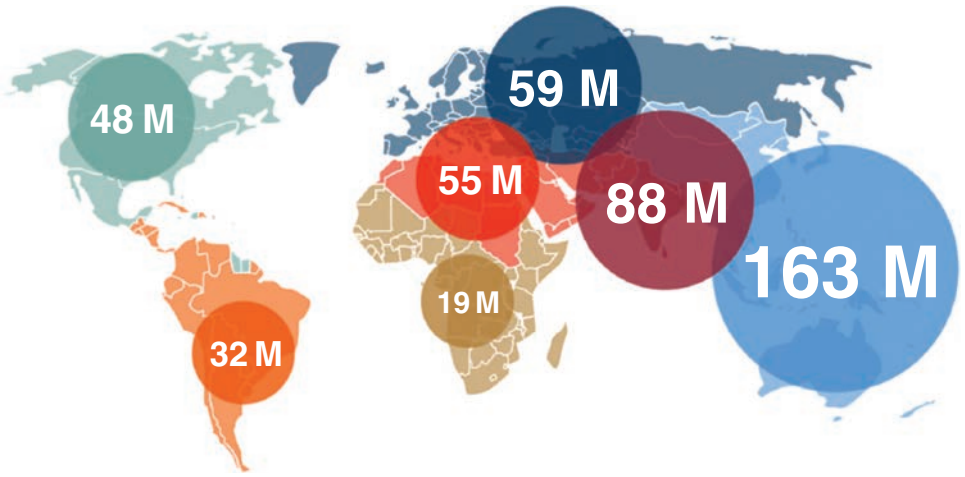

FIGURE 403-2 Worldwide prevalence of diabetes mellitus. Global estimate is 463 million individuals with diabetes in 2019. Regional estimates of the number of individuals with diabetes (20–79 years of age) are shown (2019). *(Data from the IDF Diabetes Atlas, 9th ed. The International Diabetes Federation; 2019.)*

TABLE 403-2 Criteria for Screening for Type 2 Diabetes Mellitus in Adults

1. Consider testing in overweight or obese (BMI ≥25 kg/m^2, ≥23 kg/m^2 in Asian Americans, or other ethnically relevant definition who have these risk factors:
   - Family history of diabetes (i.e., parent or sibling with type 2 diabetes)
   - Race/ethnicity (e.g., African American, Latino, Native American, Asian American, Pacific Islander)
   - Hypertension (blood pressure ≥140/90 mmHg)
   - HDL cholesterol level <35 mg/dL (0.90 mmol/L) and/or a triglyceride level >250 mg/dL (2.82 mmol/L)
   - Polycystic ovary syndrome or acanthosis nigricans
   - History of cardiovascular disease
   - Physical inactivity
   - Other condition associated with insulin resistance (severe obesity, acanthosis nigricans)
2. Individuals with previously identified IFG, IGT, or a hemoglobin A_{1c} of 5.7–6.4% should be screened annually.
3. Women who had GDM should be screened at least every 3 years.
4. For other individuals, initiate testing at 45 years of age and repeat every 3 years.
5. Individuals with HIV

Abbreviations: BMI, body mass index; GDM, gestational diabetes mellitus; HDL, high-density lipoprotein; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; HIV, human immunodeficiency virus.

Source: Adapted with permission from American Diabetes Association. 2. Classification and diagnosis of diabetes: Standards of medical care in diabetes-2021. Diabetes Care 44:S15, 2021.

the ADA, the European Association for the Study of Diabetes, and the IDF have issued diagnostic criteria for DM **(Table 403-2)** based on the following premises: (1) the FPG, the response to an oral glucose challenge (oral glucose tolerance test [OGTT]), and HbA_{1c} differ among individuals, and (2) DM is defined as the level of glycemia at which diabetes-specific complications occur rather than deviation from a population-based mean. For example, the prevalence of retinopathy in Native Americans (Pima Indian population) begins to increase at an FPG >6.4 mmol/L (116 mg/dL) **(Fig. 403-3)**.

Abnormal glucose homeostasis can be diagnosed by three distinct criteria (Fig. 403-1). First, *impaired fasting glucose* (IFG) is defined as a fasting plasma glucose (FPG) value of 5.6–6.9 mmol/L (100–125 mg/dL). Second, *impaired glucose tolerance* (IGT) is defined as a plasma glucose level of 7.8–11 mmol/L (140–199 mg/dL) following an oral glucose challenge. Third, an HbA_{1c} of 5.7–6.4% reflects dysglycemia by all mechanisms. While an HbA_{1c} of 5.7–6.4%, IFG, and IGT do not identify the same individuals (i.e., different biologic mechanisms involved), individuals in all three groups are at greater risk of progressing to type 2 DM, have an increased risk of cardiovascular disease, and should be counseled about ways to decrease these risks (see below). Some use the terms *prediabetes*, *increased risk of diabetes*, or *intermediate hyperglycemia* (World Health Organization) and slightly different metrics for this category.

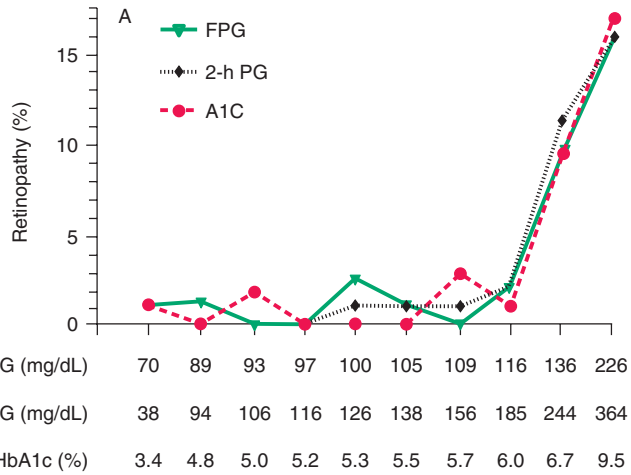

FIGURE 403-3 Relationship of diabetes-specific complication and glucose tolerance. This figure shows the incidence of retinopathy in Pima Indians as a function of the fasting plasma glucose (FPG), the 2-h plasma glucose after a 75-g oral glucose challenge (2-h PG), or the hemoglobin A_{1c} (HbA_{1c}). Note that the incidence of retinopathy greatly increases at a FPG >116 mg/dL, a 2-h PG of 185 mg/dL, or an HbA_{1c} >6.5%. (Blood glucose values are shown in mg/dL; to convert to mmol/L, divide value by 18.) *(Modified with permission from Expert Committee on the Diagnosis and Classification of Diabetes Mellitus: Report of the expert committee on the diagnosis and classification of diabetes mellitus. Diabetes Care 26:S5, 2003.)*

It is important to recognize that these values for the FPG, the glucose following an oral glucose challenge, and HbA_{1c} are continuous rather than discrete variables; risk for comorbidities increases continuously rather than discretely by diagnostic category. A FPG ≥7.0 mmol/L (126 mg/dL), a glucose ≥11.1 mmol/L (200 mg/dL) 2 h after an oral glucose challenge, or an HbA_{1c} ≥6.5% meets the criteria for the diagnosis of DM (Fig. 403-1). A random plasma glucose concentration ≥11.1 mmol/L (200 mg/dL) accompanied by classic symptoms of DM (polyuria, polydipsia, weight loss) is also sufficient for the diagnosis of DM. The current criteria for the diagnosis of DM emphasize the HbA_{1c} and the FPG as the most reliable and convenient tests for identifying DM in asymptomatic individuals. However, some individuals may meet criteria for one test but not the other. Also, it is important to note that race and ethnicity may impact the reliability of HbA_{1c} levels. For example, African Americans have a higher HbA_{1c} value compared to non-Hispanic whites with a similar level of glycemia. An OGTT, although a valid means for diagnosing DM, is not often used in routine clinical care with the exception of pregnancy care and screening for gestational diabetes.

The diagnosis of DM has profound implications for an individual from both a medical and a financial standpoint. Thus, abnormalities on screening tests for diabetes should be repeated before making a definitive diagnosis of DM, unless acute metabolic derangements or a markedly elevated plasma glucose are present. These criteria also allow for the diagnosis of DM to be withdrawn in situations when the glucose intolerance reverts to normal.

SCREENING

Widespread use of the FPG or the HbA_{1c} as a screening test for type 2 DM is recommended because (1) a large number of individuals who meet the current criteria for DM are asymptomatic and unaware that they have the disorder, (2) epidemiologic studies suggest that type 2 DM may be present for up to a decade before diagnosis, (3) some individuals with type 2 DM have one or more diabetes-specific complications at the time of their diagnosis, (4) treatment of type 2 DM may favorably alter the natural history of DM, and (5) diagnosis of prediabetes should spur efforts for diabetes prevention. The ADA recommends screening all individuals aged >45 years every 3 years and screening individuals at an earlier age if they are overweight (BMI >25 kg/m^2 or ethnically relevant definition for overweight) and have one additional risk factor for diabetes. Although a number of immunologic markers for type 1 DM are becoming available (discussed below), their routine use outside a clinical trial is discouraged, pending the identification of clinically beneficial interventions for individuals at high risk for developing type 1 DM.

REGULATION OF GLUCOSE HOMEOSTASIS

OVERALL REGULATION OF GLUCOSE HOMEOSTASIS

Glucose homeostasis reflects a balance between energy intake from ingested food, hepatic glucose production (gluconeogenesis), and peripheral tissue glucose uptake and utilization. Insulin is the most important regulator of this metabolic equilibrium, but neural input, metabolic signals, and other hormones (e.g., glucagon) result in integrated control of glucose supply and utilization **(Fig. 403-4)**. The organs that regulate glucose and lipids communicate by neural and humoral mechanisms with fat and muscle producing adipokines, myokines, and metabolites that influence liver function. In the fasting

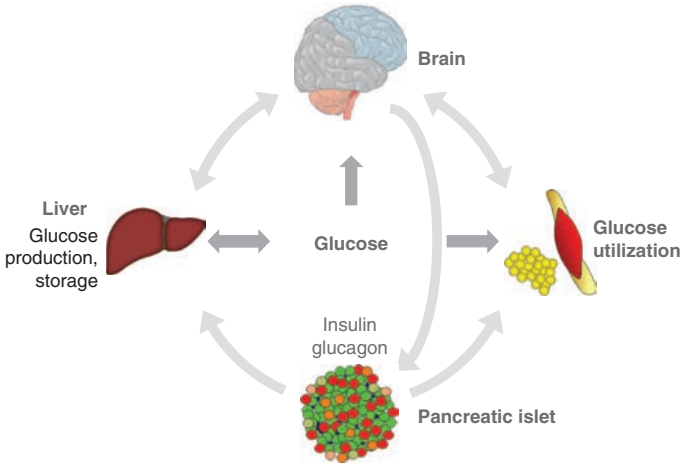

FIGURE 403-4 Regulation of glucose homeostasis. The organs shown contribute to glucose utilization, production, or storage. See text for a description of the communications (*arrows*), which can be neural or humoral. Although not shown, the GI tract and bone produce factors that influence glucose homeostasis.

state, low insulin levels, together with modest increases in glucagon, increase glucose production by promoting hepatic gluconeogenesis and glycogen breakdown (glycogenolysis). In parallel, glucose uptake in insulin-sensitive tissues (skeletal muscle and fat) is reduced, and there is increased mobilization of gluconeogenic precursors such as amino acids and free fatty acids (lipolysis). Under normal conditions alpha cells increase glucagon secretion only when blood glucose or insulin levels are low or during exercise, but it is increased in fasting and postprandially in DM and stimulates excess glycogenolysis and gluconeogenesis by the liver and to a small degree by the renal medulla **(Chap. 406)**. Conversely, in healthy people, the postprandial glucose load elicits a rise in insulin and fall in glucagon, leading to optimized glucose disposal. Insulin, an anabolic hormone, promotes the storage of carbohydrate and fat and protein synthesis. The major portion of postprandial glucose is utilized by skeletal muscle, an effect of insulin-stimulated glucose uptake. Other tissues, most notably the brain, utilize glucose in an insulin-independent fashion. Factors secreted by skeletal myocytes, adipocytes (e.g., leptin, resistin, adiponectin), and bone also influence glucose homeostasis.

INSULIN BIOSYNTHESIS

Insulin, produced by the beta cells of the pancreatic islets, is initially synthesized as a single-chain 86-amino-acid precursor polypeptide, preproinsulin. Subsequent proteolytic processing removes the amino-terminal signal peptide, giving rise to proinsulin. Proinsulin is structurally related to insulin-like growth factors I and II, which bind weakly to the insulin receptor. Cleavage of an internal 31-residue fragment from proinsulin generates C-peptide with the A (21 amino acids) and B (30 amino acids) chains of insulin being connected by disulfide bonds. The mature insulin molecule and C-peptide are stored together and co-secreted from secretory granules in the beta cells. Because C-peptide is cleared more slowly than insulin, it is a useful marker of insulin secretion and allows discrimination of endogenous and exogenous sources of insulin in the evaluation of hypoglycemia **(Chaps. 406 and 84)**. Elevated levels of serum proinsulin have been observed in both type 1 and 2 DM and are thought to be indicative of beta cell dysfunction. Pancreatic beta cells co-secrete islet amyloid polypeptide (IAPP) or amylin, a 37-amino-acid peptide, along with insulin. The role of IAPP in normal physiology is incompletely defined, but it is the major component of the amyloid fibrils found in the islets of patients with type 2 diabetes, and an analogue is sometimes used in treating type 1 and type 2 DM **(Chap. 404)**.

INSULIN SECRETION

Glucose is the key regulator of insulin secretion by the pancreatic beta cell, although amino acids, ketones, various nutrients, gastrointestinal peptides, and neurotransmitters also influence insulin secretion. Glucose levels >3.9 mmol/L (70 mg/dL) stimulate insulin synthesis,

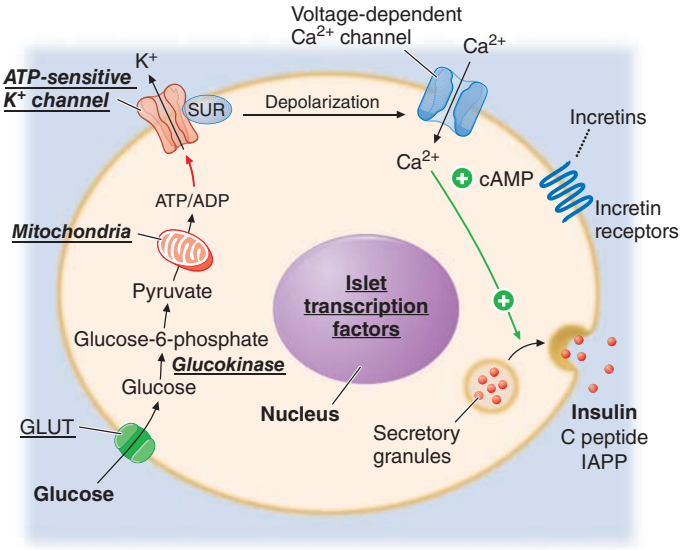

FIGURE 403-5 Mechanisms of glucose-stimulated insulin secretion and abnormalities in diabetes. Glucose and other nutrients regulate insulin secretion by the pancreatic beta cell. Glucose is transported by a glucose transporter (GLUT1 and/or GLUT2 in humans, GLUT2 in rodents); subsequent glucose metabolism by the beta cell alters ion channel activity, leading to insulin secretion. The SUR receptor is the binding site for some drugs that act as insulin secretagogues. Mutations in the events or proteins underlined are a cause of monogenic forms of diabetes. ADP, adenosine diphosphate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; IAPP, islet amyloid polypeptide or amylin; SUR, sulfonylurea receptor.

primarily by enhancing protein translation and processing. Glucose stimulation of insulin secretion begins with its transport into the beta cell by a facilitative glucose transporter **(Fig. 403-5)**. Glucose phosphorylation by glucokinase is the rate-limiting step that controls glucose-regulated insulin secretion. Further metabolism of glucose-6-phosphate via glycolysis generates ATP, which inhibits the activity of an ATP-sensitive K^+ channel. This channel consists of two separate proteins: one is the binding site for certain oral hypoglycemics (e.g., sulfonylureas, meglitinides); the other is an inwardly rectifying K^+ channel protein (Kir6.2). Inhibition of this K^+ channel induces beta cell membrane depolarization, which opens voltage-dependent calcium channels (leading to an influx of calcium) and stimulates insulin secretion. Insulin secretion occurs in two phases, a rapid first-phase response, and a more prolonged second phase. Impaired first-phase insulin responses are among the earliest detectable abnormalities during the progression of both T1DM and T2DM. A number of metabolic pathways internal to the beta cell as well as external cues amplify glucose-stimulated insulin secretion. Glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP) are incretin hormones that bind specific receptors on the beta cell to stimulate insulin secretion through cyclic AMP production, but they have this effect only when the blood glucose is above the fasting level. Incretin hormones also suppress glucagon production and secretion. Incretin analogues or pharmacologic agents that prolong the activity of endogenous GLP-1 are used to treat type 2 DM. Classically, GLP-1 release was thought to occur solely from neuroendocrine L-cells of the gastrointestinal tract following food ingestion. However, recent preclinical studies suggest that intraislet production of GLP-1 from alpha cells may play a role in the regulation of insulin secretion.

INSULIN ACTION

Insulin is secreted into the portal venous system and acts to suppress endogenous hepatic glucose production and increase hepatic glucose uptake. A large portion (50%) of secreted insulin is cleared by the liver in this first pass, yielding a portal to peripheral insulin concentration gradient of ~2:1, with important implications for the clinical use of exogenous insulin **(Ch. 404)**. Uncleared insulin enters the systemic circulation where it binds to receptors in peripheral target tissues such as skeletal muscle and adipose. Insulin binding to its receptor stimulates

intrinsic tyrosine kinase activity, leading to receptor autophosphorylation and the recruitment of intracellular signaling molecules, including the important insulin receptor substrates (IRS). IRS and other adaptor proteins initiate a complex cascade of phosphorylation and dephosphorylation reactions, resulting in the widespread metabolic and mitogenic effects of insulin. As an example, activation of the phosphatidylinositol-3′-kinase (PI-3-kinase) pathway stimulates translocation of a facilitative glucose transporter (e.g., GLUT4) to the cell surface, an event that is crucial for glucose uptake by skeletal muscle and fat. Activation of other insulin receptor signaling pathways induces glycogen synthesis, protein synthesis, lipogenesis, and regulation of various genes in insulin-responsive cells.

PATHOGENESIS

TYPE 1 DM

Type 1 DM is the result of interactions of genetic, environmental, and immunologic factors that ultimately lead to immune-mediated destruction of the pancreatic beta cells and insulin deficiency. Type 1 DM can develop at any age. Most, but not all, individuals with type 1 DM have evidence of islet-directed autoimmunity, which is detected by the presence of autoantibodies against beta cell antigens in the blood. The presence of two or more autoantibodies is now designated as stage 1 T1DM **(Fig. 403-6)**. The temporal decline of beta cell function and mass preceding the development of type 1 DM is shown schematically in Fig. 403-6. In susceptible individuals, the autoimmune process is thought to be triggered by an infectious or environmental stimulus. In the majority of patients, autoantibodies against beta cell antigens appear after this triggering event, followed by progressive loss of insulin secretion. The rate of decline in beta cell function varies widely among individuals, with some patients progressing rapidly to clinical diabetes and others evolving to diabetes more slowly and over a period of several years. Features of diabetes do not become evident until a threshold loss of insulin secretion and beta cell mass occurs. Autopsy studies suggest the degree of loss of beta cell mass is variable at the time of disease presentation. At this point, residual, functional beta cells exist but are insufficient in number and quality to maintain glucose tolerance. The events that trigger the transition from glucose intolerance to frank diabetes are often associated with increased insulin requirements, as might occur during infections or at puberty. After the initial clinical presentation of type 1 DM, a "honeymoon" phase may ensue during which time glycemic control is achieved with modest doses of insulin or, rarely, insulin is not needed. However, this fleeting phase of endogenous insulin production from residual beta cells disappears and the individual becomes insulin deficient. Many individuals with long-standing type 1 DM produce a small amount of insulin (as reflected by C-peptide production), and autopsy studies show that beta cells can persist in the pancreas decades after diagnosis.

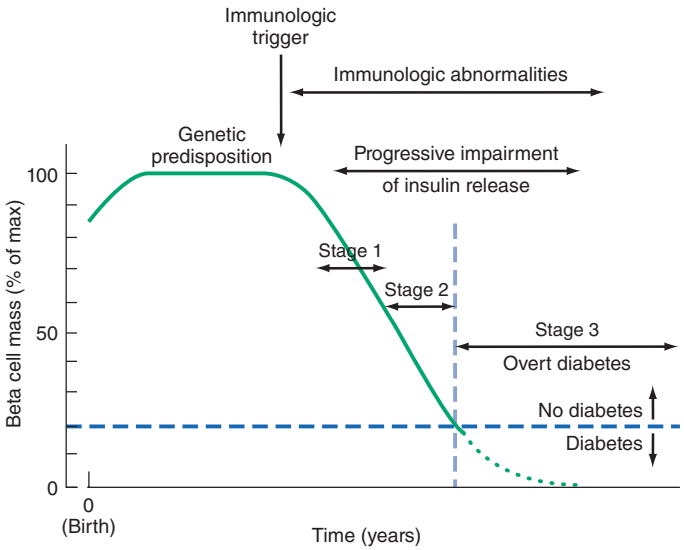

FIGURE 403-6 Temporal model for development of type 1 diabetes. Individuals with a genetic predisposition are exposed to a trigger that initiates an autoimmune process, resulting in the development of islet autoantibodies and a gradual decline in beta cell function and mass. Stage 1 disease is characterized by the development of two or more islet cell autoantibodies but the maintenance of normoglycemia. Stage 2 disease is defined by continued autoimmunity and the development of dysglycemia. Stage 3 is defined by the development of hyperglycemia that exceeds the diagnostic criteria for the diagnosis of diabetes. The downward slope of the beta cell function varies among individuals and may not be continuous. A "honeymoon" phase may be seen in the first 1 or 2 years after the onset of diabetes and is associated with reduced insulin requirements. *(Modified with permission from ER Kaufman: Medical Management of Type 1 Diabetes, 6th ed. Alexandria, VA: American Diabetes Association; 2012.)*

GENETIC CONSIDERATIONS

Susceptibility to type 1 DM involves multiple genes. The concordance of type 1 DM in identical twins ranges from 30–70%, indicating that additional modifying factors are likely involved in determining whether diabetes develops. The major susceptibility gene for type 1 DM is located in the HLA region on chromosome 6. Polymorphisms in the HLA complex account for approximately 50% of the genetic risk of developing type 1 DM. This region contains genes that encode the class II major histocompatibility complex (MHC) molecules, which present antigen to helper T cells and thus are involved in initiating the immune response **(Chap. 349)**. The ability of class II MHC molecules to present antigen is dependent on the amino acid composition of their antigen-binding sites. Amino acid substitutions may influence the specificity of the immune response by altering the binding affinity of different antigens for class II molecules.

Many individuals with type 1 DM have the HLA DR3 and/or DR4 haplotype. Refinements in genotyping of HLA loci have shown that the haplotypes DQA1*0301, DQB1*0302, and DQB1*0201 are most strongly associated with type 1 DM. These haplotypes are present in 40% of children with type 1 DM as compared to 2% of the U.S. population without type 1 DM. However, most individuals with predisposing haplotypes do not develop diabetes.

In addition to MHC class II associations, genome-wide association studies have identified more than 60 additional genetic loci that contribute susceptibility to type 1 DM (i.e., polymorphisms in the promoter region of the insulin gene, the CTLA-4 gene, interleukin 2 receptor, and PTPN22, etc.). Combined assessment of HLA and non-HLA loci using genetic risk scores has been used to improve prediction of type 1 diabetes risk. Notably, among recent cohorts of individuals with new-onset type 1 diabetes, there is a decreased representation of the highest-risk HLA alleles and increasing penetrance of disease in genotypes classically associated with lower risk, suggesting environmental factors may have an increasing role in disease pathogenesis. Genes that confer protection against the development of the disease also exist. The haplotype DQA1*0102, DQB1*0602 is extremely rare in individuals with type 1 DM (<1%) and appears to provide protection from type 1 DM.

Although the risk of developing type 1 DM is increased in relatives of individuals with the disease, the risk is relatively low: 1–9% if the parent has type 1 DM and 6–7% in a sibling (depending on which HLA haplotypes are shared). Hence, the majority of individuals with type 1 DM (>90%) do not have a relative with this disorder.

Pathophysiology Pathologically, the pancreatic islets demonstrate a modest infiltration of lymphocytes (a process termed *insulitis*); however, the frequency of insulitis is heterogeneous both within and between individuals. Studies of the autoimmune process have identified the following abnormalities in the innate and adaptive arms of the immune system: (1) islet cell autoantibodies (ICAs); (2) activated lymphocytes in the islets, and peripancreatic lymph nodes; (3) T lymphocytes that proliferate when stimulated with islet proteins; and (4) release of cytokines within the insulitis. Islet cell autoantibodies (ICAs) are a composite of several different antibodies directed at pancreatic islet molecules such as GAD, insulin, IA-2/ICA-512, and ZnT-8, and serve as a marker of the autoimmune process of type 1 DM. Testing for ICAs can be useful in classifying the type of DM as type 1 as they are

present in the majority of individuals (>85%) diagnosed with new-onset type 1 DM. ICAs can also identify nondiabetic individuals at risk for developing type 1 DM, although their use for this purpose has been restricted mostly to research studies. In children with high genetic risk followed as part of several birth cohort studies, the presence of two or more ICAs was associated with a nearly 70% risk of developing type 1 DM after 10 years of follow-up and an 80% risk of developing diabetes after 15 years of follow-up. These observations led to a revision in the staging system for type 1 DM (Fig. 403-5), in which the development of multiple autoantibodies is now defined as the onset of stage 1 type 1 DM. While ICAs can be detected in the serum, and their presence is an important biomarker of type 1 diabetes risk, the antibodies do not have a direct role in beta cell death. Beta cell destruction is mediated by direct CD8+ T cell–mediated cytotoxicity. Beta cells may exacerbate this process through the development of modified proteins or "neoantigens" and through increased presentation of these antigens on their cell surface via upregulation of MHC class I molecules. In addition, beta cells may be damaged by the toxic effects of cytokines (i.e., tumor necrosis factor α [TNF-α], interferon γ, and interleukin 1 [IL-1]) as well as reactive oxygen species generated by infiltrating immune cells. Efforts to suppress the autoimmune process at the time of diagnosis of diabetes have largely been ineffective or only temporarily effective in slowing beta cell destruction. Thus, increased emphasis has now been placed on intervening earlier in the disease course (i.e., during stage 1 and 2 disease; Fig. 403-6). In support of this notion, a single 14-day course of teplizumab, an Fc receptor-nonbinding anti-CD3 monoclonal antibody, delayed the onset of stage 3 T1D in high-risk individuals with multiple autoantibodies and dysglycemia (i.e., stage 2 T1D) by a median of 2.7 years.

Although other islet cell types (alpha cells [glucagon-producing], delta cells [somatostatin-producing], or PP cells [pancreatic polypeptide-producing]) are functionally and embryologically similar to beta cells, they are spared from the autoimmune destruction. However, altered patterns of hormone secretion from these other cell types in type 1 DM likely contribute to metabolic instability. Alpha cell dysfunction is reflected by fasting and post-prandial hyperglucagonemia but an impaired glucagon response to hypoglycemia.

Environmental Factors Numerous environmental events have been proposed to trigger the autoimmune process in genetically susceptible individuals; however, none has been conclusively linked to diabetes. Identification of an environmental trigger has been difficult because the event may precede the onset of DM by several years (Fig. 403-6). Putative environmental triggers include viruses (coxsackie, rubella, enteroviruses most prominently), bovine milk proteins, nitrosourea compounds, vitamin D deficiency, and environmental toxins. There is increasing interest in the microbiome and type 1 diabetes **(Chap. 471)**.

TYPE 2 DM

Insulin resistance and abnormal insulin secretion are central to the development of type 2 DM. Although the primary defect is controversial, most studies support the view that insulin resistance precedes an insulin secretory defect but that diabetes develops only when insulin secretion becomes inadequate. Type 2 DM likely encompasses a range of disorders with the common phenotype of hyperglycemia. Historically, our understanding of the pathophysiology and genetics is based on studies of individuals of European descent. Studies in more diverse populations have yielded unique insights into pathophysiologic differences among ethnic groups. In general, Latinos have greater insulin resistance and East Asians and South Asians have more beta cell dysfunction, but both defects are present in both populations. East and South Asians appear to develop type 2 DM at a younger age and a lower BMI. In some groups, DM that is ketosis prone (often in obese individuals) or ketosis-resistant (often lean) is sometimes seen. For example, African Americans can be more prone to nonketotic hyperosmolar presentation of diabetes exacerbations. In many forms of type 2 DM, the social determinants of health play a major role in the rates of type 2 DM.

GENETIC CONSIDERATIONS

Type 2 DM has a strong genetic component. The concordance of type 2 DM in identical twins is between 70% and 90%. Individuals with a parent with type 2 DM have an increased risk of diabetes; if both parents have type 2 DM, the risk approaches 70%. Insulin resistance, as demonstrated by reduced glucose utilization in skeletal muscle, is present in many nondiabetic, first-degree relatives of individuals with type 2 DM. The disease is polygenic and multifactorial, because in addition to genetic susceptibility, environmental factors (such as obesity, poor nutrition, and physical inactivity) modulate the phenotype. Shared environmental and lifestyle factors also contribute to the high concordance in families. Further, the in utero environment contributes to, and either increased or reduced birth weight increases the risk of type 2 DM in adult life. Children of pregnancies complicated by gestational hyperglycemia also exhibit an increased risk of type 2 DM.

The genes that predispose to type 2 DM are incompletely identified, but genome-wide association studies have identified a large number of genes that convey a relatively small risk for type 2 DM (several hundred genes each with a relative risk of 1.06–1.5). Most prominent is a variant of the transcription factor 7-like 2 gene that has been associated with both type 2 DM and IGT in several populations. Genetic polymorphisms associated with type 2 DM have also been found in the genes encoding the peroxisome proliferator–activated receptor γ, inward rectifying potassium channel, zinc transporter, IRS, and calpain 10. The mechanisms by which these genetic loci increase the susceptibility to type 2 DM are not clear, but most are predicted to alter islet function or development or insulin secretion. Although the genetic susceptibility to type 2 DM is under active investigation (it is estimated that <10% of genetic risk is determined by loci identified thus far), it is currently not possible to use a combination of known genetic loci to reliably predict type 2 DM.

Pathophysiology Type 2 DM is characterized by impaired insulin secretion, insulin resistance, excessive hepatic glucose production, abnormal fat metabolism, and systemic low-grade inflammation. Obesity, particularly visceral or central (as evidenced by the hip-waist ratio), is very common in type 2 DM (≥80% of patients are obese). In the early stages of the disorder, glucose tolerance remains near-normal, despite insulin resistance, because the pancreatic beta cells compensate by increasing insulin output **(Fig. 403-7)**. A number

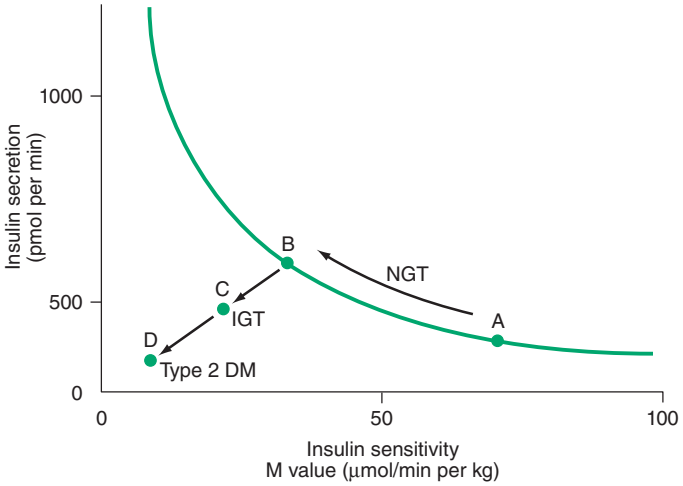

FIGURE 403-7 Metabolic changes during the development of type 2 diabetes mellitus (DM). Insulin secretion and insulin sensitivity are related, and as an individual becomes more insulin resistant (by moving from point A to point B), insulin secretion increases. A failure to compensate by increasing the insulin secretion results initially in impaired glucose tolerance (IGT; point C) and ultimately in type 2 DM (point D). NGT, normal glucose tolerance. *(Data from SE Kahn: Clinical review 135: The importance of beta-cell failure in the development and progression of type 2 diabetes. J Clin Endocrinol Metab 86:4047, 2001 and RN Bergman, M Ader: Free fatty acids and pathogenesis of type 2 diabetes mellitus. Trends Endocrinol Metab 11:351, 2000.)*

of pathophysiologic mechanisms contribute to type 2 DM and their relative importance varies from individual to individual. As insulin resistance and compensatory hyperinsulinemia progress, the pancreatic islets in certain individuals are unable to sustain the hyperinsulinemic state, manifesting as IGT, defined as elevations in postprandial glucose. A decline in insulin secretion and/or increased glucagon secretion causes an increase in hepatic glucose production leading to fasting hyperglycemia. Ultimately, frank beta cell failure ensues as a combination of these mechanisms leading to the manifestation of type 2 diabetes.

Metabolic Abnormalities Insulin resistance, the decreased ability of insulin to act effectively on target tissues (especially muscle, liver, and fat), is a prominent feature of type 2 DM and results from a combination of genetic susceptibility, obesity, and metabolic inflammation. Insulin resistance is relative, however, because supranormal levels of circulating insulin will normalize the plasma glucose. In type 2 DM, both insulin potency and efficacy are reduced leading to an overall decrease in glucose utilization under many conditions (30–60% lower than in normal individuals). Insulin resistance impairs glucose utilization by insulin-sensitive tissues (skeletal muscle) and in liver, coupled with elevated glucagon, leads to increased hepatic glucose output. Increased hepatic glucose output predominantly accounts for increased FPG levels, whereas decreased peripheral glucose utilization results in postprandial hyperglycemia.

The precise molecular mechanism leading to insulin resistance in type 2 DM has not been elucidated. Insulin receptor levels and tyrosine kinase activity in skeletal muscle are reduced, but these alterations are most likely secondary to hyperinsulinemia and are not a primary defect. Therefore, "postreceptor" defects in insulin-regulated phosphorylation/dephosphorylation appear to play the predominant role in insulin resistance. Abnormalities include the accumulation of lipid intermediates within skeletal myocytes, which may impair mitochondrial oxidative phosphorylation and reduce insulin-stimulated mitochondrial ATP production. Impaired fatty acid oxidation and lipid accumulation within skeletal myocytes also may generate reactive oxygen species such as lipid peroxides. These and other mechanisms also generate low-grade metabolic inflammation that feeds back and directly worsens insulin resistance. Of note, not all insulin signal transduction pathways are resistant to the effects of insulin (e.g., those controlling cell growth and differentiation using the mitogen-activated protein kinase pathway). Consequently, hyperinsulinemia may increase the insulin action through these pathways, potentially accelerating diabetes-related conditions such as atherosclerosis.

The obesity accompanying type 2 DM, particularly in a central or visceral location, is thought to be part of the pathogenic process (Chap. 401). In addition to these white fat depots, humans have brown fat, which has much greater thermogenic capacity. Efforts are underway to increase the activity or quantity of brown fat. The increased adipocyte mass leads to increased levels of circulating free fatty acids and other fat cell products. For example, adipocytes secrete a number of biologic products (nonesterified free fatty acids, retinol-binding protein 4, leptin, TNF-α, resistin, IL-6, and adiponectin). Further, adipose resident macrophages are an important source of metabolic inflammation in diabetes. In addition to regulating body weight, appetite, and energy expenditure, adipokines also modulate insulin sensitivity. The increased production of free fatty acids and some adipokines may cause insulin resistance in skeletal muscle and liver. The venous drainage of the visceral adipose beds is the portal circulation and this likely contributes to hepatic dysfunction. Free fatty acids also impair glucose utilization in skeletal muscle, promote glucose production by the liver, and impair beta cell function. In contrast, the production by adipocytes of adiponectin, an insulin-sensitizing peptide, is reduced in obesity, and this may contribute to hepatic insulin resistance. Adipocyte products and adipokines also produce an inflammatory state and may explain why markers of inflammation such as IL-6 and C-reactive protein are often elevated in type 2 DM.

IMPAIRED INSULIN SECRETION Insulin secretion and sensitivity are interrelated (Fig. 403-7). In type 2 DM, insulin secretion initially increases in response to insulin resistance to maintain normal glucose tolerance. Initially, the insulin secretory defect is mild and selectively involves glucose-stimulated insulin secretion, including a greatly reduced first secretory phase. The response to other nonglucose secretagogues, such as arginine, is preserved, but overall beta cell function is reduced by as much as 50% at the onset of type 2 DM. Abnormalities in proinsulin processing are reflected by increased secretion of proinsulin in type 2 DM. Eventually, the insulin secretory defect is progressive.

The reason(s) for the decline in insulin secretory capacity in type 2 DM is unclear. The assumption is that a second genetic defect—superimposed upon insulin resistance—leads to defects in beta cell function, mass, and potentially cellular identity and differentiation status. Islet amyloid polypeptide or amylin, co-secreted by the beta cell, forms amyloid fibrillar deposits found in the islets of individuals with long-standing type 2 DM. Whether such islet amyloid deposits are a primary or secondary event is not known. The metabolic environment of diabetes also negatively impacts islet function. For example, chronic hyperglycemia paradoxically impairs islet function ("glucose toxicity") and leads to a worsening of hyperglycemia. Improvement in glycemic control is often associated with improved islet function, an important clinical consideration. In addition, elevated levels of free fatty acids ("lipotoxicity"), and systemic and local elevations in pro-inflammatory cytokines from increased numbers of islet-associated macrophages, may also worsen islet function.

INCREASED HEPATIC GLUCOSE AND LIPID PRODUCTION In type 2 DM, insulin resistance in the liver reflects the failure of hyperinsulinemia to suppress gluconeogenesis, which results in fasting hyperglycemia and decreased glycogen storage by the liver in the postprandial state. Increased hepatic glucose production occurs early in the course of diabetes, although likely after the onset of insulin and glucagon secretory abnormalities and insulin resistance in skeletal muscle. As a result of insulin resistance in adipose tissue, lipolysis and free fatty acid flux from adipocytes are increased and efficiently cleared by liver leading to increased very-low-density lipoprotein (VLDL)-triglyceride synthesis in hepatocytes and secretion from liver. This is also responsible for the dyslipidemia found in type 2 DM (elevated triglycerides, reduced high-density lipoprotein [HDL], and increased small dense low-density lipoprotein [LDL] particles). If this lipid is retained, steatosis in the liver may lead to nonalcoholic fatty liver disease and abnormal liver function tests.

Insulin Resistance Syndromes The insulin resistance condition comprises a spectrum of disorders, with hyperglycemia representing one of the most readily diagnosed features. The *metabolic syndrome*, the *insulin resistance syndrome*, and *syndrome X* are terms used to describe a constellation of metabolic derangements that includes insulin resistance, hypertension, dyslipidemia (decreased HDL and elevated triglycerides), central or visceral obesity, type 2 DM or IGT/IFG, and accelerated cardiovascular disease. This syndrome is discussed in Chap. 408.

A number of relatively rare forms of severe insulin resistance include features of type 2 DM or IGT (Table 403-1). Mutations in the insulin receptor that interfere with binding or signal transduction are a rare cause of insulin resistance. Acanthosis nigricans and signs of hyperandrogenism (hirsutism, acne, and oligomenorrhea in women) are also common physical features. Two distinct syndromes of severe insulin resistance have been described in adults: (1) type A, which affects young women more severely and is characterized by severe hyperinsulinemia, obesity, and features of hyperandrogenism; and (2) type B, which affects middle-aged women and is characterized by severe hyperinsulinemia, features of hyperandrogenism, and autoimmune disorders. Individuals with type A insulin resistance syndrome have an undefined defect in the insulin-signaling pathway; individuals with type B insulin resistance syndrome have autoantibodies directed

at the insulin receptor. These receptor autoantibodies may block insulin binding or may stimulate the insulin receptor, leading to intermittent hypoglycemia.

Polycystic ovary syndrome (PCOS) is a common disorder that affects premenopausal women and is characterized by chronic anovulation and hyperandrogenism **(Chap. 392)**. Insulin resistance is seen in a significant subset of women with PCOS, and the disorder substantially increases the risk for type 2 DM, independent of the effects of obesity.

Lipodystrophies are a group of heterogeneous disorders characterized by selective loss of adipose tissue, leading to severe insulin resistance and hypertriglyceridemia. Lipodystrophies can be inherited or acquired and associated with variable degrees of adipose tissue loss.

Prevention Type 2 DM is preceded by a period of IGT or IFG, and a number of lifestyle modifications and pharmacologic agents prevent or delay the onset of DM. Individuals with prediabetes or increased risk of diabetes should be referred to a structured program to reduce body weight and increase physical activity as well as being screened for cardiovascular disease. The Diabetes Prevention Program (DPP) demonstrated that intensive changes in lifestyle (diet and exercise for 30 min/d five times/week) in individuals with IGT prevented or delayed the development of type 2 DM by 58% compared to placebo. This effect was seen in individuals regardless of age, sex, or ethnic group. In the same study, metformin prevented or delayed diabetes by 31% compared to placebo. The lifestyle intervention group lost 5–7% of their body weight during the 3 years of the study; the effects of the intervention persisted for at least 15 years. Studies in Finnish and Chinese populations noted similar efficacy of diet and exercise in preventing or delaying type 2 DM. A number of agents, including α-glucosidase inhibitors, metformin, thiazolidinediones, GLP-1 receptor pathway modifiers, SGLT-2 inhibitors, and orlistat, prevent or delay type 2 DM but are not approved by the U.S. Food and Drug Administration for this purpose. Individuals with a strong family history of type 2 DM and individuals with IFG or IGT should be strongly encouraged to achieve a normal BMI and engage in regular physical activity. Pharmacologic therapy for individuals with prediabetes is currently controversial because its cost-effectiveness and safety profile are not known. The ADA suggests that metformin be considered in individuals with both IFG and IGT who are at very high risk for progression to diabetes (age <60 years, BMI ≥35 kg/m^2, and women with a history of GDM). Individuals with IFG, IGT, or an HbA_{1c} of 5.7–6.4% should be monitored annually to determine if diagnostic criteria for diabetes are present.

GENETICALLY DEFINED, MONOGENIC FORMS OF DM RELATED TO REDUCED INSULIN SECRETION

Several monogenic forms of DM have been identified. Cases of maturity-onset diabetes of the young (MODY) or monogenic diabetes are caused by mutations in genes encoding islet-enriched transcription factors or glucokinase (Fig. 403-5; Table 403-1) and present with an autosomal dominant mode of transmission. MODY 1, MODY 3, and MODY 5 are caused by mutations in hepatocyte nuclear transcription factor (HNF) 4α, HNF-1α, and HNF-1β, respectively. As their names imply, these transcription factors are expressed in the liver but also in other tissues, including the pancreatic islets and kidney. These factors most likely affect islet development, the expression of genes important in glucose-stimulated insulin secretion or the maintenance of beta cell mass. For example, individuals with an HNF-1α mutation (MODY 3) have a progressive decline in glycemic control but may respond to sulfonylureas. In fact, some of these patients were initially thought to have type 1 DM but were later shown to respond to a sulfonylurea, and insulin was discontinued, a major clinical implication. Individuals with an HNF-1β mutation have progressive impairment of insulin secretion and hepatic insulin resistance, and require insulin treatment with minimal response to sulfonylureas. These individuals often have other abnormalities such as renal cysts, mild pancreatic exocrine insufficiency, and abnormal liver function tests. Individuals with MODY 2, the result of mutations in the glucokinase gene, have mild-to-moderate, but stable hyperglycemia that does not respond to oral hypoglycemic agents, and otherwise does not require treatment. Glucokinase catalyzes the formation of glucose-6-phosphate from glucose, a reaction that is important for glucose sensing by the beta cells (Fig. 403-5) and for glucose utilization by the liver. As a result of glucokinase mutations, higher glucose levels are required to elicit insulin secretory responses, thus altering the set point for insulin secretion. MODY 4 is a rare variant caused by mutations in pancreatic and duodenal homeobox 1, a transcription factor that regulates pancreatic development and insulin gene transcription. Homozygous inactivating mutations cause pancreatic agenesis, whereas heterozygous mutations may result in DM. Studies of populations with type 2 DM suggest that mutations in MODY-associated genes are an uncommon (<5%) cause of type 2 DM.

Transient or permanent neonatal diabetes (onset <6 months of age) occurs. Permanent neonatal diabetes is a heterogeneous group of disorders caused by genetic mutations that impact beta cell function and/or pancreatic development (Fig. 403-5). Affected individuals typically require treatment with insulin and exhibit phenotypic overlap with type 1 DM. Activating mutations in the ATP-sensitive potassium channel subunits (Kir6.2 and ABCC8) impair glucose-stimulated insulin secretion. However, these individuals may respond to sulfonylureas and can be treated with these agents. Mutations in the transcription factor *GATA6* are the most common cause of pancreatic agenesis. Homozygous glucokinase mutations cause a severe form of neonatal diabetes, while mutations in mitochondrial DNA are associated with diabetes and deafness. A number of mutations identified in the coding sequence of the insulin gene have been found to interfere with proinsulin folding, processing, and bioactivity and are designated as Mutant *Ins*-gene-induced Diabetes of Youth (MIDYs). Some of the neonatal diabetes syndromes are associated with a spectrum of neurologic dysfunction and a variety of extrapancreatic manifestations. Any individual who developed diabetes at 6 months of age or who has atypical features of type 1 or type 2 diabetes should be screened for forms of monogenic diabetes.

APPROACH TO THE PATIENT

Diabetes Mellitus

Once the diagnosis of DM is made, attention should be directed to symptoms related to diabetes (acute and chronic) and classifying the type of diabetes. DM and its complications produce a wide range of symptoms and signs; those secondary to acute hyperglycemia may occur at any stage of the disease, whereas those related to chronic hyperglycemia typically begin to appear during the second decade of hyperglycemia **(Chap. 405)**. Because of long delays in clinical recognition, individuals with previously undetected type 2 DM may present with chronic complications of DM at the time of diagnosis. The history and physical examination should assess for symptoms or signs of acute hyperglycemia and screen for chronic microvascular and macrovascular complications and conditions associated with DM **(Chap. 405)**.

HISTORY

A complete medical history should be obtained with special emphasis on DM-relevant aspects such as current weight as well as any recent changes in weight, family history of DM and its complications, sleep history, risk factors for cardiovascular disease, exercise, smoking status, history of pancreatic disease, and ethanol use. Symptoms of hyperglycemia include polyuria, polydipsia, weight loss, fatigue, weakness, blurry vision, frequent superficial infections (vaginitis, fungal skin infections), and slow healing of skin lesions after minor trauma. Metabolic derangements relate mostly to hyperglycemia (osmotic diuresis) and to the catabolic state of the patient (urinary loss of glucose and calories, muscle breakdown due

to protein degradation and decreased protein synthesis). Blurred vision results from changes in the water content of the lens and resolves as hyperglycemia is controlled.

In a patient with established DM, the initial assessment should include a review of symptoms at the time of the initial diabetes diagnosis. This is an essential part of the history that can help define whether the correct type of DM has been diagnosed. Special emphasis should be placed on prior diabetes care, including types of therapies tried, the nature of any intolerance to previous therapies, prior HbA_{1c} levels, self-monitoring blood glucose results, frequency of hypoglycemia (<3.0 mmol/L, <54 mg/dL), presence of DM-specific complications, and assessment of the patient's knowledge about diabetes, exercise, nutrition, and sleep history. Diabetes-related complications may afflict several organ systems, and an individual patient may exhibit some, all, or none of the symptoms related to the complications of DM **(Chap. 405)**. In addition, the presence of DM-related comorbidities should be established (cardiovascular disease, hypertension, dyslipidemia). Pregnancy plans should be ascertained in women of childbearing age. The American Diabetes Association recommends that all women of childbearing age be counseled about the importance of tight glycemic control (HbA_{1c} <6.5%) prior to conception.

PHYSICAL EXAMINATION

In addition to a complete physical examination, special attention should be given to DM-relevant aspects such as weight and BMI, retinal examination, orthostatic blood pressure, foot examination, peripheral pulses, and insulin injection sites. Depending on other risk factors, a blood pressure >130/80 mmHg or >140/90 mmHg is considered hypertension in individuals with diabetes. Because periodontal disease is more frequent in DM, the teeth and gums should also be examined.

An annual foot examination should (1) assess blood flow (pedal pulses), sensation (vibratory sensation [128-MHz tuning fork at the base of the great toe], the ability to sense touch with a monofilament [5.07, 10-g monofilament]), pinprick sensation, ankle reflexes, and nail care; (2) look for the presence of foot deformities such as hammer or claw toes and Charcot foot; and (3) identify sites of potential ulceration. The ADA recommends annual screening for distal symmetric polyneuropathy beginning with the initial diagnosis of diabetes and annual screening for autonomic neuropathy 5 years after diagnosis of type 1 DM and at the time of diagnosis of type 2 DM. This testing is aimed at detecting loss of protective sensation (LOPS) caused by diabetic neuropathy **(Chap. 405)**.

CLASSIFICATION OF DM IN AN INDIVIDUAL PATIENT

The etiology of diabetes in an individual with new-onset disease can usually be assigned on the basis of clinical criteria. Individuals with type 1 DM are more likely to have the following characteristics: (1) lean body habitus; (2) requirement of insulin as the initial therapy; (3) propensity to develop ketoacidosis; and (4) a family or personal history of other autoimmune disorders such as autoimmune thyroid disease, adrenal insufficiency, pernicious anemia, celiac disease, and vitiligo. In contrast, individuals with type 2 DM often exhibit the following features: (1) obesity; 80% are obese, but elderly individuals may be lean; (2) may not require insulin therapy initially; and (3) may have associated conditions such as insulin resistance, hypertension, cardiovascular disease, dyslipidemia, or polycystic ovarian syndrome. In type 2 DM, insulin resistance is often associated with abdominal obesity (as opposed to hip and thigh obesity) and hypertriglyceridemia. Although most individuals diagnosed with type 2 DM are older, the age of diagnosis is declining, and there is a marked increase among overweight children and adolescents. Some individuals with phenotypic type 2 DM present with diabetic ketoacidosis but lack autoimmune markers and may be later treated with oral glucose-lowering agents rather than insulin (this clinical picture is sometimes referred to as *ketosis-prone type 2 DM*). On the other hand, some individuals (5–10%) with the phenotypic appearance of type 2 DM do not have absolute insulin deficiency but have autoimmune markers (GAD and other ICA autoantibodies) suggestive of type 1 DM (sometimes termed *latent autoimmune diabetes of the adult*). Such individuals are more likely to require insulin treatment within 5 years. Monogenic forms of diabetes should be considered in those with diabetes onset in childhood or early adulthood and especially those diagnosed within the first 6 months of life, an autosomal pattern of diabetes inheritance, diabetes without typical features of type 1 or 2 diabetes, and stable mild fasting hyperglycemia. Genetic testing should be considered in individuals suspected of having a monogenic form of diabetes as this may guide therapy selection. Despite recent advances in the understanding of the pathogenesis of diabetes, it often remains difficult to categorize some patients unequivocally. Individuals who deviate from the clinical profile of type 1 and type 2 DM, or who have other associated defects such as deafness, pancreatic exocrine disease (type 3c DM), and other endocrine disorders, should be classified accordingly (Table 403-1). A major goal is personalized or precision medicine in the diagnosis and treatment of diabetes.

LABORATORY ASSESSMENT

The laboratory assessment should first determine whether the patient meets the diagnostic criteria for DM (Fig. 403-1) and then assess the degree of glycemic control **(Chap. 404)**. In addition to the standard laboratory evaluation, the patient should be screened for DM-associated conditions (e.g., albuminuria, dyslipidemia, thyroid dysfunction).

The classification of the type of DM may be facilitated by laboratory assessments. Serum C-peptide measurements may be useful but should always be interpreted with a concurrent blood glucose level. A low C-peptide in the setting of an elevated blood glucose level may confirm a patient's need for insulin. However, C-peptide levels are unable to completely distinguish type 1 from type 2 DM as many individuals with type 1 DM retain some C-peptide production. Measurement of islet cell antibodies at the time of diabetes onset may be useful if the type of DM is not clear based on the characteristics described above.

404 Diabetes Mellitus: Management and Therapies

Alvin C. Powers, Michael J. Fowler, Michael R. Rickels

OVERALL GOALS

The goals of therapy for type 1 or type 2 diabetes mellitus (DM) are to (1) eliminate symptoms related to hyperglycemia, (2) reduce or eliminate the long-term microvascular and macrovascular complications of DM (Chap. 405), and (3) allow the patient to achieve as normal a lifestyle as possible. To reach these goals, the physician should identify a target level of glycemic control for each patient, provide the patient with the educational and pharmacologic resources necessary to reach this level, and monitor/treat DM-related complications. Symptoms of diabetes usually resolve when the plasma glucose is <11.1 mmol/L (200 mg/dL), and thus most DM treatment focuses on achieving the second and third goals. This chapter first reviews the ongoing treatment of diabetes in the outpatient setting and then discusses the treatment of severe hyperglycemia, as well as the treatment of diabetes in hospitalized patients.

The care of an individual with either type 1 or type 2 DM requires a multidisciplinary team. Central to the success of this team are the patient's participation, input, and enthusiasm, all of which are essential for optimal diabetes management. Members of the health care team usually include the primary care provider and/or the endocrinologist or diabetologist, a certified diabetes educator, a nutritionist, a psychologist, and possibly a social worker. In addition, when the complications of DM arise, subspecialists (including ophthalmologists, neurologists, podiatrists, nephrologists, cardiologists, and cardiovascular surgeons) with experience in DM-related complications are essential.

ONGOING ASPECTS OF COMPREHENSIVE DIABETES CARE

A number of names are sometimes applied to different approaches to diabetes care, such as intensive insulin therapy, intensive glycemic control, and "tight control." The current chapter, and other sources, uses the term *comprehensive diabetes care* to emphasize the fact that optimal diabetes therapy involves more than glucose management and medications and is patient-centered and individualized as advocated by the American Diabetes Association (ADA). Although glycemic control is central to optimal diabetes therapy, comprehensive diabetes care of both type 1 and type 2 DM should also detect and manage DM-specific complications (Chap. 405), and modify risk factors for DM-associated diseases. The key elements of comprehensive diabetes care are summarized in Table 404-1. The morbidity and mortality of DM can be greatly reduced by timely and consistent surveillance, including the detection, prevention, and management of DM-related complications (Table 404-1 and Chap. 405). Such screening procedures are indicated for all individuals with DM, but many individuals with diabetes do not receive these or comprehensive diabetes care. In addition to the physical aspects of DM, social, family, financial, cultural, and employment-related issues may impact diabetes care. The treatment goals for patients with diabetes summarized in Table 404-2 should be individualized. The prevention and treatment of clinically significant hypoglycemia (<3.0 mmol/L or 54 mg/dL) is discussed in Chap. 406. This chapter, while recognizing that resources available for diabetes care vary widely throughout the world, provides guidance for comprehensive diabetes care in health care settings with considerable societal resources.

Lifestyle Management in Diabetes Care The patient with type 1 or type 2 DM should receive education about nutrition, physical activity, psychosocial support, care of diabetes during illness, and medications to lower the plasma glucose. Patient education allows and encourages individuals with DM to assume greater responsibility for their care, leading to improved compliance.

TABLE 404-1 Guidelines for Ongoing, Comprehensive Medical Care for Individuals with Diabetes

- Individualized glycemic goal and therapeutic plan
- Self-monitoring at individualized frequency of blood glucose (capillary/meter) or interstitial glucose (continuous glucose monitoring)
- HbA_{1c} testing (2–4 times/year)
- Lifestyle management in the care of diabetes, including:
  - Diabetes self-management education and support
  - Nutrition therapy
  - Physical activity
  - Psychosocial care, including evaluation for depression, anxiety
- Detection, prevention, or management of diabetes-related complications, including:
  - Diabetes-related eye examination (annual or biannual; Chap. 405)
  - Diabetes-related foot examination (1–2 times/year by provider; daily by patient; Chap. 403)
  - Diabetes-related neuropathy examination (annual; Chap. 403)
  - Diabetes-related kidney disease testing (annual; Chap. 405)
- Manage or treat diabetes-relevant conditions, including:
  - Blood pressure (assess 2–4 times/year; Chap. 405)
  - Lipids (1–2 times/year; Chap. 405)
  - Consider antiplatelet therapy with low-dose aspirin (Chap. 405)
  - Influenza/pneumococcal/hepatitis B/coronavirus immunizations (Chap. 6)

Abbreviation: HbA_{1c}, glycosylated hemoglobin A_{1c}.

Diabetes Self-Management Education and Support (DSMES) DSMES refers to ways to improve the patient's knowledge, skills, and abilities necessary for diabetes self-care and should also emphasize psychosocial issues and emotional well-being. Patient education is a continuing process with regular visits for reinforcement; it is not a process completed after one or two visits. It should receive special emphasis at the diagnosis of diabetes, annually, or at times when diabetes treatment goals are not attained, and during transitions in life or medical care. DSMES is delivered by a diabetes educator who is a health care professional (nurse, dietician, or pharmacist) with specialized patient-education skills and who is certified in diabetes education (e.g., Association of Diabetes Care & Education Specialists). Education topics important for optimal diabetes self-care include self-monitoring of blood glucose (SMBG) and/or continuous glucose monitoring (CGM); urine or blood ketone monitoring (type 1 DM); insulin administration; guidelines for diabetes management during illnesses;

TABLE 404-2 Treatment Goals for Adults with Diabetes[a]

INDEX OF GLYCEMIC CONTROL[b]	GOAL (NONPREGNANT ADULTS)	GOAL (OLDER/HIGH-RISK ADULTS)
HbA_{1c}	<7.0% (53 mmol/mol)[c]	<8.0% (64 mmol/mol)[c]
Preprandial capillary blood glucose	4.4–7.2 mmol/L (80–130 mg/dL)	5.0–7.8 mmol/L (90–140 mg/dL)
Postprandial capillary blood glucose[d]	<10.0 mmol/L (<180 mg/dL)	<11.1 mmol/L (200 mg/dL)
Time in range 3.9–10.0 mmol/L (70–180 mg/dL)[e]	>70%	>50%
Time below 3.9 mmol/L (70 mg/dL)[e]	<4%	<1%
Glucose variability, % coefficient of variation[e]	≤36%	<33%

[a]As recommended by the American Diabetes Association; goals should be individualized for each patient (see text) with personalized goals for different patients. [b]HbA_{1c} is primary goal and may also be estimated from 14 or more days of continuous glucose monitoring (CGM) data as the Glycemic Management Indicator (GMI). [c]Diabetes Control and Complications Trial-based assay. [d]1–2 h after beginning of a meal. [e]Derived from 14 days of CGM data.

Abbreviation: HbA_{1c}, glycosylated hemoglobin A_{1c}.

Source: Data from American Diabetes Association: 6. Glycemic targets: Standards of medical care in diabetes-2021. Diabetes Care 44(Suppl 1):S73, 2021.

prevention and management of hypoglycemia (Chap. 406); foot and skin care; diabetes management before, during, and after exercise; and risk factor–modifying activities. The focus is providing patient-centered, individualized education. More frequent contact between the patient and the diabetes management team (e.g., electronic, telephone, video) improves glycemic control.

Nutrition Therapy *Medical nutrition therapy* (MNT) is a term used by the ADA to describe the optimal coordination of caloric intake with other aspects of diabetes therapy (insulin, exercise, and weight loss). Some aspects of MNT are directed at preventing or delaying the onset of type 2 DM in high-risk individuals (obese or with prediabetes) by promoting weight reduction. Other measures of MNT are directed at improving glycemic control through limiting carbohydrate intake and avoiding simple sugars and fructose and managing diabetes-related complications (cardiovascular disease [CVD], nephropathy). Medical treatment of obesity including pharmacologic approaches that facilitate weight loss and metabolic surgery should be considered in selected patients (Chaps. 401 and 402).

In general, the components of optimal MNT are similar for individuals with type 1 or type 2 DM—high-quality, nutrient-dense with limits on carbohydrate intake required for glycemic control and weight management (Table 404-3). The data are currently inconclusive about various eating patterns (intermittent fasting, etc.). Dietary advice should be individualized, acknowledging personal preferences, culture, and religious traditions. Using the *glycemic index*, an estimate of the postprandial rise in the blood glucose when a certain amount of that food is consumed, may reduce postprandial glucose excursions and improve glycemic control.

The goal of MNT in type 1 DM is to coordinate and match the carbohydrate intake, both temporally and quantitatively, with the appropriate amount of insulin. MNT in type 1 DM is informed by SMBG and/or CGM that should be integrated to define the optimal insulin regimen. Based on the patient's estimate of the carbohydrate content of a meal, an insulin-to-carbohydrate ratio determines the bolus insulin dose for a meal or snack. MNT must be flexible enough to allow for exercise, and the insulin regimen must allow for variations in caloric intake. An important component of MNT in type 1 DM is to minimize the weight gain often associated with intensive insulin therapy and is best achieved by placing limits on carbohydrate intake.

TABLE 404-3 Nutritional Recommendations for Adults with Diabetes or Prediabetes[a]

General dietary guidelines

- Vegetable, fruits, whole grains, legumes, low-fat dairy products and food higher in fiber and lower in glycemic content; optimal diet composition and eating pattens are not known

Fat in diet (optimal % of diet is not known; should be individualized)

- Mediterranean-style diet rich in monounsaturated and polyunsaturated fatty acids
- Minimal or no trans fat consumption

Carbohydrate in diet (optimal % of diet is not known; should be individualized)

- Monitor carbohydrate intake in regard to calories and set limits for meals to reduce postprandial glycemia
- Avoid fructose- and sucrose-containing beverages and minimize consumption of foods with added sugar that may displace healthier, more nutrient-dense food choices and elevate postprandial glycemia
- Estimate grams of carbohydrate in diet for flexible insulin dosing (type 1 DM and insulin-dependent type 2 DM)
- Consider using glycemic index to predict how consumption of a particular food may affect blood glucose

Protein in diet (optimal % of diet is not known; should be individualized)

Other components

- Reduced-calorie and nonnutritive sweeteners may be useful
- Routine supplements of vitamins, antioxidants, or trace elements not supported by evidence
- Sodium intake as advised for general population

[a]See text for differences for patients with type 1 or type 2 diabetes.

Source: Data from American Diabetes Association: 5. Facilitating behavior change and well-being to improve health outcomes: Standards of medical care in diabetes-2021. Diabetes Care 44(Suppl 1):S53, 2021.

The goals of MNT in type 2 DM should focus on weight loss and address the greatly increased prevalence of cardiovascular risk factors (hypertension, dyslipidemia, obesity) and disease in this population. The majority of these individuals are obese, and weight loss is strongly encouraged. Very-low-carbohydrate diets that induce weight loss may result in rapid and dramatic glucose lowering in individuals with new-onset type 2 DM. MNT for type 2 DM should emphasize modest caloric reduction, increased physical activity, and weight loss (goal of at least 5–10% loss). Weight loss and exercise each independently improve insulin sensitivity.

Fasting for religious reasons, such as during Ramadan, presents a challenge for individuals with diabetes, especially those taking medications to lower the plasma glucose. Under International Diabetes Federation (IDF) guidelines on fasting during Ramadan, individuals are risk-stratified as those who can safely fast with medical evaluation and supervision and those in whom fasting is not advised. Thus, patient education and regular glucose monitoring are critical.

Physical Activity Exercise has multiple positive benefits including cardiovascular risk reduction, reduced blood pressure, maintenance of muscle mass, reduction in body fat, and weight loss. For individuals with type 1 or type 2 DM, exercise is also useful for lowering plasma glucose (during and following exercise) and increasing insulin sensitivity. In patients with diabetes, the ADA recommends 150 min/week (distributed over at least 3 days) of moderate aerobic physical activity with no gaps longer than 2 days. Resistance exercise, flexibility and balance training, and reduced sedentary behavior throughout the day are advised.

Despite its benefits, exercise may present challenges for some individuals with DM because they lack the normal glucoregulatory mechanisms (normally, insulin falls and glucagon rises during exercise). Skeletal muscle is a major site for metabolic fuel consumption in the resting state, and the increased muscle activity during vigorous, aerobic exercise greatly increases fuel requirements. Individuals with type 1 DM are prone to either hyperglycemia or hypoglycemia during exercise, depending on the preexercise plasma glucose, the circulating insulin level, lactate, and the level of exercise-induced catecholamines. If the insulin level is too low, the delivery of lactate to the liver and rise in catecholamines may increase the plasma glucose excessively, promote ketone body formation, and possibly lead to ketoacidosis. Conversely, if the circulating insulin level is excessive, this relative hyperinsulinemia may reduce hepatic glucose production (decreased glycogenolysis, decreased gluconeogenesis) and increase glucose entry into muscle, leading to hypoglycemia.

To avoid exercise-related hyper- or hypoglycemia, individuals with type 1 DM should (1) monitor blood glucose before, during, and after exercise; (2) delay exercise if blood glucose is >14 mmol/L (250 mg/dL) and ketones are present; (3) if the blood glucose is <5.0 mmol/L (90 mg/dL), ingest carbohydrate before exercising; (4) monitor glucose during exercise and ingest carbohydrate as needed to prevent hypoglycemia; (5) decrease insulin doses (based on previous experience) before and after exercise and inject insulin into a nonexercising area; and (6) learn individual glucose responses to different types of exercise. In individuals with type 2 DM, exercise-related hypoglycemia is less common but can occur in individuals taking either insulin or insulin secretagogues. Untreated proliferative retinopathy is a relative contraindication to vigorous exercise, because this may lead to vitreous hemorrhage or retinal detachment (Chap. 405).

Psychosocial Care Because the individual with DM faces challenges that affect many aspects of daily life, psychosocial assessment and support are a critical part of comprehensive diabetes care. The patient should view himself/herself as an essential member of the diabetes care team and not as someone who is cared for by the diabetes management team. Even with considerable effort, normoglycemia can be an elusive goal, and solutions to worsening glycemic control may not be easily identifiable. Depression, anxiety, or "diabetes distress," defined by the ADA as "…negative psychological reactions related to

emotional burdens…in having to manage a chronic disease like diabetes," should be recognized and may require the care of a mental health specialist. Emotional stress may provoke a change in behavior so that individuals no longer adhere to a dietary, exercise, or therapeutic regimen. Eating disorders, including binge eating disorders, bulimia, and anorexia nervosa, appear to occur more frequently in individuals with type 1 or type 2 DM.

MONITORING THE LEVEL OF GLYCEMIC CONTROL

Optimal monitoring of glycemic control involves glucose measurements by the patient and an assessment of long-term control by the providers on the diabetes management team (measurement of hemoglobin A_{1c} [HbA_{1c}] and review of the patient's SMBG and/or CGM). These measurements are complementary: the patient's measurements provide a picture of short-term glycemic control, whereas the HbA_{1c} reflects average glycemic control over the previous 2–3 months. Most measurements should be performed prior to a meal and supplemented with postprandial measurements to assist in reaching glucose targets (Table 404-2). By combining glucose measurements with diet and exercise history, the diabetes management team and patient can improve glycemic control. Clinical practice is changing rapidly with CGM replacing SMBG is many patients, especially those with T1 DM.

Self-Monitoring of Blood Glucose In SMBG, a small drop of blood (3–10 μL) and an enzymatic reaction allow rapid and accurate measurement of the capillary blood glucose by glucose monitors (calibrated to provide plasma glucose value even though blood glucose is measured). The blood is obtained from the fingertip; alternative testing sites (e.g., forearm) are less reliable. The frequency of SMBG measurements should be individualized. Individuals with type 1 DM or individuals with type 2 DM taking multiple insulin injections each day should measure their blood glucose >3 times/day (some measure >10 times/day). Most individuals with type 2 DM require less frequent monitoring, although the optimal frequency of SMBG has not been clearly defined. Individuals with type 2 DM who are taking insulin should use SMBG more frequently than those on oral agents. Individuals with type 2 DM who are on oral medications should use SMBG as a means of assessing the efficacy of their medication and the impact of dietary choices and exercise. Because glucose levels fluctuate less in these individuals, one or two SMBG measurements per day may be sufficient.

Continuous Glucose Monitoring CGM technology utilizes a sensor or electrode to detect interstitial glucose, which is in equilibrium with blood glucose, but may lag behind when the blood glucose is changing. In one CGM approach, the interstitial glucose is detected and reported essentially continuously while in another approach, the sensor is in place, but the glucose is only recorded when a detector is placed over the sensor. The glucose sensors are placed subcutaneously and are replaced every 3–14 days. Some CGM requires calibration by SMBG. CGM provides unlimited glucose datapoints that can be used to define a time in a glycemic range (TIR, or time in range), the ambulatory glucose profile, the amount of time in the hypoglycemic range, and the glucose management indicator (GMI), which correlates with A1C **(Fig. 404-1; Table 404-2)**. TIR and GMI are useful metrics but CGM also allows the patient to monitor the rate of glucose change and glucose trends that can be used to avoid predicted hyper- or hypoglycemia. CGM in type 1 DM especially in those with hypoglycemia unawareness can decrease the frequency of serious hypoglycemia (especially nocturnal hypoglycemia). The combination of an insulin-infusion device (discussed below) and a CGM can now automate insulin delivery with either predictive suspension of insulin delivery to avoid hypoglycemia or closed-loop control that automatically adjusts insulin delivery by a predictive algorithm (Fig. 404-1).

Assessment of Long-Term Glycemic Control Measurement of glycated hemoglobin (HbA_{1c}) is the standard method for assessing long-term glycemic control. When plasma glucose is consistently elevated, there is an increase in nonenzymatic glycation of hemoglobin; this alteration reflects the glycemic history over the previous 2–3 months, because erythrocytes have an average life span of 120 days (glycemic

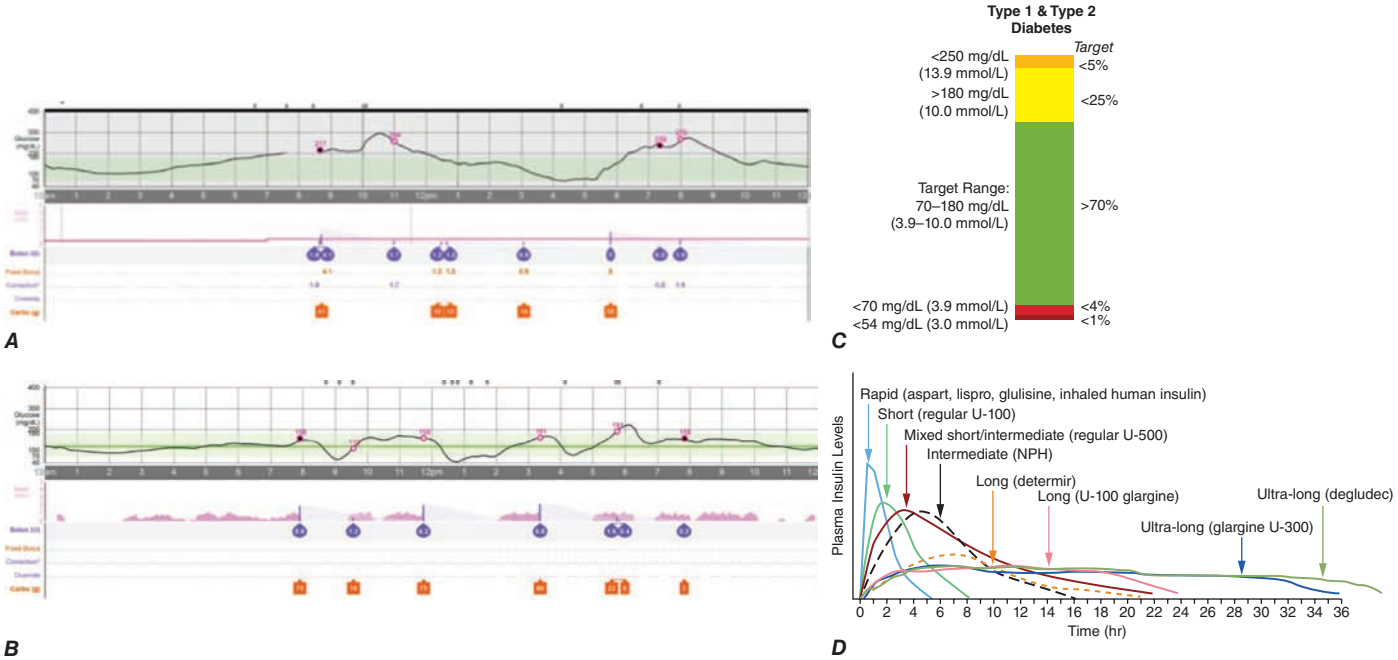

FIGURE 404-1 Glycemic monitoring and insulin administration options for treatment of diabetes. ***A.*** CGM profile and delivery of rapid-acting insulin analog by continuous subcutaneous insulin infusion pump involves a basal rate (*light purple line*) and prandial and correction boluses (*purple circles*) based on estimated carbohydrate intake (*orange squares*) and an insulin sensitivity factor. ***B.*** CGM profile with sensor-communicating insulin pump that automates insulin delivery by suspending delivery for predicted hypoglycemia and increasing basal delivery for predicted hyperglycemia (*light purple curves*) while still requiring user input for estimated carbohydrate intake (*orange squares*) to provide prandial insulin boluses (*purple circles*). ***C.*** CGM profile is used to generate an estimate of time-in-range with glycemic goal shown on the left side of the bar and target % time in that glycemic range shown on the right side of the bar. ***D.*** Pharmacokinetic profile of individual insulin products. ***(C.*** *Reproduced with permission from T Battelino et al: Clinical targets for continuous glucose monitoring data interpretation: Recommendations from the International Consensus on Time in Range. level in the preceding month contributes about 50% to the HbA_{1c} value). Measurement of HbA_{1c} at the "point of care" allows for more rapid feedback and may therefore assist in adjustment of therapy.

HbA_{1c} should be measured in all individuals with DM during their initial evaluation and as part of their comprehensive diabetes care. As the primary predictor of long-term complications of DM, the HbA_{1c} should mirror, to a certain extent, the short-term measurement by SMBG or CGM. Measurements of HbA_{1c} and actual glucose levels are complementary in that recent intercurrent illnesses may impact SMBG or CGM measurements but not the HbA_{1c}. The HbA_{1c} may reflect postprandial or nocturnal hyperglycemia not detected by SMBG of fasting and preprandial capillary blood glucose. However, it does not detect interprandial or nocturnal hypoglycemia—these require very frequent SMBG or CGM for detection. The HbA_{1c} is an "average" and thus does not detect glycemic variability in the way SMBG and CGM can. In standardized assays, the HbA_{1c} approximates the following mean plasma glucose values: an HbA_{1c} of 6% = 7.0 mmol/L (126 mg/dL), 7% = 8.6 mmol/L (154 mg/dL), 8% = 10.2 mmol/L (183 mg/dL), 9% = 11.8 mmol/L (212 mg/dL), 10% = 13.4 mmol/L (240 mg/dL), 11% = 14.9 mmol/L (269 mg/dL), and 12% = 16.5 mmol/L (298 mg/dL). However, there is interindividual variability in the HbA_{1c} to mean glucose relationship, and in blacks the HbA_{1c} is on average 0.4% higher than in whites for the same mean glucose. Clinical conditions leading to abnormal RBC parameters such as hemoglobinopathies, anemias, reticulocytosis, transfusions, and uremia may alter the HbA_{1c} result. In patients achieving their glycemic goal, the ADA recommends measurement of the HbA_{1c} at least twice per year. More frequent testing (every 3 months) is warranted when glycemic control is inadequate or when therapy has changed. Laboratory standards for the HbA_{1c} test have been established and should be correlated to the reference assay of the Diabetes Control and Complications Trial (DCCT). The degree of glycation of other proteins, such as albumin, or measurement of 1,5-anhydroglucitol can be used as an alternative, shorter-term indicator of glycemic control when the HbA_{1c} is inaccurate. The fructosamine assay (measuring glycated albumin) reflects the glycemic status over the prior 2 weeks.

PHARMACOLOGIC TREATMENT OF DIABETES

Comprehensive care of type 1 and type 2 DM requires an emphasis on nutrition, exercise, and monitoring of glycemic control but also usually involves glucose-lowering medication(s). This chapter discusses classes of such medications but does not describe every glucose-lowering agent available worldwide. The initial step is to select an individualized, glycemic goal for the patient.

ESTABLISHMENT OF TARGET LEVEL OF GLYCEMIC CONTROL

Because the complications of DM are related to glycemic control, normoglycemia or near-normoglycemia is the desired, but often elusive, goal for most patients. Normalization or near-normalization of the plasma glucose for long periods of time is extremely difficult, as demonstrated by the DCCT and United Kingdom Prospective Diabetes Study (UKPDS). Regardless of the level of hyperglycemia, improvement in glycemic control will lower the risk of diabetes-specific complications, most notably the microvascular complications **(Chap. 405)**.

The target for glycemic control (as reflected by the HbA_{1c}) must be individualized, and the goals of therapy should be developed in consultation with the patient after considering a number of medical, social, and lifestyle issues. The ADA calls this a *patient-centered approach*, and other organizations such as the IDF and American Association of Clinical Endocrinologists (AACE) also suggest an individualized glycemic goal. Important factors to consider include the patient's age and ability to understand and implement a complex treatment regimen, presence and severity of complications of diabetes, known CVD, ability to recognize hypoglycemic symptoms, presence of other medical conditions or treatments that might affect survival or the response to therapy, lifestyle and occupation (e.g., possible consequences of experiencing hypoglycemia on the job), and level of support available from family and friends.

In general, the ADA suggests that the goal is to achieve an HbA_{1c} as close to normal as possible without significant hypoglycemia. In most individuals, the target HbA_{1c} should be <7% (Table 404-2) with a more stringent (≤6.5%) target for some patients. With modern implementation of intensive insulin therapy for type 1 DM, the level of HbA_{1c} is no longer inversely related to the frequency and severity of hypoglycemia as seen in the DCCT; nevertheless, it may still be appropriate to set a higher HbA_{1c} target <7.5 or 8% for patients with impaired awareness of hypoglycemia. A higher HbA_{1c} goal may also be appropriate for the very young or old or in individuals with limited life span or comorbid conditions. For individuals using CGM, maximizing time-in-range 70–180 mg/dL, representing normoglycemia, while minimizing time-below-range <70 mg/dL, representing hypoglycemia, are shorter-term targets of therapy.

More stringent glycemic control (HbA_{1c} ≤6%) is not beneficial, and may be detrimental, in patients with type 2 DM and a high risk of CVD. Large clinical trials (UKPDS, Action to Control Cardiovascular Risk in Diabetes [ACCORD], Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation [ADVANCE], Veterans Affairs Diabetes Trial [VADT]; **Chap. 405**) examined glycemic control in type 2 DM in individuals with low risk of CVD, with high risk of CVD, or with established CVD and have found that more intense glycemic control is not beneficial and, in some patient populations, may have a negative impact on some outcomes. These divergent outcomes stress the need for individualized glycemic goals based on the following general guidelines: (1) early in the course of type 2 diabetes when the CVD risk is lower, improved glycemic control likely leads to improved cardiovascular outcome, but this benefit may occur more than a decade after the period of improved glycemic control; (2) intense glycemic control in individuals with established CVD or at high risk for CVD is not advantageous, and may be deleterious, over a follow-up of 3–5 years; (3) hypoglycemia in such high-risk populations (elderly, CVD) should be avoided; and (4) improved glycemic control reduces microvascular complications of diabetes **(Chap. 405)** even if it does not improve macrovascular complications like CVD.

TYPE 1 DIABETES MELLITUS

General Aspects The ADA recommendations for glycemic goals and HbA_{1c} targets are summarized in Table 404-2. The goal is to design and implement insulin regimens that mimic physiologic insulin secretion. Because individuals with type 1 DM partially or completely lack endogenous insulin production, administration of basal insulin is essential for regulating glycogen breakdown, gluconeogenesis, lipolysis, and ketogenesis (i.e., largely fine-tuning hepatic and adipose metabolism). Likewise, insulin replacement for meals should be appropriate for the carbohydrate intake and insulin sensitivity, promoting normal glucose utilization and storage.

Intensive Management Intensive insulin therapy has the goal of achieving near-normal glycemia. This approach requires multiple resources, including thorough and continuing patient education, comprehensive recording of plasma glucose measurements and nutrition intake by the patient, and a variable insulin regimen that matches carbohydrate intake and insulin dose. Insulin regimens include multiple-component insulin regimens, multiple daily injections (MDIs), or continuous subcutaneous (SC) insulin infusion (CSII).

The benefits of intensive insulin therapy and improved glycemic control include a reduction in the acute metabolic and chronic microvascular complications of DM. From a psychological standpoint, the patient experiences greater control over his or her diabetes and often notes an improved sense of well-being, greater flexibility in the timing and content of meals, and the capability to alter insulin dosing with exercise. In addition, intensive insulin therapy prior to and during pregnancy reduces the risk of fetal malformations and morbidity. Intensive insulin therapy is encouraged in newly diagnosed patients with type 1 DM because it may prolong the period of C-peptide production, which may result in better glycemic control and a reduced risk of serious hypoglycemia. Although intensive management confers impressive benefits, it is also accompanied by significant personal and financial costs and therefore may not be appropriate at all times for all individuals.

TABLE 404-4 Properties of Insulin Preparations[a]

PREPARATION	TIME OF ACTION		
	ONSET, h	PEAK, h	EFFECTIVE DURATION, h
Short-acting			
Aspart[b]	<0.25	0.5–1.5	3–5
Glulisine	<0.25	0.5–1.5	3–5
Lispro[c]	<0.25	0.5–1.5	3–5
Regular[d]	0.5–1.0	2–3	4–8
Inhaled human insulin	<0.5	1–2	3
Long-acting			
Degludec	1–9	—[e]	42[f]
Detemir	1–4	—[e]	12–24[f]
Glargine[g]	2–4	—[e]	20–24
NPH	2–4	4–10	10–16
Examples of insulin combinations[h]			
75/25–75% protamine lispro, 25% lispro	<0.25	Dual[i]	10–16
70/30–70% protamine aspart, 30% aspart	<0.25	Dual[i]	15–18
50/50–50% protamine lispro, 50% lispro	<0.25	Dual[i]	10–16
70/30–70% NPH, 30% regular	0.5–1	Dual[i]	10–16
Combination of long-acting insulin and GLP-1 receptor agonist	See text		

[a]Injectable insulin preparations (with exception of inhaled formulation) available in the United States; others are available in the United Kingdom and Europe. Standard formulations are U-100 (100 units of insulin per mL solution). [b]Formulation with niacinamide (vitamin B3) has a slightly more rapid onset and offset. [c]Lispro-aabc formulation has a slightly more rapid onset and offset; both formulations are also available in U-200 concentration. [d]Formulation also available in U-500 concentration with delayed onset and offset. [e]Degludec, determir, and glargine have minimal peak activity. [f]Duration is dose-dependent. [g]Formulation also available in U-300 concentration with delayed onset and offset. [h]Other insulin combinations are available. [i]Dual: two peaks—one at 2–3 h and the second one several hours later.

Insulin Preparations Current insulin preparations are generated by recombinant DNA technology and consist of the amino acid sequence of human insulin or variations thereof. In the United States, most insulin is formulated as U-100 (100 units/mL); short-acting insulin formulated as U-200 (200 units/mL; lispro) and long-acting as U-300 (300 units/mL; glargine) are available in order to limit injection volumes for patients with high insulin requirements. Regular insulin formulated as U-500 (500 units/mL) is sometimes used in patients with severe insulin resistance. Human insulin has been formulated with distinctive pharmacokinetics (regular and neutral protamine Hagedorn [NPH] insulin have the native insulin amino acid sequence) or genetically modified to alter insulin absorption and hence insulin action. Insulins can be classified as short-acting or long-acting **(Table 404-4; Figure 404-1D)**. For example, one short-acting insulin formulation, insulin lispro, is an insulin analogue in which the 28th and 29th amino acids (lysine and proline) on the insulin B chain have been reversed by recombinant DNA technology. Insulin aspart and insulin glulisine are genetically modified insulin analogues with properties similar to lispro. A biosimilar version of lispro has been approved. These insulin analogues have full biologic activity but less tendency for self-aggregation, resulting in more rapid absorption and onset of action and a shorter duration of action. These characteristics are particularly advantageous for allowing entrainment of insulin injection and action to rising plasma glucose levels following meals. The shorter duration of action also appears to be associated with a decreased number of hypoglycemic episodes, primarily because the decay of insulin action corresponds to the decline in plasma glucose after a meal. Thus, insulin aspart, lispro, or glulisine is preferred over regular insulin for prandial coverage in many patients. Insulin glargine is a long-acting biosynthetic human insulin that differs from normal insulin in that asparagine is replaced by glycine at amino acid 21, and two arginine residues are added to the C terminus of the B chain, leading to the formation of microprecipitates at physiologic pH in subcutaneous tissue. Compared to NPH insulin, the onset of insulin glargine action is later, the duration of action is longer (~24 h), and there is a less pronounced peak. A lower incidence of hypoglycemia, especially at night, has been reported with insulin glargine when compared to NPH insulin. A biosimilar version is available. Insulin detemir has a fatty acid side chain that reversibly binds to albumin and prolongs its action by slowing absorption and catabolism, but its duration of action may only reach 12–20 h. Twice-daily injections of glargine, or especially detemir, are sometimes required to provide optimal 24-h basal insulin coverage. Because of modification and extension of the carboxy-terminus of the B chain, insulin degludec forms multihexamers in subcutaneous tissue and binds albumin, prolonging its duration of action (>42 h); it provides similar glycemic control as glargine but with less frequent nocturnal and severe hypoglycemia. Other modified insulins, such as one with a duration of action of several days, are in development.

Basal insulin requirements are provided by long-acting insulin formulations (NPH insulin, insulin glargine, insulin detemir, or insulin degludec) (Fig. 404-1D; Table 404-4). These are usually prescribed with short-acting insulin in an attempt to mimic physiologic insulin release with meals. Although mixing of NPH and short-acting insulin formulations is common practice, this mixing may alter the insulin absorption profile (especially the short-acting insulins). For example, lispro absorption is delayed by mixing with NPH. The alteration in insulin absorption when the patient mixes different insulin formulations should not prevent mixing insulins. However, the following guidelines should be followed: (1) mix the different insulin formulations in the syringe immediately before injection (inject within 2 min after mixing); (2) do not store insulin as a mixture; (3) follow the same routine in terms of insulin mixing and administration to standardize the physiologic response to injected insulin; and (4) do not mix insulin glargine, detemir, or degludec with other insulins. The miscibility of some insulins allows for the production of combination insulins that contain 70% NPH and 30% regular (70/30), or equal mixtures of NPH and regular (50/50). By including the insulin analogue mixed with protamine, several additional combinations have a short-acting and long-acting profile (Table 404-4; Fig. 404-1D). Although more convenient for the patient (only two injections/day), combination insulin formulations do not allow independent adjustment of short-acting and long-acting activity. Several insulin formulations are available as insulin "pens," which are more convenient for some patients. Insulin delivery by inhalation to provide meal-time insulin is approved, but not widely used. Prior to its use, the forced expiratory volume in 1 second (FEV_1) should be measured. Inhaled insulin can cause bronchospasm and cough and should not be used by individuals with lung disease or those who smoke. Long-acting insulin/glucagon-like peptide-1 (GLP-1) receptor agonist combinations in fixed doses (degludec + liraglutide or glargine + lixisenatide) are effective, and are associated with less weight gain.

Insulin Regimens There is considerable patient-to-patient variation in the peak and duration. In all regimens, long-acting insulins (NPH, glargine, detemir, or degludec) supply basal insulin, whereas regular, insulin aspart, glulisine, or lispro provide prandial insulin (Fig. 404-1D; Table 404-4). Short-acting insulin analogues should be injected just before (<10 min) and regular insulin 30–45 min prior to a meal. Sometimes short-acting insulin analogues are injected just after a meal (gastroparesis, unpredictable food intake).

A shortcoming of current insulin regimens is that injected insulin immediately enters the systemic circulation, whereas endogenous insulin is secreted into the portal venous system. Thus, exogenous insulin administration exposes the liver to subphysiologic insulin levels. No current insulin regimen reproduces the precise insulin secretory pattern of the pancreatic islet. However, the most physiologic regimens entail more frequent insulin injections, greater reliance on short-acting insulin, and more frequent SMBG and/or CGM. In general, individuals with type 1 DM require 0.3-0.7 units/kg per day of insulin divided into

multiple doses, with approximately 50% of daily insulin given as basal insulin and 50% as prandial insulin.

MDI regimens refer to the combination of basal insulin and bolus insulin (preprandial short-acting insulin). The timing and dose of short-acting, preprandial insulin are altered to accommodate the SMBG or CGM results, anticipated food intake, and physical activity. Such regimens offer the patient with type 1 DM more flexibility in terms of lifestyle and the best chance for achieving near normoglycemia. Most often basal insulin with glargine, detemir, or degludec is used in conjunction with preprandial lispro, glulisine, or insulin aspart. The insulin aspart, glulisine, or lispro dose is based on individualized algorithms that integrate the preprandial glucose and the anticipated carbohydrate intake. To determine the meal component of the preprandial insulin dose, the patient uses an insulin-to-carbohydrate ratio (a common ratio for type 1 DM is 1 unit/10–15 g of carbohydrate, but this must be determined for each individual). To this insulin dose is added the supplemental or correcting insulin based on the preprandial blood glucose (one formula uses 1 unit of insulin for every 1.6–3.3 mmol/L [30–60 mg/dL] over the preprandial glucose target; this correction factor can be estimated from 1500/[total daily insulin dose]). Such calculations must be adjusted based on each individual's sensitivity to insulin. Other variations of this regimen use twice daily NPH as basal insulin but have the disadvantage that NPH has a significant peak, making hypoglycemia more common. Frequent SMBG (≥4 times per day) or CGM is essential for these types of insulin regimens.

CSII is a very effective insulin regimen for the patient with type 1 DM (Fig. 404-1). To the basal insulin infusion, a preprandial insulin ("bolus") is delivered by the insulin infusion device based on instructions from the patient, who uses an individualized algorithm incorporating the preprandial plasma glucose and anticipated carbohydrate intake. These sophisticated devices can accurately deliver small doses of insulin (microliters per hour) and have several advantages: (1) multiple basal infusion rates can be programmed to accommodate nocturnal versus daytime basal insulin requirement; (2) basal infusion rates can be altered during periods of exercise; (3) different waveforms of insulin infusion with meal-related bolus allow better matching of insulin depending on meal composition; and (4) programmed algorithms consider ongoing action of prior insulin administration and blood glucose values in calculating the insulin dose. These devices require instruction by a health professional with considerable experience with insulin infusion devices and frequent patient interactions with the diabetes management team. Insulin infusion devices may present unique challenges, such as infection at the infusion site, unexplained hyperglycemia because the infusion set becomes obstructed, or diabetic ketoacidosis (DKA) if the insulin infusion device becomes disconnected. Because most physicians use lispro, glulisine, or insulin aspart in CSII, the extremely short half-life of these insulins quickly leads to insulin deficiency if the delivery system is interrupted. Essential to the safe use of infusion devices is thorough patient education, frequent SMBG and/or CGM, and a backup plan for injecting long- and/or rapid-acting insulins in the event of insulin infusion device failure. CGM sensor-augmented insulin infusion devices integrate the information from the CGM to inform insulin delivery (Fig. 404-1). Currently, sensor communicating functions can interrupt basal insulin delivery during hypoglycemia (threshold suspension) or when hypoglycemia is anticipated (predictive suspension), which may be particularly useful for addressing nocturnal hypoglycemia. Hybrid closed-loop systems have recently become available that combine patient-directed preprandial boluses with automated adjustment of between-meal and basal insulin delivery based on CGM. Clinical experience with closed-loop systems is rapidly increasing and expanding. Bihormonal infusion devices that deliver both insulin and glucagon are under development.

Other Agents That Improve Glucose Control The role of amylin, a 37-amino-acid peptide co-secreted with insulin from pancreatic beta cells, in normal glucose homeostasis is uncertain. However, based on the rationale that patients who are insulin deficient are also amylin deficient, an analogue of amylin (pramlintide) was created and found to reduce postprandial glycemic excursions in individuals with type 1 or type 2 DM taking insulin. Pramlintide injected just before a meal slows gastric emptying and suppresses glucagon but does not alter insulin levels. Pramlintide is approved for insulin-treated patients with type 1 or type 2 DM. Addition of pramlintide produces a modest reduction in the HbA_{1c} and seems to dampen meal-related glucose excursions. In type 1 DM, pramlintide is started as a 15-μg SC injection before each meal and titrated up to a maximum of 30–60 μg as tolerated. In type 2 DM, pramlintide is started as a 60-μg SC injection before each meal and may be titrated up to a maximum of 120 μg. The major side effects are nausea and vomiting, and dose escalations should be slow to limit these side effects. Because pramlintide slows gastric emptying, it may influence absorption of other medications and should not be used in combination with other drugs that slow gastrointestinal (GI) motility. The short-acting insulin given before the meal should initially be reduced to avoid hypoglycemia and then titrated as the effects of the pramlintide become evident. Because pramlintide suppresses glucagon, it may worsen hypoglycemia recovery and should not be used in patients with hypoglycemia unawareness.

TYPE 2 DIABETES MELLITUS

General Aspects The goals of glycemia-controlling therapy for type 2 DM are similar to those in type 1 DM. Whereas glycemic control tends to dominate the management of type 1 DM, the care of individuals with type 2 DM must also include attention to the treatment of conditions associated with type 2 DM (e.g., obesity, hypertension, dyslipidemia, CVD) and detection/management of DM-related complications **(Fig. 404-2; Chap. 405)**. Reduction in cardiovascular risk is of paramount importance because this is the leading cause of mortality in these individuals.

Type 2 DM management should begin with MNT (discussed above). An exercise regimen to increase insulin sensitivity and promote weight loss should also be instituted. Pharmacologic approaches to the management of type 2 DM include oral glucose-lowering agents, insulin, and other agents that improve glucose control; most physicians and patients prefer oral glucose-lowering agents as the initial choice. Any therapy that improves glycemic control reduces "glucose toxicity" to beta cells and may improve endogenous insulin secretion. However, type 2 DM is a progressive disorder and ultimately requires multiple therapeutic agents and often insulin in most patients.

Glucose-Lowering Agents Advances in the therapy of type 2 DM have generated oral glucose-lowering agents that target different pathophysiologic processes in type 2 DM. Based on their mechanisms of action, glucose-lowering agents are subdivided into agents that increase insulin secretion, reduce glucose production, increase insulin sensitivity, enhance GLP-1 action, or promote urinary excretion of glucose **(Table 404-5)**. Glucose-lowering agents other than insulin (with the exception of amylin analogue) are ineffective in type 1 DM and should not be used for glucose management of severely ill individuals with type 2 DM. Insulin is sometimes the initial glucose-lowering agent in type 2 DM.

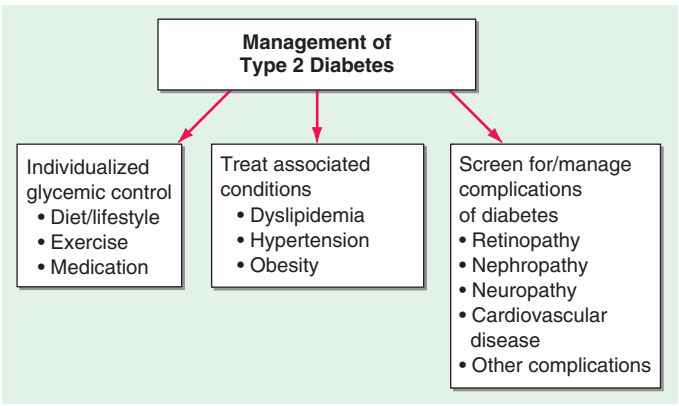

FIGURE 404-2 Essential elements in comprehensive care of type 2 diabetes.

TABLE 404-5 Agents Used for Treatment of Type 1 or Type 2 Diabetes

	MECHANISM OF ACTION	EXAMPLES[a]	HBA_{1C} REDUCTION (%)[b]	AGENT-SPECIFIC ADVANTAGES	AGENT-SPECIFIC DISADVANTAGES	CONTRAINDICATIONS
Oral						
Biguanides[c**]	↓ Hepatic glucose production, ↑ insulin sensitivity, influence gut function	Metformin	1–2	Weight neutral, do not cause hypoglycemia, inexpensive, extensive experience, ↓ CV events	Diarrhea, nausea, lactic acidosis, vitamin B12 deficiency	Renal insufficiency (see text for GFR <30 mL/min), CHF, radiographic contrast studies, hospitalized patients, acidosis
α-Glucosidase inhibitors[c***]	↓ GI glucose absorption	Acarbose, miglitol, voglibose	0.5–0.8	Reduce postprandial glycemia	GI flatulence, elevated liver function tests	Renal/liver insufficiency
Dipeptidyl peptidase IV inhibitors[c***]	Prolong endogenous GLP-1 action; ↑ Insulin, ↓ glucagon	Alogliptin, linagliptin, saxagliptin, sitagliptin, vildagliptin	0.5–0.8	Well tolerated, do not cause hypoglycemia	Angioedema/urticarial and immune-mediated dermatologic effects	Reduced dose with renal insufficiency
Insulin secretagogues: Sulfonylureas[c*]	↑ Insulin secretion	Glibornuride, gliclazide, glimepiride, glipizide, gliquidone, glyburide, glyclopyramide	1–2	Short onset of action, lower postprandial glucose, inexpensive	Hypoglycemia, weight gain	Renal/liver insufficiency
Insulin secretagogues: Nonsulfonylureas[c***]	↑ Insulin secretion	Mitiglinide, nateglinide, repaglinide	0.5–1.0	Short onset of action, lower postprandial glucose	Hypoglycemia	Renal/liver insufficiency (except repaglinide)
Sodium-glucose cotransporter 2 inhibitors[c***]	↑ Renal glucose excretion	Canagliflozin, dapagliflozin, empagliflozin, ertugliflozin	0.5–1.0	Do not cause hypoglycemia, ↓ weight and BP, renal protective, ↓ CV events	Urinary and genital infections, polyuria, dehydration, exacerbate tendency to hyperkalemia and DKA; see text	Moderate renal insufficiency, insulin-deficient DM[f]
Thiazolidinediones[c***]	↓ Insulin resistance, ↑ glucose utilization	Pioglitazone, rosiglitazone	0.5–1.4	Lower insulin requirements	Peripheral edema, CHF, weight gain, fractures, macular edema	CHF, renal/liver insufficiency
Parenteral/Oral						
GLP-1 receptor agonists[c***]	↑ Insulin, ↓ glucagon, slow gastric emptying, satiety	Dulaglutide, exenatide, liraglutide, lixisenatide, semaglutide (oral formulation available)	0.5–1.0	Weight loss, do not cause hypoglycemia (unless combined with another insulin secretagogue or insulin); ↓ CV events	Injection, nausea, pancreatitis[e]	Renal disease, agents that also slow GI motility; medullary carcinoma of thyroid, pancreatic disease
Parenteral						
Amylin agonists[c,d***]	Slow gastric emptying, ↓ glucagon	Pramlintide	0.25–0.5	Reduce postprandial glycemia, weight loss	Injection, nausea, ↑ risk of hypoglycemia with insulin	Agents that also slow GI motility
Insulin[c,d****]	↑ Glucose utilization, ↓ hepatic glucose production, and other anabolic actions	See text and Table 404-4	Not limited	Known safety profile	Injection, weight gain, hypoglycemia	None
Medical nutrition therapy and physical activity[c*]	↓ Insulin resistance, ↑ insulin secretion	Low-calorie, carbohydrate-controlled diet, exercise	1–3	Other health benefits	Compliance difficult, long-term success low	None

[a]Examples are approved for use in the United States; others are available in other countries. Examples may not include all agents in the class. [b]HbA_{1c} reduction (absolute) depends partly on starting HbA_{1c}. [c]Used for treatment of type 2 diabetes. [d]Used in conjunction with insulin for treatment of type 1 diabetes. Cost of agent in the United States: *low, **moderate, ***high, ****variable. [e]Degree of risk uncertain, avoid in individuals with risk factors for pancreatitis. [f]Risk of euglycemic DKA) in patients with insulin deficiency (e.g., type 1 diabetes).

Note: Some agents used to treat type 2 diabetes are not included in table (see text).

Abbreviations: CHF, congestive heart failure; CV, cardiovascular; GI, gastrointestinal; HbA_{1c}, glycosylated hemoglobin A_{1c}.

BIGUANIDES Metformin, representative of this class of agents, reduces hepatic glucose production and improves peripheral glucose utilization slightly (Table 404-5). Metformin activates AMP-dependent protein kinase and enters cells through organic cation transporters (polymorphisms of these may influence the response to metformin). Metformin acts in multiple tissues, but its mechanism of action remains undefined. There is evidence for reducing hepatic glucose production by antagonizing cAMP generation in hepatocytes as well as for actions in the gut. Metformin reduces fasting plasma glucose (FPG) and insulin levels, improves the lipid profile, and promotes modest weight loss. An extended-release form is available and may have fewer GI side effects (diarrhea, anorexia, nausea, metallic taste). Because of its metformin's relatively slow onset of action and GI symptoms with higher doses, the initial dose should be low and then escalated every 1–2 weeks to a maximally tolerated dose of 2000 mg daily. Metformin is effective as monotherapy and can be used in combination with other oral agents or with insulin. Long-term use is associated with reduced micro- and macrovascular complications. The major toxicity of metformin, lactic acidosis, is very rare and can be prevented by careful patient selection. Vitamin B_{12} levels are lower during metformin treatment and should be monitored. Metformin should not be used in patients with moderate renal insufficiency (glomerular filtration rate [GFR] <30 mL/min), any

form of acidosis, unstable congestive heart failure (CHF), liver disease, or severe hypoxemia. Metformin should be discontinued in hospitalized patients, in patients who can take nothing orally, and in those receiving radiographic contrast material. Insulin should be used until metformin can be restarted.

INSULIN SECRETAGOGUES—AGENTS THAT AFFECT THE ATP-SENSITIVE K^+ CHANNEL Insulin secretagogues stimulate insulin secretion by interacting with the ATP-sensitive potassium channel on the beta cell **(Chap. 403)**. These drugs are most effective in individuals with type 2 DM of relatively recent onset (<5 years) who have residual endogenous insulin production. First-generation sulfonylureas (chlorpropamide, tolazamide, tolbutamide) have a longer half-life, a greater incidence of hypoglycemia, and more frequent drug interactions, and are no longer used. Second-generation sulfonylureas have a more rapid onset of action and better coverage of the postprandial glucose rise, but the shorter half-life of some agents may require more than once-a-day dosing. Sulfonylureas reduce both fasting and postprandial glucose and should be initiated at low doses and increased at 1- to 2-week intervals based on SMBG. In general, sulfonylureas increase insulin acutely and thus should be taken shortly before a meal; with chronic therapy, though, the insulin release is more sustained. Long-term use is associated with reduced micro- and macrovascular complications. Glimepiride and glipizide can be given in a single daily dose and are preferred over glyburide, especially in the elderly. Repaglinide, nateglinide, and mitiglinide are not sulfonylureas but also interact with the ATP-sensitive potassium channel. Because of their short half-life, these glinide agents are given immediately before each meal to reduce meal-related glucose excursions.

Insulin secretagogues, especially the longer acting ones, have the potential to cause hypoglycemia, especially in elderly individuals. Hypoglycemia is usually related to delayed meals, increased physical activity, alcohol intake, or renal insufficiency. Individuals who ingest an overdose of some agents develop prolonged and serious hypoglycemia and should be monitored closely in the hospital **(Chap. 406)**. Most sulfonylureas are metabolized in the liver to compounds (some of which are active, such as those of glyburide and the glinide nateglinide) that are cleared by the kidney. Thus, their use in individuals with significant hepatic or renal dysfunction is not advisable. For patients with chronic kidney disease requiring an insulin secretagogue, the shorter-acting sulfonylureas glimepiride or glipizide or the glinide repaglinide may be used with caution. Weight gain, a common side effect of sulfonylurea therapy, results from the increased insulin levels and improvement in glycemic control. Some sulfonylureas have significant drug interactions with alcohol and some medications including warfarin, aspirin, ketoconazole, α-glucosidase inhibitors, and fluconazole. A related isoform of ATP-sensitive potassium channels is present in the myocardium and the brain. All of these agents except glyburide have a low affinity for this isoform. Despite concerns that this agent might affect the myocardial response to ischemia and observational studies suggesting that sulfonylureas increase cardiovascular risk, studies have not shown an increased cardiac mortality with glyburide or other agents in this class.

INSULIN SECRETAGOGUES—AGENTS THAT ENHANCE GLP-1 RECEPTOR SIGNALING "Incretins" amplify glucose-stimulated insulin secretion **(Chap. 403)**. Agents that either act as a GLP-1 receptor agonist or enhance endogenous GLP-1 activity are approved for the treatment of type 2 DM (Table 404-5). Agents in this class do not cause hypoglycemia because of the glucose-dependent nature of incretin-stimulated insulin secretion (unless there is concomitant use of an agent that can lead to hypoglycemia—sulfonylureas, etc.). GLP-1 receptor agonists increase glucose-stimulated insulin secretion, suppress glucagon, and slow gastric emptying. These agents do not promote weight gain; in fact, most patients experience modest weight loss and appetite suppression. Short-acting GLP-1 receptor agonists are exenatide twice daily, liraglutide daily, and lixisenatide daily. Long-acting GLP-1 receptor agonists include sustained-release exenatide, dulaglutide, lixisenatide, and semaglutide, all administered weekly. Short-acting GLP-1 receptor agonists provide mostly postprandial coverage whereas the long-acting GLP-1 receptor agonists reduce both the postprandial and fasting glucose. Daily oral semaglutide is now available that depends on gastric absorption to avoid proteolytic degradation in the small intestine. All are modified to avoid enzymatic inactivation by dipeptidyl peptidase IV (DPP-IV) in the circulation.

For example, exenatide, a synthetic version of a peptide initially identified in the saliva of the Gila monster (exendin-4), is an analogue of GLP-1. Unlike native GLP-1, which has a half-life of ~2 min, differences in the exenatide amino acid sequence render it resistant to DPP-IV. Thus, exenatide has prolonged GLP-1-like action. Liraglutide, another GLP-1 receptor agonist, is almost identical to native GLP-1 except for an amino acid substitution and addition of a fatty acyl group (coupled with a γ-glutamic acid spacer) that promote binding to albumin and plasma proteins and prolong its half-life. Higher doses of liraglutide and semaglutide than used for glucose-lowering effects are effective for weight-loss therapy for obesity. Liraglutide treatment has also been associated with a decrease in CVD events in patients with type 2 DM and established CVD and with lower rates of diabetic kidney disease. In similar patient populations, semaglutide treatment has been associated with fewer CVD events and reduced diabetic kidney disease, but with an increased rate of retinopathy-related complications, while dulaglutide treatment has been associated with both a reduction in CVD events and in composite microvascular retinopathy and nephropathy-related complications primarily driven by prevention of renal events. Similar reductions in CVD events have not been observed with exenatide once weekly or lixisenatide. Treatment with GLP-1 receptor agonists should start at a low dose to minimize initial side effects (nausea being the limiting one). GLP-1 receptor agonists can be used as combination therapy with metformin, sulfonylureas, and thiazolidinediones. Some patients taking insulin secretagogues may require a reduction in those agents to prevent hypoglycemia. The major side effects are nausea, vomiting, and diarrhea. Some formulations carry a black box warning from the FDA because of an increased risk of thyroid C-cell tumors in rodents and are contraindicated in individuals with medullary carcinoma of the thyroid or multiple endocrine neoplasia. Because GLP-1 receptor agonists slow gastric emptying, they may influence the absorption of other drugs. Whether GLP-1 receptor agonists enhance beta cell survival or promote beta cell proliferation in humans as in rodents is not known, but these agents do not appear to alter the natural history of type 2 DM.

DPP-IV inhibitors inhibit degradation of native GLP-1 and thus enhance the incretin effect. DPP-IV, which is widely expressed on the cell surface of endothelial cells and some lymphocytes, degrades a wide range of peptides (not GLP-1 specific). DPP-IV inhibitors promote insulin secretion in the absence of hypoglycemia or weight gain and appear to have a preferential effect on postprandial blood glucose. The levels of GLP-1 action in the patient are greater with the GLP-1 receptor agonists than with DPP-IV inhibitors. DPP-IV inhibitors are used either alone or in combination with other oral agents in type 2 DM. Reduced doses should be given to patients with renal insufficiency. Allergy, including rash, hypersensitivity reactions (including anaphylaxis, angioedema, and Stevens-Johnson syndrome), and severe joint pain have been reported in association with DPP-IV inhibitors. There is evidence concerning a potentially increased risk for acute pancreatitis with GLP-1 receptor agonists and less so with DPP-IV inhibitors. For now, it is reasonable to avoid these agents in patients with pancreatic disease or with other significant risk factors for acute pancreatitis (e.g., heavy alcohol use, severely elevated serum triglycerides, hypercalcemia).

α-GLUCOSIDASE INHIBITORS α-Glucosidase inhibitors reduce postprandial hyperglycemia by delaying glucose absorption; they do not affect glucose utilization or insulin secretion (Table 404-5). Postprandial hyperglycemia, secondary to impaired hepatic and peripheral glucose disposal, contributes significantly to the hyperglycemic state in type 2 DM. These drugs, taken just before each meal, reduce glucose absorption by inhibiting the enzyme that cleaves oligosaccharides into simple sugars in the intestinal lumen. Therapy should be initiated at a

low dose with the evening meal and increased to a maximal dose over weeks to months. The major side effects (diarrhea, flatulence, abdominal distention) are related to increased delivery of oligosaccharides to the large bowel and can be reduced somewhat by gradual upward dose titration. α-Glucosidase inhibitors may increase levels of sulfonylureas and increase the incidence of hypoglycemia. Simultaneous treatment with bile acid resins and antacids should be avoided. These agents should not be used in individuals with inflammatory bowel disease, gastroparesis, or a serum creatinine >177 μmol/L (2 mg/dL). This class of agents is not as potent as other oral agents in lowering the HbA_{1c} but is unique because it reduces the postprandial glucose rise. If hypoglycemia from other diabetes treatments occurs while taking these agents, the patient should consume glucose because the degradation and absorption of complex carbohydrates will be retarded.

THIAZOLIDINEDIONES Thiazolidinediones (Table 404-5) reduce insulin resistance by binding to the peroxisome proliferator-activated receptor γ (PPAR-γ) nuclear receptor (which forms a heterodimer with the retinoid X receptor). The PPAR-γ receptor is found at highest levels in adipocytes but is expressed at lower levels in many other tissues. Agonists of this receptor regulate a large number of genes, promote adipocyte differentiation, reduce hepatic fat accumulation, and promote fatty acid storage. Thiazolidinediones promote a redistribution of fat from central to peripheral locations. Circulating insulin levels decrease with use of the thiazolidinediones, indicating a reduction in insulin resistance. Although direct comparisons are not available, the two currently available thiazolidinediones appear to have similar efficacy. The prototype of this class of drugs, troglitazone, was withdrawn from the U.S. market after reports of hepatotoxicity and an association with an idiosyncratic liver reaction that sometimes led to hepatic failure. Although rosiglitazone and pioglitazone do not appear to induce the liver abnormalities seen with troglitazone, the FDA recommends measurement of liver function tests prior to initiating therapy. Modestly increased transaminase levels related to underlying fatty liver disease should not preclude treatment as these levels may improve with thiazolidinediones due to a reduction in hepatic fat content.

Rosiglitazone raises low-density lipoprotein (LDL), high-density lipoprotein (HDL), and triglycerides slightly. Pioglitazone raises HDL to a greater degree and LDL a lesser degree but lowers triglycerides. The clinical significance of the lipid changes with these agents is not known and may be difficult to ascertain because most patients with type 2 DM are also treated with a statin.

Thiazolidinediones are associated with weight gain (2–3 kg), a small reduction in the hematocrit, and a mild increase in plasma volume. Peripheral edema and CHF are more common in individuals treated with these agents. These agents are contraindicated in patients with hepatic insufficiency or CHF (class III or IV). The FDA has issued an alert that rare patients taking these agents may experience a worsening of diabetic macular edema. An increased risk of fractures has been noted in postmenopausal women taking these agents. Thiazolidinediones have been shown to induce ovulation in premenopausal women with polycystic ovary syndrome. Women should be warned about the risk of pregnancy because the safety of thiazolidinediones in pregnancy is not established.

Concerns about increased cardiovascular risk associated with rosiglitazone led to considerable restrictions on its use and to the FDA issuing a black box warning in 2007. However, based on new information, the FDA has revised its guidelines and categorizes rosiglitazone similar to other drugs for type 2 DM. According to an FDA review, pioglitazone may be associated with an increased risk of bladder cancer. In one study, pioglitazone lowered the risk for recurrent stroke or myocardial infarction in insulin-resistant individuals without diabetes who had a prior stroke or transient ischemic attack.

Sodium-Glucose Co-Transporter 2 (SGLT2) Inhibitors These agents (Table 404-5) lower the blood glucose by selectively inhibiting this co-transporter, which is expressed almost exclusively in the proximal, convoluted tubule in the kidney. This inhibits glucose reabsorption, lowers the renal threshold for glucose, and leads to increased urinary glucose excretion. Thus, the glucose-lowering effect is insulin independent and not related to changes in insulin sensitivity or secretion. The loss of urinary glucose may promote modest weight reduction. Since these agents also impair proximal reabsorption of sodium, their use is associated with a diuretic effect and 3–6 mmHg reduction in systolic blood pressure. Due to the increased urinary glucose, urinary and genital mycotic infections are more common in both men and women, and the diuretic effect can lead to reduced intravascular volume and acutely impaired kidney function. Inhibition of SGLT2 may lead to increased glucagon and consequently liver production of glucose and ketones. Euglycemic DKA may occur during illness or when ongoing glucosuria masks stress-induced requirements for insulin. These agents should not be prescribed for patients with type 1 DM or pancreatogenic forms of DM associated with insulin deficiency. Empagliflozin or canagliflozin reduces CVD events and all cause cardiovascular mortality in patients with type 2 DM and established CVD. All SGLT2 inhibitors may reduce hospitalization for CHF. Empagliflozin, canagliflozin, and dapagliflozin have all been shown to reduce progression of diabetic kidney disease but should not be initiated in patients with stage 3b CKD (eGFR <45 mL/min per 1.73 m^2) and should not be used with stage 4 CKD (eGFR <30 mL/min per 1.73 m^2). A possible increased risk of bladder cancer has been seen with dapagliflozin.

OTHER THERAPIES FOR TYPE 2 DM • Bile Acid–Binding Resins Evidence indicates that bile acids, by signaling through nuclear receptors, may have a role in metabolism. Bile acid metabolism is abnormal in type 2 DM. The bile acid–binding resin colesevelam has been approved for the treatment of type 2 DM (already approved for treatment of hypercholesterolemia). Because bile acid–binding resins are minimally absorbed into the systemic circulation, how bile acid–binding resins lower blood glucose is not known. The most common side effects are GI (constipation, abdominal pain, and nausea). Bile acid–binding resins can increase plasma triglycerides and should be used cautiously in patients with a tendency for hypertriglyceridemia. The role of this class of drugs in the treatment of type 2 DM is not yet defined.

Bromocriptine A formulation of the dopamine receptor agonist bromocriptine (Cycloset) has been approved by the FDA for the treatment of type 2 DM. However, its role in the treatment of type 2 DM is uncertain.

INSULIN THERAPY IN TYPE 2 DM Insulin should be considered as part of the initial therapy in type 2 DM, particularly in lean individuals or those with severe weight loss, in individuals with underlying renal or hepatic disease that precludes oral glucose-lowering agents, or in individuals who are hospitalized or acutely ill. Insulin therapy is ultimately required by a substantial number of individuals with type 2 DM because of the progressive nature of the disorder and the relative insulin deficiency that develops in patients with long-standing diabetes. Both physician and patient reluctance often delay the initiation of insulin therapy, but glucose control and patient well-being are improved by insulin therapy in patients who have not reached glycemic targets.

Because endogenous insulin secretion continues and is capable of providing some coverage of mealtime caloric intake, insulin is usually initiated in a single dose of long-acting insulin (0.1–0.4 U/kg per day), given in the evening or just before bedtime (NPH, glargine, detemir, or degludec). Because fasting hyperglycemia and increased hepatic glucose production are prominent features of type 2 DM, bedtime insulin is more effective in clinical trials than a single dose of morning insulin. Glargine given at bedtime has less nocturnal hypoglycemia than NPH insulin. Some physicians prefer a relatively low, fixed starting dose of long-acting insulin (5–15 units) or a weight-based dose (0.1 units/kg). The insulin dose may then be adjusted in 10–20% increments as dictated by SMBG results. Both morning and bedtime long-acting insulin may be used in combination with oral glucose-lowering agents. Initially, basal insulin may be sufficient, but often prandial insulin coverage with multiple insulin injections is needed as diabetes progresses (see insulin regimens used for type 1 DM). Other insulin formulations that have a combination of short-acting and long-acting

insulin (Table 404-4) are sometimes used in patients with type 2 DM because of convenience but do not allow independent adjustment of short-acting and long-acting insulin dose and often do not achieve the same degree of glycemic control as basal/bolus regimens. In selected patients with insulin-deficient type 2 DM, insulin infusion devices may be considered.

CHOICE OF INITIAL GLUCOSE-LOWERING AGENT The level of hyperglycemia and the patient's individualized goal (see "Establishment of Target Level of Glycemic Control") should influence the initial choice of therapy. Patients with mild hyperglycemia (FPG <7.0–11.0 mmol/L [126–199 mg/dL]) often respond well to a single, oral glucose-lowering agent, while those with moderate hyperglycemia (FPG 11.1–13.9 mmol/L [200–250 mg/dL]) will usually require more than one oral agent or insulin. Patients with more severe hyperglycemia (FPG >13.9 mmol/L [250 mg/dL]) may respond partially but are unlikely to achieve normoglycemia with oral therapy. Insulin can be used as initial therapy in individuals with severe hyperglycemia (FPG <13.9–16.7 mmol/L [250–300 mg/dL]) or in those who are symptomatic from the hyperglycemia. This approach is based on the rationale that more rapid glycemic control will reduce "glucose toxicity" to the islet cells, improve endogenous insulin secretion, and possibly allow oral glucose-lowering agents to be more effective. If this occurs, the insulin may be discontinued.

Insulin secretagogues, biguanides, α-glucosidase inhibitors, thiazolidinediones, GLP-1 receptor agonists, DPP-IV inhibitors, SLGT2 inhibitors, and insulin are approved for monotherapy of type 2 DM. Although each class of oral glucose-lowering agents has advantages and disadvantages (Table 404-5), certain generalizations apply: (1) insulin secretagogues, biguanides, GLP-1 receptor agonists, and thiazolidinediones improve glycemic control to a similar degree (1–2% reduction in HbA_{1c}) and are more effective than α-glucosidase inhibitors, DPP-IV inhibitors, and SLGT2 inhibitors; (2) insulin secretagogues, GLP-1 receptor agonists, DPP-IV inhibitors, α-glucosidase inhibitors, and SLGT2 inhibitors begin to lower the plasma glucose immediately, whereas the glucose-lowering effects of the biguanides and thiazolidinediones are delayed by weeks; (3) not all agents are effective in all individuals with type 2 DM; (4) biguanides, α-glucosidase inhibitors, GLP-1 receptor agonists, DPP-IV inhibitors, thiazolidinediones, and SLGT2 inhibitors do not directly cause hypoglycemia; (5) most individuals will eventually require treatment with more than one class of oral glucose-lowering agents or insulin, reflecting the progressive nature of type 2 DM; and (6) durability of glycemic control is slightly less for sulfonylureas compared to metformin or thiazolidinediones.

Considerable clinical experience exists with metformin and sulfonylureas because they have been available for several decades. It is assumed that the α-glucosidase inhibitors, GLP-1 receptor agonists, DPP-IV inhibitors, thiazolidinediones, and SLGT2 inhibitors will reduce DM-related complications by improving glycemic control. Pioglitazone may reduce CVD events through targeting a fundamental abnormality in type 2 DM, namely insulin resistance. A reduction in CVD events and in progression of diabetic kidney disease seen with some GLP-1 agonists and SGLT2 inhibitors may also operate through glucose-independent mechanisms **(Chap. 405)**.

Treatment algorithms by several professional societies (ADA/European Association for the Study of Diabetes [EASD], IDF, AACE) suggest metformin as initial therapy because of its efficacy, known side-effect profile, and low cost **(Fig. 404-3)**. Initiation of pharmacologic therapy should be accompanied by an emphasis on lifestyle modification (e.g., MNT, increased physical activity, and weight loss). Metformin's advantages are that it promotes mild weight loss, lowers insulin levels, and improves the lipid profile slightly. Based on SMBG results and the HbA_{1c}, the dose of metformin should be increased until the glycemic target is achieved or maximum dose is reached.

COMBINATION THERAPY WITH GLUCOSE-LOWERING AGENTS A number of combinations of therapeutic agents are successful in type 2 DM: metformin + second oral agent, metformin + GLP-1 receptor agonist, metformin + insulin, or combinations of a long-acting insulin and a GLP-1 receptor agonist. Because mechanisms of action of the first and second agents should be different, the effect on glycemic control is usually additive. There are little data to support the choice of one combination over another combination. Recent results from the NIH-funded Glycemia Reduction Approaches in Diabetes: A Comparative Effectiveness Study (GRADE) indicated that addition of liraglutide or basal insulin to metformin leads to better glycemic control than glimepiride or sitagliptin (SLGT2 inhibitors were not studied). Based on recent demonstrations of a beneficial cardiovascular effect in certain individuals with type 2 DM and CVD, or at high risk of CVD, a GLP-1 receptor agonist or a SGLT2 inhibitor should now be considered in these populations. Medication costs vary considerably (Table 404-5), and this often factors into medication choice. Several fixed-dose combinations of oral agents are available, but evidence that they are superior to titration of a single agent to a maximum dose and then addition of a second agent is lacking. If adequate control is not achieved with the combination of two agents (based on reassessment of the HbA_{1c} every 3 months), a third oral agent, GLP-1 receptor agonist, or basal insulin should be added (Fig. 404-3). Treatment approaches vary considerably from country to country. For example, α-glucosidase inhibitors are used commonly in South Asian patients (Indian), but infrequently in the United States or Europe. Whether this reflects an underlying difference in the disease or physician preference is not clear.

Treatment with insulin often becomes necessary as type 2 DM enters the phase of relative insulin deficiency and is signaled by inadequate glycemic control with one or two oral glucose-lowering agents. Insulin alone or in combination should be used in patients who fail to reach glycemic targets. For example, a single dose of long-acting insulin at bedtime is often effective in combination with metformin. As endogenous insulin production falls further, multiple injections of long-acting together with short-acting insulin are necessary to control postprandial glucose excursions. These insulin regimens are identical to the long-acting and short-acting combination regimens discussed above for type 1 DM, although usually at higher doses given insulin resistance. Weight gain and hypoglycemia are the major adverse effects

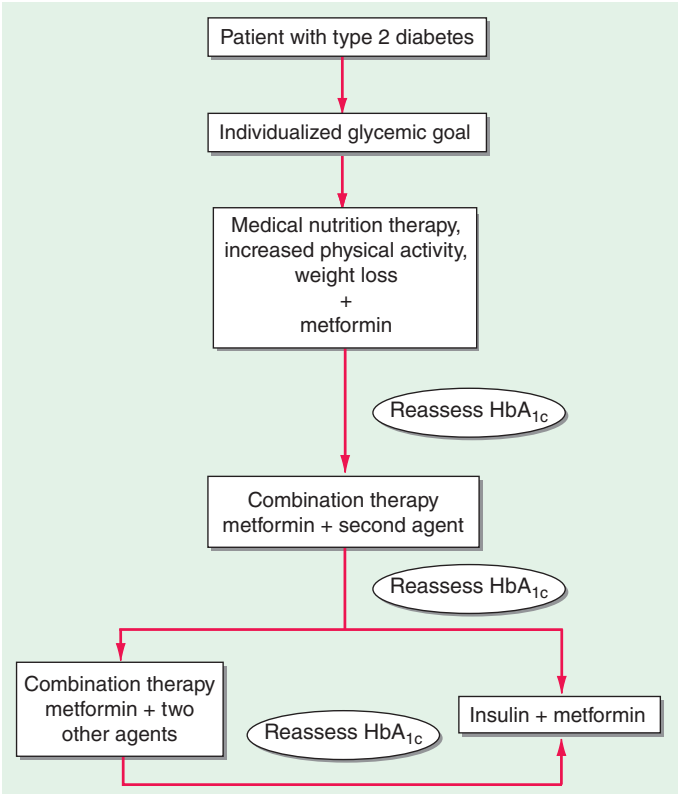

FIGURE 404-3 Glycemic management of type 2 diabetes. See text for discussion of treatment of severe hyperglycemia or symptomatic hyperglycemia. Agents that can be combined with metformin include insulin secretagogues, thiazolidinediones, α-glucosidase inhibitors, DPP-IV inhibitors, GLP-1 receptor agonists, SLGT2 inhibitors, and insulin. HbA_{1c}, hemoglobin HbA_{1c}.

of insulin therapy. The daily insulin dose required can become quite large (1–2 units/kg per day) as endogenous insulin production falls and insulin resistance persists. Individuals who require >1 unit/kg per day of long-acting insulin should be considered for combination therapy with metformin a GLP-1 receptor agonist, or a thiazolidinedione as these can reduce insulin requirements in some individuals with type 2 DM. Insulin plus a thiazolidinedione promotes weight gain and may be associated with peripheral edema. Addition of a thiazolidinedione to a patient's insulin regimen may necessitate a reduction in the insulin dose to avoid hypoglycemia. Patients requiring large doses of insulin (>200 units/day) can be treated with a more concentrated form of insulin.

OTHER THERAPIES FOR DIABETES

Metabolic (also referred to as bariatric) surgery for obese individuals with type 2 DM has shown considerable promise, sometimes with dramatic resolution of the diabetes or major reductions in the needed dose of glucose-lowering therapies **(Chap. 402)**. Several large, nonrandomized clinical trials have demonstrated a much greater efficacy of metabolic surgery compared to medical management in the treatment of type 2 DM and may be considered in individuals with type 2 DM and a BMI >35 kg/m^2. The ADA clinical guidelines state that metabolic surgery should be considered in individuals with type 2 DM and a body mass index >30 kg/m^2 if hyperglycemia is inadequately controlled despite optimal medical therapy.

Short-term intense caloric restriction (very-low-calorie diet, typically 800–1000 calories/day) can dramatically improve type 2 DM, sometimes leading to resolution of the diabetes. Such an approach is more effective in recent-onset type 2 DM and should be supervised by a provider with expertise and should be followed by a long-term, weight-maintenance program.

Whole-pancreas transplantation can normalize glucose control in type 1 DM and when performed simultaneously with or after kidney transplantation can prolong the life of the kidney transplant by offering protection against recurrent diabetic nephropathy. Pancreatic islet transplantation is available as a less invasive form of beta-cell replacement therapy for type 1 DM, but it remains investigational in the United States. Due to the risks associated with chronic immunosuppression, whole-pancreas and pancreatic islet transplantation may be considered for patients with severe metabolic instability or already requiring immunosuppression in support of a kidney or other organ transplant. Patients with chronic pancreatitis and preserved islet function who require pancreatectomy for pain relief may benefit from autologous islet transplantation as this may prevent or ameliorate postsurgical DM.

EMERGING THERAPIES

Many individuals with long-standing type 1 DM still produce very small amounts of insulin or have insulin-positive cells within the pancreas. This suggests that beta cells may slowly regenerate but are quickly destroyed by the autoimmune process. Particularly early in the disease course, efforts to suppress the autoimmune process, for example with anti-CD3 monoclonal antibodies that target T lymphocytes, are being tested at the time of diagnosis of type 1 DM, and for prevention in autoantibody-positive individuals at stages 1 and 2 of type 1 DM **(Chap. 403)**. Agents that target thioredoxin-interacting protein (TXNIP), especially Ca++ channel blockers, have some promise in recent-onset T1D and in rodent models of diabetes. Closed-loop insulin infusion devices that automate insulin delivery in response to changing glucose levels are progressing rapidly. New therapies under evaluation or development for type 2 DM include activators of glucokinase, inhibitors of 11 β-hydroxysteroid dehydrogenase-1, GPR40 agonists, dual agonists targeting the glucose-dependent insulinotropic polypeptide receptor and the GLP1-receptor, combined SLGT1 and SLGT2 inhibitors, and agents that may reduce inflammation, for example by inhibiting IL-1β.

Because whole-pancreas and pancreatic islet transplantation are both limited by organ availability from deceased donors, stem cell–derived islet cells and xenogeneic sources of islets may eventually allow for a limitless supply of insulin-producing cells for transplantation.

ADVERSE EFFECTS OF THERAPY FOR DM

As with any therapy, the benefits of efforts directed toward glycemic control must be balanced against the risks of treatment (Table 404-5). Side effects of intensive treatment include an increased frequency of serious hypoglycemia, weight gain, increased economic costs, and greater demands on the patient. In the DCCT, quality of life was very similar in the intensive and standard therapy groups. The most serious complication of therapy for DM is hypoglycemia, and its treatment with oral glucose or glucagon injection is discussed in **Chap. 406**. Severe, recurrent, or unexplained hypoglycemia warrants examination of treatment regimen and glycemic goal for the individual patient. Weight gain occurs with most (insulin, insulin secretagogues, thiazolidinediones) but not all (metformin, α-glucosidase inhibitors, GLP-1 receptor agonists, DPP-IV inhibitors) therapies. The weight gain is partially due to the anabolic effects of insulin and the reduction in glucosuria.

ACUTE DISORDERS RELATED TO SEVERE HYPERGLYCEMIA

Individuals with type 1 or type 2 DM and severe hyperglycemia (>13.9 mmol/L [250 mg/dL]) should be assessed for clinical stability, including mentation and hydration. Depending on the patient and the rapidity and duration of the severe hyperglycemia, an individual may require more intense and rapid therapy to lower the blood glucose. However, many patients with poorly controlled diabetes and hyperglycemia have few symptoms. The physician should assess if the patient is stable or if DKA or a hyperglycemic hyperosmolar state (HHS) should be considered. Ketones, an indicator of DKA, should be measured in individuals with type 1 DM when the plasma glucose is persistently >13.9 mmol/L (250 mg/dL), during a concurrent illness, or with symptoms such as nausea, vomiting, or abdominal pain. Blood measurement of β-hydroxybutyrate is preferred over urine testing with nitroprusside-based assays that measure only acetoacetate and acetone.

DKA and HHS are acute, severe disorders directly related to diabetes. DKA was formerly considered a hallmark of type 1 DM, but it also occurs in individuals with type 2 DM who can sometimes subsequently be treated with oral glucose-lowering agents (frequently in individuals of Hispanic or African-American descent). HHS is primarily seen in individuals with type 2 DM. Both disorders are associated with absolute or relative insulin deficiency, volume depletion, and acid–base abnormalities. DKA and HHS exist along a continuum of hyperglycemia, with or without ketosis. The metabolic similarities and differences in DKA and HHS are highlighted in **Table 404-6**. Both disorders are associated with potentially serious complications if not promptly diagnosed and carefully treated.

DIABETIC KETOACIDOSIS

Clinical Features The symptoms and physical signs of DKA are listed in **Table 404-7** and usually develop over 24 h. DKA may be the initial symptom complex that leads to a diagnosis of type 1 DM, but more frequently, it occurs in individuals with established diabetes. Nausea and vomiting are often prominent, and their presence in an individual with diabetes warrants laboratory evaluation for DKA. Abdominal pain may be severe and can resemble acute pancreatitis or ruptured viscus. Hyperglycemia leads to glucosuria, volume depletion, and tachycardia. Hypotension can occur because of volume depletion in combination with peripheral vasodilatation. Kussmaul respirations and a fruity odor on the patient's breath (secondary to metabolic acidosis and increased acetone) are classic signs of the disorder. Lethargy and central nervous system depression may evolve into coma with severe DKA but should also prompt evaluation for other reasons for altered mental status (e.g., infection, hypoxemia). Cerebral edema, an extremely serious complication of DKA, is seen most frequently in children. Signs of infection, which may precipitate DKA, should be sought on physical examination, even in the absence of fever. Failure to augment insulin therapy during physiologic stress often compounds the problem. Tissue ischemia (heart, brain) can also be a precipitating factor. Omission of insulin because of an infusion pump delivery site

TABLE 404-6 Laboratory Values in Diabetic Ketoacidosis (DKA), Hyperglycemic Hyperosmolar State (HHS), and Euglycemic DKA (Representative Ranges at Presentation)

	DKA	HHS	EUGLYCEMIC DKA[c]
Glucose,[a] mmol/L (mg/dL)	13.9–33.3 (250–600)	33.3–66.6 (600–1200)	<11.1-13.9 (<200–250)[c]

[a]Large changes occur during treatment of DKA. [b]Although plasma levels may be normal or high at presentation, total-body stores are usually depleted. [c]Sometimes occurs with SGLT2 inhibitor treatment; disproportionate glucosuria is consistent with SGLT2 inhibitor effect.

occlusion or device malfunction, eating disorder, mental health disorders, or an unstable psychosocial environment may sometimes be a factor precipitating DKA. Complete omission or inadequate administration of insulin by the patient or health care team (in a hospitalized patient with type 1 DM) may precipitate DKA.

Pathophysiology DKA results from relative or absolute insulin deficiency combined with counterregulatory hormone excess (glucagon, catecholamines, cortisol, and growth hormone). Both insulin deficiency and glucagon excess, in particular, are necessary for DKA to develop. The decreased ratio of insulin to glucagon promotes gluconeogenesis, glycogenolysis, and ketone body formation in the liver, as well as increases in substrate delivery from fat and muscle (free fatty acids, amino acids) to the liver. Ketosis results from a marked increase in free fatty acid release from adipocytes, with a resulting shift toward ketone body synthesis in the liver. Reduced insulin levels, in combination with elevations in catecholamines and growth hormone, also increase lipolysis and the release of free fatty acids. Markers of inflammation (cytokines, C-reactive protein) are elevated in both DKA and HHS.

Laboratory Abnormalities and Diagnosis The timely diagnosis of DKA is crucial and allows for prompt initiation of therapy. DKA is characterized by hyperglycemia (serum glucose >13.9 mmol/L [250 mg/dL], ketosis, and metabolic acidosis [serum bicarbonate <15–18 mmol/L with increased anion gap]) along with a number of secondary metabolic derangements (Table 404-6). Occasionally, the serum glucose is only minimally elevated and may even be normal (euglycemic DKA). This has been noted especially in individuals treated with SGLT2 inhibitors. Arterial pH usually ranges between 6.8 and 7.3, depending on the severity of the acidosis. Despite a total-body potassium deficit, the serum potassium at presentation may be mildly elevated, secondary to the acidosis and volume depletion. Total-body stores of sodium, chloride, phosphorus, and magnesium are also reduced in DKA but are not accurately reflected by their levels in the serum because of hypovolemia and hyperglycemia. Elevated blood urea nitrogen (BUN) and serum creatinine levels reflect intravascular volume depletion. Leukocytosis, hypertriglyceridemia, and hyperlipoproteinemia are commonly found as well. Hyperamylasemia may suggest a diagnosis of pancreatitis, especially when accompanied by abdominal pain. However, in DKA the amylase is usually of salivary origin and thus is not diagnostic of pancreatitis. Serum lipase should be obtained if pancreatitis is suspected.

The measured serum sodium is reduced as a consequence of the hyperglycemia (1.6-mmol/L [1.6-meq] reduction in serum sodium for each 5.6-mmol/L [100-mg/dL] rise in the serum glucose). A normal serum sodium in the setting of DKA indicates a more profound water deficit.

In DKA, the ketone body, β-hydroxybutyrate, is synthesized at a threefold greater rate than acetoacetate; however, acetoacetate is preferentially detected by a commonly used ketosis detection reagent (nitroprusside). Serum ketones are present at significant levels (usually positive at serum dilution of ≥1:8). The nitroprusside tablet, or stick, is often used to detect urine ketones; certain medications such as captopril or penicillamine may cause false-positive reactions. Serum or plasma assays for β-hydroxybutyrate are preferred because they more accurately reflect the true ketone body level.

The metabolic derangements of DKA exist along a spectrum, beginning with mild acidosis with moderate hyperglycemia evolving into more severe findings. The degree of acidosis and hyperglycemia do not necessarily correlate closely because a variety of factors determine the level of hyperglycemia (oral intake, urinary glucose loss). Ketonemia is a consistent finding in DKA and distinguishes it from simple hyperglycemia. The differential diagnosis of DKA includes starvation ketosis, alcoholic ketoacidosis (bicarbonate usually >15 meq/L), and other forms of increased anion-gap acidosis (Chap. 55).

TABLE 404-7 Manifestations of Diabetic Ketoacidosis

Symptoms	Physical Findings
Nausea/vomiting	Tachycardia
Thirst/polyuria	Dehydration/hypotension
Abdominal pain	Tachypnea/Kussmaul respirations/ respiratory distress
Shortness of breath	Abdominal tenderness (may resemble acute pancreatitis or surgical abdomen)
Precipitating events	Lethargy/obtundation/cerebral edema/possibly coma
Inadequate insulin administration	
Infection (pneumonia/UTI/ gastroenteritis/sepsis)	
Infarction (cerebral, coronary, mesenteric, peripheral)	
Pancreatitis	
Drugs (cocaine)	
Pregnancy	

Abbreviation: UTI, urinary tract infection.

TREATMENT

Diabetic Ketoacidosis

The management of DKA is outlined in Table 404-8. After initiating IV fluid replacement and insulin therapy, the agent or

TABLE 404-8 Management of Diabetic Ketoacidosis

1. Confirm diagnosis (↑ serum glucose, ↑ serum β-hydroxybutyrate, metabolic acidosis).
2. Admit to hospital; intensive care setting may be necessary for frequent monitoring, if pH <7.00, labored respiration, or impaired level of arousal.
3. Assess:
   Serum electrolytes (K^+, Na^+, Mg^{2+}, Cl^-, bicarbonate, phosphate)
   Acid-base status—pH, HCO_3^-, PCO_2, β-hydroxybutyrate
   Renal function (creatinine, urine output)
4. Replace fluids: 2–3 L of 0.9% saline or lactated Ringer's over first 1–3 h (10–20 mL/kg per hour); subsequently, 0.45% saline at 250–500 mL/h; change to 5% glucose and 0.45% saline or lactated Ringer's at 150–250 mL/h when blood glucose reaches 250 mg/dL (13.9 mmol/L).
5. Administer short-acting regular insulin: IV (0.1 units/kg), then 0.1 units/kg per hour by continuous IV infusion; increase two- to threefold if no response by 2–4 h. If the initial serum potassium is <3.3 mmol/L (3.3 meq/L), do not administer insulin until the potassium is corrected. Subcutaneous insulin may be used in uncomplicated, mild-moderate DKA with close monitoring.
6. Assess patient: What precipitated the episode (noncompliance, infection, trauma, pregnancy, infarction, cocaine)? Initiate appropriate workup for precipitating event (cultures, CXR, ECG, etc.).
7. Measure blood glucose every 1–2 h; measure electrolytes (especially K^+, bicarbonate, phosphate) and anion gap every 4 h for first 24 h.
8. Monitor blood pressure, pulse, respirations, mental status, fluid intake and output every 1–4 h.
9. Replace K^+: 10 meq/h when plasma K^+ <5.0–5.2 meq/L (or 20–30 meq/L of infusion fluid), ECG normal, urine flow and normal creatinine documented; administer 40–80 meq/h when plasma K^+ <3.5 meq/L or if bicarbonate is given. If initial serum potassium is >5.2 mmol/L (5.2 meq/L), do not supplement K^+ until the potassium is corrected.
10. See text about bicarbonate or phosphate supplementation.
11. Continue above until patient is stable, glucose goal is 8.3–11.1 mmol/L (150–200 mg/dL), and acidosis is resolved. Insulin infusion may be decreased to 0.02–0.1 units/kg per hour.
12. Administer long-acting insulin as soon as patient is eating. Allow for a 2- to 4-h overlap in insulin infusion and SC long-acting insulin injection.

Abbreviations: CXR, chest x-ray; ECG, electrocardiogram.

event that precipitated the episode of DKA should be sought and aggressively treated. If the patient is vomiting or has altered mental status, a nasogastric tube should be inserted to prevent aspiration of gastric contents. Central to successful treatment of DKA is careful monitoring and frequent reassessment to ensure that the patient and the metabolic derangements are improving. A comprehensive flow sheet should record chronologic changes in vital signs, fluid intake and output, and laboratory values as a function of insulin administered.

After the initial bolus of normal saline or lactated Ringer's, replacement of the sodium and free water deficit is carried out over the next 24 h (fluid deficit is often 3–5 L). When hemodynamic stability and adequate urine output are achieved, IV fluids should be switched to 0.45% saline or lactated Ringer's depending on the calculated volume deficit. The change to 0.45% saline or using lactated Ringer's helps to reduce the trend toward hyperchloremia later in the course of DKA.

A bolus of IV (0.1 units/kg) short-acting regular insulin is usually administered immediately (Table 404-8), and subsequent treatment should provide continuous and adequate levels of circulating insulin. IV administration is usually preferred (0.1 units/kg of regular insulin per h) in patients with severe or complicated DKA because it ensures rapid distribution and allows adjustment of the infusion rate as the patient responds to therapy. Mild to moderate uncomplicated DKA can also be treated with SC short-acting insulin analogues. If chosen, IV regular insulin should be continued until the acidosis resolves and the patient is metabolically stable. As the acidosis and insulin resistance associated with DKA resolve, the insulin infusion rate can be decreased (to 0.02–0.1 units/kg per h). Long-acting insulin, in combination with SC short-acting insulin, should be administered as soon as the patient resumes eating, because this facilitates transition to an outpatient insulin regimen and reduces length of hospital stay. It is crucial to continue the insulin infusion or insulin SC until adequate insulin levels are achieved by administering long-acting insulin by the SC route. Even relatively brief periods of inadequate insulin administration in this transition phase may result in DKA relapse. In euglycemic DKA associated with SGLT2 inhibitors, the pharmacologic effect may persist for 10–14 days following discontinuation of SGLT2 inhibitor therapy as evidenced by ongoing glucosuria despite normoglycemia (glucose <180 mg/dL), during which time relapse of ketoacidosis is common if nutritional intake has not advanced (e.g., in the postoperative setting).

Hyperglycemia usually improves at a rate of 4.2–5.6 mmol/L (50–100 mg/dL) per h as a result of insulin-mediated glucose disposal, reduced hepatic glucose release, and rehydration. Rehydration reduces catecholamines, increases urinary glucose loss, and expands the intravascular volume. The decline in the plasma glucose within the first 1–2 h may be more rapid and is mostly related to volume expansion. When the plasma glucose reaches 11.1–13.9 mmol/L (200–250 mg/dL), glucose should be added to the 0.45% saline infusion to maintain the plasma glucose in the 8.3–11.1 mmol/L (150–200 mg/dL) range, and the insulin infusion should be continued at a lower rate to inhibit ketogenesis. More rapid correction of the serum glucose can precipitate the development of cerebral edema. Ketoacidosis begins to resolve as insulin reduces lipolysis, increases peripheral ketone body use, suppresses hepatic ketone body formation, and promotes bicarbonate regeneration. However, the acidosis and ketosis resolve more slowly than hyperglycemia. Depending on the rise of serum chloride, the anion gap (but not bicarbonate) will normalize. A hyperchloremic acidosis (serum bicarbonate of 15–18 mmol/L [15–18 meq/L]) often follows successful treatment and gradually resolves as the kidneys regenerate bicarbonate and excrete chloride.

Potassium stores are depleted in DKA (estimated deficit 3–5 mmol/kg [3–5 meq/kg]). During treatment with insulin and fluids, various factors contribute to the development of hypokalemia. These include insulin-mediated potassium transport into cells, resolution of the acidosis (which also promotes potassium entry into cells), and urinary loss of potassium salts of organic acids. Thus, potassium repletion should commence as soon as adequate urine output and a normal serum potassium are documented. If the initial serum potassium level is elevated, then potassium repletion should be delayed until the potassium falls into the normal range. Inclusion of 20–40 meq of potassium in each liter of IV fluid is reasonable, but additional potassium supplements may also be required. To reduce the amount of chloride administered, potassium phosphate or acetate can be substituted for the chloride salt. The goal is to maintain the serum potassium at >3.5 mmol/L (3.5 meq/L).

Despite a bicarbonate deficit, bicarbonate replacement is not usually necessary. In fact, theoretical arguments suggest that bicarbonate administration and rapid reversal of acidosis may impair cardiac function, reduce tissue oxygenation, and promote hypokalemia. The results of most clinical trials do not support the routine use of bicarbonate replacement, and one study in children found that bicarbonate use was associated with an increased risk of cerebral edema. However, in the presence of severe acidosis (arterial pH <7.0), sodium bicarbonate (50 mmol [meq/L] in 200 mL of sterile water with 10 meq/L KCl per h) may be administered for the first 2 h until the pH is >7.0. Hypophosphatemia may result from increased glucose usage, but randomized clinical trials have not demonstrated that phosphate replacement is beneficial in DKA. If the serum phosphate is <0.32 mmol/L (1 mg/dL), then phosphate supplement should be considered and the serum calcium monitored. Hypomagnesemia may develop during DKA therapy and may also require supplementation.

With appropriate therapy, the mortality rate of DKA is low (<1%) and is related more to the underlying or precipitating event, such as infection or myocardial infarction. Venous thrombosis, upper GI bleeding, and acute respiratory distress syndrome occasionally complicate DKA. The major nonmetabolic complication of DKA therapy is cerebral edema, which most often develops in children as DKA is resolving. The etiology of and optimal therapy for cerebral edema are not well established, but overreplacement of free water and rapid normalization of serum glucose should be avoided.

Following treatment, the physician and patient should review the sequence of events that led to DKA to prevent future recurrences. Foremost is patient education about the symptoms of DKA, its precipitating factors, and the management of diabetes during a concurrent illness.

HYPERGLYCEMIC HYPEROSMOLAR STATE

Clinical Features The prototypical patient with HHS is an elderly individual with type 2 DM, with a several-week history of polyuria, weight loss, and diminished oral intake that culminates in mental confusion, lethargy, or coma. The physical examination reflects profound dehydration and hyperosmolality and reveals hypotension, tachycardia, and altered mental status. Notably absent are symptoms of nausea, vomiting, and abdominal pain and the Kussmaul respirations characteristic of DKA. HHS is often precipitated by a serious, concurrent illness such as myocardial infarction or stroke. Sepsis, pneumonia, and other serious infections are frequent precipitants and should be sought. In addition, a debilitating condition (prior stroke or dementia) or social situation that compromises water intake usually contributes to the development of the disorder.

Pathophysiology Relative insulin deficiency and inadequate fluid intake are the underlying causes of HHS. Insulin deficiency increases hepatic glucose production (through glycogenolysis and gluconeogenesis) and impairs glucose utilization in skeletal muscle (see above discussion of DKA). Hyperglycemia induces an osmotic diuresis that leads to intravascular volume depletion, which is exacerbated by inadequate fluid replacement. The absence of ketosis in HHS is not understood. Presumably, the insulin deficiency is only relative and less severe than in DKA. Lower levels of counterregulatory hormones and free fatty acids have been found in HHS than in DKA in some studies. It is also possible that the liver is less capable of ketone body synthesis or that the insulin/glucagon ratio does not favor ketogenesis.

Laboratory Abnormalities and Diagnosis The laboratory features in HHS are summarized in Table 404-6. Most notable are the marked hyperglycemia (plasma glucose may be >55.5 mmol/L [1000 mg/dL]), hyperosmolality (>350 mOsm/L), and prerenal azotemia. The measured serum sodium may be normal or slightly low despite the marked hyperglycemia. The corrected serum sodium is usually increased (add 1.6 meq to measured sodium for each 5.6-mmol/L [100-mg/dL] rise in the serum glucose). In contrast to DKA, acidosis and ketonemia are absent or mild. A small anion-gap metabolic acidosis may be present secondary to increased lactic acid. Moderate ketonuria, if present, is secondary to starvation.

TREATMENT

Hyperglycemic Hyperosmolar State

Volume depletion and hyperglycemia are prominent features of both HHS and DKA. Consequently, therapy of these disorders shares several elements (Table 404-8). In both disorders, careful monitoring of the patient's fluid status, laboratory values, and insulin infusion rate is crucial. Underlying or precipitating problems should be aggressively sought and treated. In HHS, fluid losses and dehydration are usually more pronounced than in DKA due to the longer duration of the illness. The patient with HHS is usually older, more likely to have mental status changes, and more likely to have a life-threatening precipitating event with accompanying comorbidities. Even with proper treatment, HHS has a substantially higher mortality rate than DKA (up to 15% in some clinical series).

Fluid replacement should initially stabilize the hemodynamic status of the patient (1–3 L of 0.9% normal saline over the first 2–3 h). Because the fluid deficit in HHS is accumulated over a period of days to weeks, the rapidity of reversal of the hyperosmolar state must balance the need for free water repletion with the risk that too rapid a reversal may worsen neurologic function. If the serum sodium is >150 mmol/L (150 meq/L), 0.45% saline should be used. After hemodynamic stability is achieved, the IV fluid administration is directed at reversing the free water deficit using hypotonic fluids (0.45% saline initially, then 5% dextrose in water [D_5W]). The calculated free water deficit (which can be as great as 9–10 L) should be reversed over the next 1–2 days (infusion rates of 200–300 mL/h of hypotonic solution). Potassium repletion is usually necessary and should be dictated by repeated measurements of the serum potassium. In patients taking diuretics, the potassium deficit can be quite large and may be accompanied by magnesium deficiency. Hypophosphatemia may occur during therapy and can be improved by using KPO_4 and beginning nutrition.

As in DKA, rehydration and volume expansion lower the plasma glucose initially, but insulin is also required. A reasonable regimen for HHS begins with an IV insulin bolus of 0.1 unit/kg followed by IV insulin at a constant infusion rate of 0.1 unit/kg per hour. If the serum glucose does not fall, increase the insulin infusion rate by twofold. As in DKA, glucose should be added to IV fluid when the plasma glucose falls to 11.1–13.9 mmol/L (200–250 mg/dL), and the insulin infusion rate should be decreased to 0.02–0.1 unit/kg per h. The insulin infusion should be continued until the patient has resumed eating and can be transferred to an SC insulin regimen. The patient should be discharged from the hospital on insulin, although some patients can later switch to oral glucose-lowering agents.

MANAGEMENT OF DIABETES IN A HOSPITALIZED PATIENT

Virtually all medical and surgical subspecialties are involved in the care of hospitalized patients with diabetes. Hyperglycemia, whether in a patient with known diabetes or in someone without known diabetes, appears to be a predictor of poor outcome in hospitalized patients. General anesthesia, surgery, infection, or concurrent illness raises the levels of counterregulatory hormones (cortisol, growth hormone, catecholamines, and glucagon) and cytokines that may lead to transient insulin resistance and hyperglycemia. These factors increase insulin requirements by increasing glucose production and impairing glucose utilization and thus may worsen glycemic control. The concurrent illness or surgical procedure may lead to variable insulin absorption and also prevent the patient with DM from eating normally and, thus, may promote hypoglycemia. Glycemic control should be assessed on admission using the HbA_{1c}. Electrolytes, renal function, and intravascular volume status should be assessed as well. The high prevalence of CVD in individuals with DM (especially in type 2 DM) may necessitate preoperative cardiovascular evaluation (Chap. 405).

The goals of diabetes management during hospitalization are near-normoglycemia, avoidance of hypoglycemia, and transition back to the outpatient diabetes treatment regimen. Upon hospital admission, frequent glycemic monitoring should begin, as should planning for diabetes management after discharge. CGM in the hospital or ICU setting is not FDA-approved but is under study. Glycemic control appears to improve the clinical outcomes in a variety of settings, but optimal glycemic goals for the hospitalized patient are incompletely defined. In a number of cross-sectional studies of patients with diabetes, a greater degree of hyperglycemia was associated with worse cardiac, neurologic, and infectious outcomes. In some studies, patients who do not have preexisting diabetes but who develop modest blood glucose elevations during their hospitalization appear to benefit from achieving near-normoglycemia using insulin treatment. However, a large randomized clinical trial (Normoglycemia in Intensive Care Evaluation Survival Using Glucose Algorithm Regulation [NICE-SUGAR])

of individuals in the intensive care unit (ICU) (most of whom were receiving mechanical ventilation) found an increased mortality rate and a greater number of episodes of severe hypoglycemia with very strict glycemic control (target blood glucose of 4.5–6 mmol/L or 81–108 mg/dL) compared to individuals with a more moderate glycemic goal (target blood glucose of <10 mmol/L or 180 mg/dL). Currently, most data suggest that very strict blood glucose control in acutely ill patients likely worsens outcomes and increases the frequency of hypoglycemia. The ADA suggests the following glycemic goals for hospitalized patients: (1) in critically or non–critically ill patients: glucose of 7.8–10.0 mmol/L or 140–180 mg/dL; (2) in selected patients: glucose of 6.1–7.8 mmol/L or 110–140 mg/dL with avoidance of hypoglycemia; (3) the target range in the perioperative period should be 80–180 mg/dL (4.4–10.0 mmol/L).

Critical aspects for optimal diabetes care in the hospital include the following. (1) A hospital-wide system approach to treatment of hyperglycemia and prevention of hypoglycemia is needed. Inpatient diabetes management teams consisting of nurse practitioners and physicians are increasingly common. (2) Diabetes treatment plans should focus on the transition from the ICU and the transition from the inpatient to outpatient setting. (3) Adjustment of the discharge treatment regimen of patients whose diabetes was poorly controlled on admission (as reflected by the HbA_{1c}) is important.

The physician caring for an individual with diabetes in the perioperative period, during times of infection or serious physical illness, or simply when the patient is fasting for a diagnostic procedure must monitor the plasma glucose vigilantly, adjust the diabetes treatment regimen, and provide glucose infusion as needed. Hypoglycemia is frequent in hospitalized patients, and many of these episodes are avoidable. Hospital systems should have a diabetes management protocol to avoid inpatient hypoglycemia. Measures to reduce or prevent hypoglycemia include frequent glucose monitoring, but it is also important to prevent hypoglycemia by anticipating drops in insulin requirement by factors such as decreasing renal function, decreasing glucocorticoid doses, or interruption of nutrition (parenteral or enteral or PO).

Depending on the severity of the patient's illness and the hospital setting, the physician can use either an insulin infusion or SC insulin. Insulin infusions are preferred in the ICU or in a clinically unstable setting because the half-life of the infused insulin is quite short (minutes). The absorption of SC insulin may be variable in such situations. Insulin infusions can also effectively control plasma glucose in the perioperative period and when the patient is unable to take anything by mouth, although for relatively short (<4 h) procedures most patients can remain on SC insulin. Regular insulin is used rather than insulin analogues for IV insulin infusion because it is less expensive and equally effective. The physician must consider carefully the clinical setting in which an insulin infusion will be used, including whether adequate ancillary personnel are available to monitor the blood glucose frequently and whether they can adjust the insulin infusion rate to maintain the blood glucose within the optimal range. Insulin-infusion algorithms should integrate the insulin sensitivity of the patient, frequent blood glucose monitoring, and the trend of changes in the blood glucose to determine the insulin-infusion rate. Insulin-infusion algorithms jointly developed and implemented by nursing and physician staff are advised. Because of the short half-life of IV regular insulin, it is necessary to administer long-acting insulin prior to discontinuation of the insulin infusion (2–4 h before the infusion is stopped) to avoid a period of insulin deficiency.

In patients who are not critically ill or not in the ICU, basal or "scheduled" insulin is provided by SC, long-acting insulin supplemented by prandial and/or "corrective" insulin using a short-acting insulin (insulin analogues preferred). "Sliding scale," short-acting insulin alone, where no insulin is given unless the blood glucose is elevated, is inadequate for inpatient glucose management and should not be used. The short-acting, prandial insulin dose should include coverage for food consumption (based on anticipated carbohydrate intake) plus corrective insulin based on the patient's insulin sensitivity and the blood glucose. For example, if the patient is thin (and likely insulin-sensitive), an insulin correction factor might be 1 unit for each 2.7 mmol/L (50 mg/dL) over the glucose target. If the patient is obese and insulin-resistant, then the insulin correction factor might be 2 units for each 2.7 mmol/L (50 mg/dL) over the glucose target. It is critical to individualize the regimen and adjust the basal or "scheduled" insulin dose frequently, based on the corrective insulin required. A consistent carbohydrate-controlled diabetes meal plan for hospitalized patients provides a predictable amount of carbohydrate for a particular meal each day (but not necessarily the same amount for breakfast, lunch, and supper) and avoids concentrated sweets. Individuals with type 1 DM who are undergoing general anesthesia and surgery or who are seriously ill should receive continuous insulin, either through an IV insulin infusion, their insulin infusion device, or by SC administration of a reduced dose of long-acting insulin. Short-acting insulin alone is insufficient. Prolongation of a surgical procedure or delay in the recovery room is not uncommon and may result in periods of insulin deficiency leading to DKA. Insulin infusion is the preferred method for managing patients with type 1 DM over a prolonged (several hours) perioperative period or when serious concurrent illness is present (0.5–1.0 units/h of regular insulin). If the diagnostic or surgical procedure is brief (<4 h), a reduced dose of SC insulin may suffice (20–50% basal reduction, with short-acting bolus insulin withheld or reduced). This approach prevents interruption of insulin infusion device therapy, or for MDI, facilitates the transition back to long-acting insulin after the procedure. The blood glucose should be monitored frequently during the illness or in the perioperative period.

Individuals with type 2 DM can be managed with either an insulin infusion or SC long-acting insulin (20–50% reduction depending on clinical setting) plus preprandial, short-acting insulin. Oral glucose-lowering agents should be discontinued upon admission (or up to a week prior to planned admission for SGLT2 inhibitors) and are not useful in regulating the plasma glucose in clinical situations where the insulin requirements and glucose intake are changing rapidly. Moreover, these oral agents may be dangerous if the patient is fasting (e.g., hypoglycemia with sulfonylureas, euglycemic DKA with SGLT2 inhibitors) or at risk for declining kidney function due to, for example, radiographic contrast media or unstable CHF (lactic acidosis with metformin). Once clinically stable, oral glucose-lowering agents may be resumed in anticipation of discharge.

SPECIAL CONSIDERATIONS IN DM

TOTAL PARENTERAL NUTRITION (TPN)/TOTAL ENTERAL NUTRITION (TEN)

(See also Chap. 335) TPN or TEN greatly increases insulin requirements. In addition, individuals not previously known to have DM may become hyperglycemic during TPN or TEN and require insulin treatment. For TPN, IV insulin infusion is the preferred treatment for hyperglycemia, and rapid titration to the required insulin dose is done most efficiently using a separate insulin infusion. After the total insulin dose has been determined, a proportion of this insulin may be added directly to the TPN solution to cover the nutritional requirements for insulin, and adjusted based on the need for modified dosing of short-acting insulin. In TEN, hyperglycemia may be limited by using high-protein formulations, but often requires insulin treatment. Short-acting insulins should be used to cover bolus or continuous enteral feeding to minimize the risk for hypoglycemia should the TEN be interrupted or held. Patients with insulin deficiency (type 1 DM and pancreatogenic DM) should also receive long-acting insulin (0.1–0.2 units/kg per day) to cover basal insulin requirements should the TPN or TEN be interrupted or cycled.

GLUCOCORTICOIDS

Glucocorticoids increase insulin resistance, decrease glucose utilization, increase hepatic glucose production, and impair insulin secretion. These changes lead to a worsening of glycemic control in individuals with DM and may precipitate hyperglycemia in other individuals. If new-onset hyperglycemia remains during chronic treatment with supraphysiologic doses of glucocorticoid (>5 mg of prednisone or equivalent), the DM may be called "steroid-induced diabetes." The

effects of glucocorticoids on glucose homeostasis are dose-related, usually reversible, most pronounced in the postprandial period, and dependent on the timing and type of glucocorticoid. If the FPG is near the normal range, oral diabetes agents (e.g., sulfonylureas, metformin) may be sufficient to reduce hyperglycemia. If the FPG is >11.1 mmol/L (200 mg/dL), oral agents are usually not efficacious, and insulin therapy is required. Short-acting insulin may be sufficient alone or together with long-acting insulin in order to control postprandial glucose excursions.

DIABETES MANAGEMENT IN OLDER ADULTS

Diabetes is very common in older adults, being present in ~25% of individuals over the age of 65 years. Increasingly, individuals with many years of type 1 DM are part of the patient population. As discussed above, individualized therapeutic goals and modalities in older adults should consider biologic age, other comorbidities and risk factors (hypertension, CV disease, etc.), neurocognitive and physical functional status, living arrangements, social support, and other medications. For example, the HbA_{1c} goal for a highly functional 80-year-old should be different from that for an individual with diabetes in long-term care (skilled nursing facilities). In the former, the HbA_{1c} goal (<7.0–7.5%) and selected therapies may be similar to younger individuals whereas in an individual with complex/poor health or cognitive impairment, an HbA_{1c} goal of <8.0–8.5% would be reasonable. Critical to diabetes management in all older individuals is the avoidance of hypoglycemia, which can worsen underlying cognitive impairment or CV disease. For individuals using CGM, <1% of time should be spent with glucose <70 mg/dL and spending >50% of time in the target range of 70–180 mg/dL is acceptable. Thus, medications that can cause hypoglycemia (insulin secretagogues, insulin) should be used carefully. In choosing medications for diabetes, the adverse effects (Table 404-5) should be considered (especially heart failure, renal insufficiency, etc.). Hypertension and dyslipidemia should be treated in elderly individuals with diabetes because there is clear benefit of blood pressure control with the benefit for lipid-lowering medications being less clearly demonstrated.

REPRODUCTIVE ISSUES

Reproductive capacity in either men or women with DM appears to be normal. Menstrual cycles may be associated with alterations in glycemic control in women with DM. Pregnancy is associated with marked insulin resistance; the increased insulin requirements often precipitate DM and lead to the diagnosis of gestational diabetes mellitus (GDM). Glucose, which at high levels is a teratogen to the developing fetus, readily crosses the placenta, but insulin does not. Thus, hyperglycemia from the maternal circulation may stimulate insulin secretion in the fetus. The anabolic and growth effects of insulin may result in macrosomia. GDM complicates ~7% (range 1–14%) of pregnancies. The incidence of GDM is greatly increased in certain ethnic groups, including blacks and Latinas, consistent with a similar increased risk of type 2 DM. Current recommendations advise screening for glucose intolerance between weeks 24 and 28 of pregnancy in women not known to have diabetes. Therapy for GDM is similar to that for individuals with pregnancy-associated diabetes and involves MNT and insulin, if hyperglycemia persists. Oral glucose-lowering agents are not approved for use during pregnancy, but studies using metformin or glyburide have shown efficacy and have not found toxicity. With current practices, the morbidity and mortality rates of the mother with GDM and the fetus are not different from those in the nondiabetic population. Individuals who develop GDM are at marked increased risk for developing type 2 DM in the future and should be screened periodically for DM (see screening recommendations in **Chap. 403**). Most individuals with GDM revert to normal glucose tolerance after delivery, but some will continue to have overt diabetes or impairment of glucose tolerance after delivery. In addition, children of women with GDM appear to be at risk for obesity and glucose intolerance and have an increased risk of diabetes beginning in the later stages of adolescence.

Pregnancy in individuals with known DM requires meticulous planning and adherence to strict treatment regimens. Intensive insulin therapy and near-normalization of the HbA_{1c} (<6.5%) are essential for individuals with existing DM who are planning pregnancy. Consideration should be given to insulin infusion and CGM devices that may help to improve glycemic control prior to conception since the most crucial period of glycemic control is soon after fertilization. The risk of fetal malformations is increased 4–10 times in individuals with uncontrolled DM at the time of conception, and normal blood glucose during the preconception period and throughout the periods of organ development in the fetus should be the goal, with more frequent monitoring of HbA_{1c} every 2 months throughout gestation. Maintenance of the HbA_{1c} <6.0–6.5% reduces the incidence and severity of fetal macrosomia and neonatal hypoglycemia related to fetal hyperinsulinism driven by elevated maternal glucose.

LIPODYSTROPHIC DM

Lipodystrophy, or the loss of SC fat tissue, may be generalized in certain genetic conditions such as leprechaunism, or acquired as part of an autoimmune disorder. Generalized lipodystrophy is associated with leptin deficiency and severe insulin resistance and is often accompanied by acanthosis nigricans, hepatic steatosis, and severe hypertriglyceridemia. Recombinant human leptin (metreleptin) may allow for the achievement of metabolic control in generalized lipodystrophy, but is associated with the development of neutralizing antibodies and is available only through a restricted program under a Risk Evaluation and Mitigation Strategy (REMS). Partial lipodystrophy may also be caused by certain genetic or acquired (e.g., treatment of HIV infection) conditions that produce a metabolic syndrome of insulin resistance, ectopic fat accumulation (hepatic steatosis), and glucose intolerance and dyslipidemia. Treatment of early childhood cancer with total-body irradiation may affect adipose tissue development and predisposes survivors to similar metabolic syndrome of adipose tissue dysfunction with potentially severe insulin resistance, hepatic steatosis, hypertriglyceridemia, and diabetes.

HIV-Associated Lipodystrophy Protease inhibitors and nucleoside reverse transcriptase inhibitors used in the treatment of HIV disease **(Chap. 202)** have been associated with a centripetal accumulation of fat (visceral and abdominal area), accumulation of fat in the dorsocervical region, loss of extremity fat, decreased insulin sensitivity (elevations of the fasting insulin level and reduced glucose tolerance on IV glucose tolerance testing), hepatic steatosis, and dyslipidemia. Although many aspects of the physical appearance of these individuals resemble Cushing's syndrome, increased cortisol levels do not account for this appearance. The possibility remains that this is related to HIV infection or highly active antiretroviral therapy by some undefined mechanism, because the syndrome can be observed in individuals not treated with protease inhibitors. Therapy for HIV-related lipodystrophy and associated metabolic dysfunction may include metformin, especially for abdominal fat accumulation, pioglitazone, especially for lipoatrophy and hepatic steatosis. Tesamorelin, a growth hormone–releasing hormone analog, is effective for reducing excess abdominal fat but requires monitoring of the serum insulin-like growth factor-1 (IGF-1) level, and may worsen glucose tolerance or exacerbate hyperglycemia in individuals with diabetes.

405 Diabetes Mellitus: Complications

Alvin C. Powers, John M. Stafford, Michael R. Rickels

Diabetes-related complications affect many organ systems and are responsible for the majority of morbidity and mortality associated with the disease. For many years in the United States, diabetes has been the leading cause of new blindness in adults, renal failure, and nontraumatic lower extremity amputation and is a leading contributor to coronary heart disease (CHD). Diabetes-associated microvascular complications usually do not appear until the second decade of hyperglycemia. In contrast, diabetes-associated CHD risk, related in part to insulin resistance and its resultant dyslipidemeia, may develop before hyperglycemia is established. Because type 2 diabetes mellitus (DM) often has a long asymptomatic period of hyperglycemia before diagnosis, many individuals with type 2 DM have both glucose-related and insulin resistance–related complications at the time of diagnosis. Fortunately, many of the diabetes-related complications can be prevented or mitigated with aggressive glycemic, lipid, and blood pressure control, as well as efforts at early detection.

Diabetes-related complications can be divided into vascular and nonvascular complications and are similar for type 1 and type 2 DM (Table 405-1). The vascular complications of DM are further subdivided into microvascular (retinopathy, neuropathy, nephropathy) and macrovascular complications (CHD, peripheral arterial disease [PAD], cerebrovascular disease). Microvascular complications are diabetes-specific, whereas macrovascular complications have additional pathophysiologic features that are shared with the general population. Nonvascular complications include infections, skin changes, hearing loss, and increased risk of dementia and impaired cognitive function.

TABLE 405-1 Diabetes-Related Complications

Microvascular
Eye disease
Retinopathy (nonproliferative/proliferative)
Macular edema
Neuropathy
Sensory and motor (mono- and polyneuropathy)
Autonomic
Nephropathy (albuminuria and declining renal function)
Macrovascular
Coronary heart disease
Peripheral arterial disease
Cerebrovascular disease
Other
Gastrointestinal (gastroparesis, diarrhea)
Genitourinary (uropathy/sexual dysfunction)
Dermatologic
Infectious
Cataracts
Glaucoma
Cheiroarthropathy[a]
Periodontal disease
Hearing loss
Other comorbid conditions associated with type 1 or type 2 diabetes (relationship to hyperglycemia is uncertain): depression, obstructive sleep apnea, fatty liver disease, hip fracture, osteoporosis, cognitive impairment or dementia, low testosterone in men.

[a]Thickened skin and reduced joint mobility.

GLYCEMIC CONTROL AND COMPLICATIONS

The microvascular complications of both type 1 and type 2 DM result from chronic hyperglycemia (Fig. 405-1). Evidence implicating a causative role for chronic hyperglycemia in the development of macrovascular complications is less conclusive as other factors such as dyslipidemia and hypertension also play important roles in macrovascular complications. CHD events and mortality rate are two to four times greater in patients with type 2 DM, correlate with fasting and

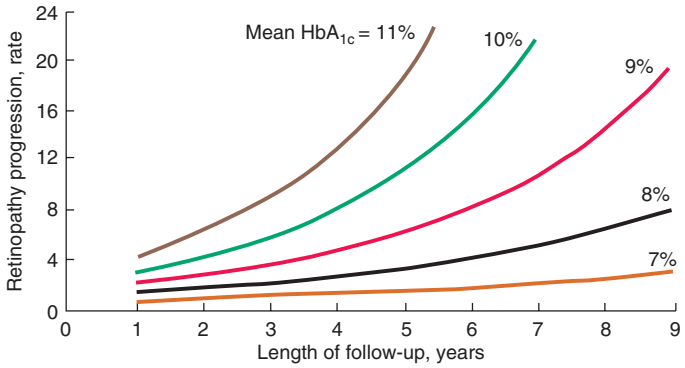

FIGURE 405-1 Relationship of glycemic control and diabetes duration to diabetic retinopathy. The progression of retinopathy in individuals in the Diabetes Control and Complications Trial is graphed as a function of the length of follow-up with different curves for different hemoglobin A_{1c} (HbA_{1c}) values. *(Modified with permission from The relationship of glycemic exposure (HbA1c) to the risk of development and progression of retinopathy in the diabetes control and complications trial. Diabetes 44:968, 1995.)*

postprandial plasma glucose levels as well the hemoglobin A_{1c} (HbA_{1c}), and can be reduced by intensive diabetes management as demonstrated in patients with type 1 DM.

The Diabetes Control and Complications Trial (DCCT) provided definitive proof that reduction in chronic hyperglycemia can prevent many complications of type 1 DM (Fig. 405-1). This large multicenter clinical trial randomized >1400 individuals with type 1 DM to either intensive or conventional diabetes management and prospectively evaluated the development of diabetes-related complications during a mean follow-up of 6.5 years. Individuals in the intensive diabetes management group received insulin by multiple daily injections or pump delivery along with extensive educational, psychological, and medical support, and achieved a substantially lower HbA_{1c} (7.3%) than individuals in the conventional diabetes management group (9.1%). After the DCCT results were reported in 1993, study participants were all offered intensive therapy and continue to be followed in the Epidemiology of Diabetes Intervention and Complications (EDIC) trial, which has completed >30 years of follow-up (DCCT + EDIC). During the subsequent follow-up of >18 years, the initial separation in glycemic control disappeared with both arms maintaining a mean HbA_{1c} of 8.0%, allowing assessment of a legacy effect of 6.5 years of near-normoglycemia on the development of long-term complications.

The DCCT phase demonstrated that improvement of glycemic control reduced nonproliferative and proliferative retinopathy (47% reduction), albuminuria (39% reduction), clinical nephropathy (54% reduction), and neuropathy (60% reduction). Improved glycemic control also slowed the progression of early diabetic complications. During the DCCT phase, weight gain (4.6 kg) and severe hypoglycemia (requiring assistance of another person to treat) were more common in the intensive therapy group. The benefits of an improvement in glycemic control occurred over the entire range of elevated HbA_{1c} values (Fig. 405-1). The results of the DCCT predicted that individuals in the intensive diabetes management group would gain 7.7 additional years of vision, 5.8 additional years free from end-stage renal disease (ESRD), and 5.6 years free from lower extremity amputations. If all complications of DM were combined, individuals in the intensive diabetes management group would experience >15.3 more years of life without significant microvascular complications of DM, compared to individuals who received standard therapy. This translates into an additional 5.1 years of life expectancy for individuals in the intensive diabetes management group. The 30-year follow-up data in the intensively treated group show a continued reduction in retinopathy, nephropathy, and cardiovascular disease. For example, individuals in the intensive therapy group had a 42–57% reduction in cardiovascular events (nonfatal myocardial infarction [MI], stroke, or death from a cardiovascular event) at a mean follow-up of 18 years, even though their subsequent glycemic control was the same as those in the conventional diabetes management group from years 6.5 to 17. During the EDIC phase, <1% of the cohort had become blind, lost a limb to amputation, or required dialysis. Other complications of diabetes, including autonomic neuropathy, bladder and sexual dysfunction, and cardiac autonomic neuropathy, were reduced in the intensive therapy group.

The United Kingdom Prospective Diabetes Study (UKPDS) studied the course of >5000 individuals with type 2 DM for >10 years. This study used multiple treatment regimens and monitored the effect of intensive glycemic control and risk factor treatment on the development of diabetic complications. Newly diagnosed individuals with type 2 DM were randomized to (1) intensive management using various combinations of insulin, a sulfonylurea, or metformin or (2) conventional therapy using dietary modification and pharmacotherapy with the goal of symptom prevention. In addition, individuals were randomly assigned to different antihypertensive regimens. Individuals in the intensive treatment arm achieved an HbA_{1c} of 7% compared to 7.9% in the standard treatment group. The UKPDS demonstrated that each percentage point reduction in HbA_{1c} was associated with a 35% reduction in microvascular complications. As in the DCCT, there was a continuous relationship between glycemic control and development of complications. Improved glycemic control also reduced the cardiovascular event rate in the follow-up period of >10 years.

One of the major findings of the UKPDS was that strict blood pressure control significantly reduced both macro- and microvascular complications. In fact, the beneficial effects of blood pressure control were greater than the beneficial effects of glycemic control. Lowering blood pressure to moderate goals (144/82 mmHg) reduced the risk of DM-related death, stroke, microvascular endpoints, retinopathy, and heart failure (risk reductions between 32 and 56%). The American Diabetes Association (ADA) recommends blood pressure control <130/80 mmHg for individuals with high cardiovascular risk and <140/90 mmHg for individuals with lower cardiovascular risk.

Similar reductions in the risks of retinopathy and nephropathy were also seen in a small trial of lean Japanese individuals with type 2 DM randomized to either intensive glycemic control or standard therapy with insulin (Kumamoto study). These results demonstrate the effectiveness of improved glycemic control in individuals of different ethnicity and, presumably, a different etiology of DM (i.e., phenotypically different from those in the DCCT and UKPDS). The Action to Control Cardiovascular Risk in Diabetes (ACCORD) and Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation (ADVANCE) trials also found that improved glycemic control reduced microvascular complications.

Thus, these large clinical trials in type 1 and type 2 DM indicate that chronic hyperglycemia plays a causative role in the pathogenesis of diabetic micro- and macrovascular complications. In both the DCCT and the UKPDS, cardiovascular events were reduced at follow-up of >10 years, even though the improved glycemic control was not maintained. This legacy effect for a positive impact of a period of improved glycemic control on later diabetes complications has been attributed to the benefits of *metabolic memory*. Of note, despite long-standing DM, some individuals never develop retinopathy or nephropathy, suggesting a genetic susceptibility for developing particular complications.

MECHANISMS OF COMPLICATIONS

Chronic hyperglycemia is the important etiologic factor leading to complications of DM, but the mechanism(s) by which it leads to such diverse cellular and organ dysfunction is unknown. The complications are likely multifactorial with an emerging hypothesis that hyperglycemia leads to epigenetic changes **(Chap. 466)** that influence gene expression in affected cells. Chronic hyperglycemia leads to formation of advanced glycosylation end products (AGEs; e.g., pentosidine, glucosepane, and carboxymethyllysine), which bind to specific cell surface receptor and/or the nonenzymatic glycosylation of intra- and extracellular proteins, leading to cross-linking of proteins, glomerular dysfunction, endothelial dysfunction, altered extracellular matrix composition, and accelerated atherosclerosis. The reduction of cellular glucose entry afforded in certain tissues such as myocardium and renal tubular epithelium through inhibition of the sodium glucose co-transporter-2 (SGLT-2) may contribute to the reduction in CHD events and renoprotective effects.

Growth factors may play an important role in some diabetes-related microvascular complications, and their production is increased by most of these proposed pathways. For example, vascular endothelial growth factor A (VEGF-A) is increased locally in diabetic proliferative retinopathy, decreases after laser photocoagulation, and is the target inhibited by intravitreous injection therapy. A possible unifying mechanism is that hyperglycemia leads to increased production of reactive oxygen species or superoxide in the mitochondria and this may activate several pathways. Although hyperglycemia serves as the initial trigger for complications of diabetes, it is still unknown whether the same pathophysiologic processes are operative in all complications or whether some pathways predominate in certain organs.

The mechanisms of diabetes-related macrovascular complications including MI and stroke are glucose-related mechanisms but also include traditional cardiovascular risk factors (dyslipidemia, hypertension) and insulin resistance. In type 2 diabetes, insulin resistance is present years prior to diagnosis and is associated with obesity and ectopic accumulation of lipids in muscle and liver. Additionally, insulin fails to appropriately suppress lipolysis from adipose tissue, which results in increased delivery of fatty acids to liver, muscle, endothelial cells, and

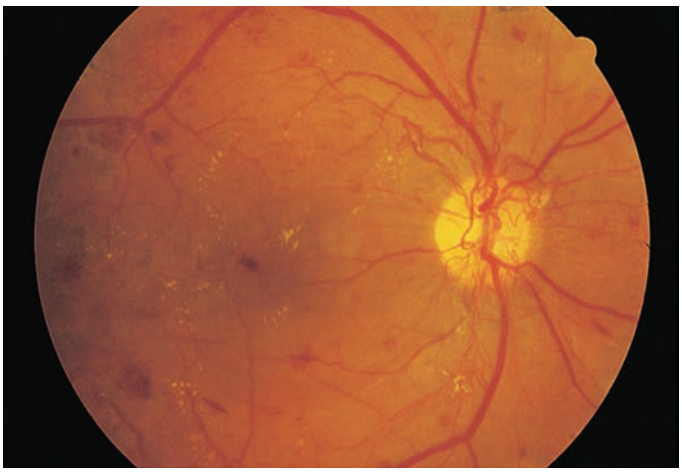

FIGURE 405-2 Diabetic retinopathy results in scattered hemorrhages, yellow exudates, and neovascularization. This patient has neovascular vessels proliferating from the optic disc, requiring urgent panretinal laser photocoagulation.

cardiac tissues, leading to tissue accumulation of triglycerides, diacylglycerol, and ceramides.

OPHTHALMOLOGIC COMPLICATIONS OF DIABETES MELLITUS

DM is the leading cause of blindness between the ages of 20 and 74 in the United States. Severe vision loss is primarily the result of progressive diabetic retinopathy, which leads to significant macular edema and new blood vessel formation. Diabetic retinopathy is classified into two stages: nonproliferative and proliferative. Nonproliferative diabetic retinopathy usually appears late in the first decade or early in the second decade of hyperglycemia and is marked by retinal vascular microaneurysms, blot hemorrhages, and cotton-wool spots **(Fig. 405-2)**. Mild nonproliferative retinopathy may progress to more extensive disease, characterized by changes in venous vessel caliber, intraretinal microvascular abnormalities, and more numerous microaneurysms and hemorrhages. The pathophysiologic mechanisms invoked in nonproliferative retinopathy include loss of retinal pericytes, increased retinal vascular permeability, alterations in retinal blood flow, and abnormal retinal microvasculature, all of which can lead to retinal ischemia.

The appearance of neovascularization in response to retinal hypoxemia is the hallmark of proliferative diabetic retinopathy (Fig. 405-2). These newly formed vessels appear near the optic nerve and/or macula and rupture easily, leading to vitreous hemorrhage, fibrosis, and ultimately retinal detachment. Not all individuals with nonproliferative retinopathy go on to develop proliferative retinopathy, but the more severe the nonproliferative disease, the greater the chance of evolution to proliferative retinopathy within 5 years. This creates an important opportunity for early detection and treatment of diabetic retinopathy. Clinically significant macular edema can occur in the context of nonproliferative or proliferative retinopathy. Fluorescein angiography and optical coherence tomography are useful to detect macular edema, which is associated with a 25% chance of moderate visual loss over the next 3 years. Duration of DM and degree of glycemic control are the best predictors of the development of retinopathy; hypertension, nephropathy, and dyslipidemia are also risk factors. Nonproliferative retinopathy is found in many individuals who have had DM for >20 years. Although there is genetic susceptibility for retinopathy, it confers less influence than either the duration of DM or the degree of glycemic control.

TREATMENT

Diabetic Retinopathy

The most effective therapy for diabetic retinopathy is prevention. Intensive glycemic and blood pressure control will delay the development and slow the progression of retinopathy in individuals with either type 1 or type 2 DM. Paradoxically, during the first 6–12 months of improved glycemic control, established diabetic retinopathy may transiently worsen. Fortunately, this progression is temporary, and in the long term, improved glycemic control is associated with less diabetic retinopathy. Individuals with known retinopathy may be candidates for prophylactic laser photocoagulation when initiating intensive therapy, and especially prior to pancreas or islet transplantation that can rapidly normalize glycemia. Women with type 1 or type 2 DM who are planning pregnancy should be screened prior to and during pregnancy. Once advanced retinopathy is present, improved glycemic control imparts less benefit, although adequate ophthalmologic care can prevent most blindness. Lowering elevated levels of triglycerides with fenofibrate may reduce the progression of retinopathy.

Regular, comprehensive eye examinations are essential for all individuals with DM (see Table 404-1). Most diabetic eye disease can be successfully treated if detected early. Routine, nondilated eye examinations by the primary care provider or diabetes specialist are inadequate to detect diabetic eye disease, which requires a dilated eye exam performed by an optometrist or ophthalmologist, and subsequent management by a retinal specialist. Treatment of severe nonproliferative or proliferative retinopathy or macular edema with laser photocoagulation and/or anti-VEGF therapy (intravitreous injection) usually is successful in preserving vision. Aspirin therapy (up to 650 mg/d) does not appear to influence the natural history of diabetic retinopathy, and antiplatelet agents and anticoagulation may be continued in patients receiving intravitreal injections of anti-VEGF agents. Patients with severe proliferative retinopathy with vitreous hemorrhage and/or traction involving the macula often require surgical vitrectomy.

RENAL COMPLICATIONS OF DIABETES MELLITUS

Diabetic nephropathy is the leading cause of chronic kidney disease (CKD) and ESRD requiring renal replacement therapy. CKD in individuals with DM is associated with an increased risk of cardiovascular disease, and the prognosis of individuals with diabetes on dialysis is poor. Individuals with diabetic nephropathy commonly have diabetic retinopathy. The presence of CKD in individuals with DM and no retinopathy should prompt investigation for alternative causes of kidney disease.

Like other microvascular complications, the pathogenesis of diabetic nephropathy is related to chronic hyperglycemia. The mechanisms by which chronic hyperglycemia leads to diabetic nephropathy, although incompletely defined, involve the effects of soluble factors (growth factors, angiotensin II, endothelin, AGEs), hemodynamic alterations in the renal microcirculation (glomerular hyperfiltration or hyperperfusion, increased glomerular capillary pressure), and structural changes in the glomerulus (increased extracellular matrix, basement membrane thickening, mesangial expansion, fibrosis). Some of these effects may be mediated through angiotensin II and mineralocorticoid receptors. Smoking accelerates the decline in renal function. Because only 20–40% of patients with diabetes develop diabetic nephropathy, additional genetic or environmental susceptibility factors likely contribute. Known risk factors include a family history of diabetic nephropathy. Diabetic nephropathy and ESRD secondary to DM develop more commonly in blacks, Native Americans, and Hispanic individuals with diabetes.

The natural history of diabetic nephropathy is characterized by a sequence of events that was initially defined for individuals with type 1 DM but appears similar in type 2 DM **(Fig. 405-3)**. Glomerular hyperperfusion and renal hypertrophy occur in the first years after the onset of DM and are associated with an increase of the estimated glomerular filtration rate (GFR). During the first 5 years of DM, thickening of the glomerular basement membrane, glomerular hypertrophy, and mesangial volume expansion occur as the GFR returns to normal. After 5–10 years of type 1 DM, many individuals begin to excrete small amounts of albumin in the urine. The ADA defines albuminuria as a persistently increased urinary albumin-to-creatinine ratio >30 mg/g

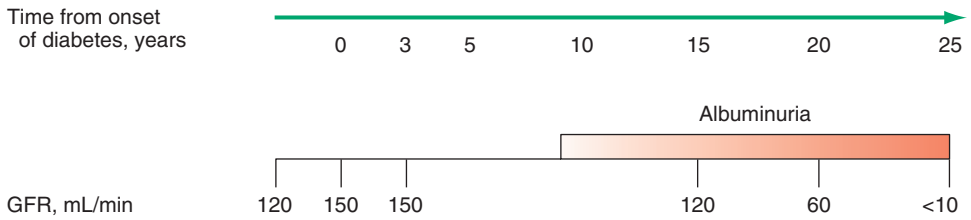

FIGURE 405-3 Time course of development of diabetic nephropathy. The relationship of time from onset of diabetes, albuminuria, and the glomerular filtration rate (GFR) are shown. This figure is typical for type 1 diabetes; individuals with type 2 diabetes may present with a lower GFR at the time of diagnosis.

on a spot specimen. In some individuals with DM and albuminuria of short duration, the albuminuria can regress with improvement in glycemic control **(Fig. 405-4)** or with improvement in blood pressure control using angiotensin-aldosterone system blockade and/or SGLT-2 inhibitor therapy. Diabetic kidney disease refers to albuminuria and reduced GFR (<60 mL/min per 1.73 m^2); CKD related to diabetes, which may not be accompanied by albuminuria, is also discussed in **Chap. 311**. Once there is marked albuminuria and a reduction in GFR, the pathologic changes are likely irreversible.

The nephropathy that develops in type 2 DM differs from that of type 1 DM in that albuminuria may be present when type 2 DM is diagnosed, reflecting its long asymptomatic period, and hypertension more often contributes to albuminuria and reduced GFR. Finally, it should be noted that albuminuria in type 2 DM may be secondary to factors unrelated to DM, such as hypertension, congestive heart failure (CHF), prostate disease, or infection.

As part of comprehensive diabetes care **(Chap. 404)**, albuminuria should be detected at an early stage when effective therapies can be instituted. Because some individuals with type 1 or type 2 DM have a decline in GFR in the absence of albuminuria, assessment should include a spot urinary albumin-to-creatinine ratio and an estimated GFR. The urine protein measurement by routine urinalysis does not detect low levels of albumin excretion. Screening for albuminuria should commence 5 years after the onset of type 1 DM and at the time of diagnosis of type 2 DM.

Type IV renal tubular acidosis (hyporeninemic hypoaldosteronism) may occur in type 1 or 2 DM. These individuals develop a propensity to hyperkalemia and acidemia, which may be exacerbated by medications (especially angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], and mineralocorticoid receptor antagonists). Patients with DM are predisposed to radiocontrast-induced nephrotoxicity. Risk factors for radiocontrast-induced nephrotoxicity are preexisting nephropathy and volume depletion. Individuals with DM undergoing radiographic procedures with contrast dye should be well hydrated before and after dye exposure, and the serum creatinine should be monitored for 24–48 h following the procedure. Metformin should be held until postintervention confirmation of preserved kidney function.

TREATMENT

Diabetic Nephropathy

The optimal therapy for diabetic nephropathy is prevention by control of glycemia (**Chap. 404 outlines glycemic goals and approaches**). Interventions effective in slowing progression of

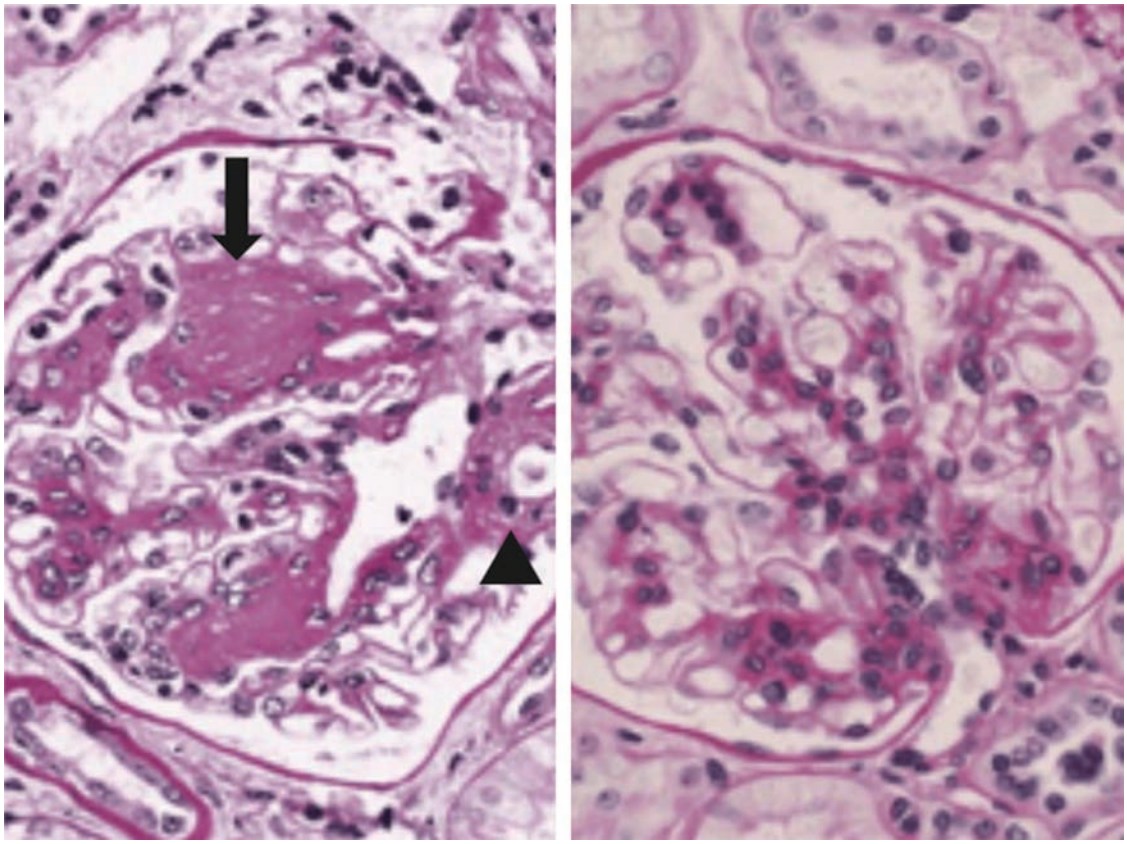

FIGURE 405-4 Diabetic glomerular changes in a patient with type 1 diabetes are reversed by 10 years of normoglycemia as a result of pancreas transplantation. Left panel shows diabetic glomerulosclerosis (*arrow*) and arteriolar hyalinosis (*arrowhead*) on kidney biopsy. Right panel shows a near-normal glomerulus in the same patient after 10 years of normoglycemia from pancreas transplantation. *(Reproduced with permission from P Fioretto et al: Reversal of lesions of diabetic nephropathy after pancreas transplantation. N Engl J Med 339:69, 1998.)*

albuminuria and declining kidney function include (1) improved glycemic control, (2) strict blood pressure control, (3) administration of an ACE inhibitor or ARB, and (4) in individuals with type 2 DM, administration of a SGLT-2 inhibitor. Dyslipidemia should also be treated.

Improved glycemic control reduces the rate at which albuminuria appears and progresses in type 1 and type 2 DM. However, once there is a large amount of albuminuria, it becomes more difficult for improved glycemic control to slow progression of renal disease, although 10-years of normoglycemia resulting from pancreas transplantation may lead to regression of mesangial glomerular lesions (Fig. 405-4). During the later phase of declining renal function, insulin requirements may fall as the kidney is a site of insulin degradation. As the GFR decreases with progressive nephropathy, the use and dose of glucose-lowering agents should be reevaluated **(see Table 404-5)**. Some glucose-lowering medications (sulfonylureas and metformin) are contraindicated in advanced renal insufficiency, while others may require dose adjustment (glinides and DPP-4 inhibitors).

Many individuals with type 1 or type 2 DM develop hypertension. Numerous studies in both type 1 and type 2 DM demonstrate the effectiveness of strict blood pressure control in reducing albumin excretion and slowing the decline in renal function. Blood pressure should be maintained at <140/90 mmHg in individuals with diabetes and possibly <130/80 mmHg in individuals at increased risk for CVD and CKD progression.

Either ACE inhibitors or ARBs should be used to reduce the albuminuria and the associated decline in GFR in individuals with type 1 or type 2 DM (see "Hypertension," below). Most experts believe that the two classes of drugs are equivalent in patient with diabetes. ARBs can be used as an alternative in patients who develop ACE inhibitor–associated cough or angioedema. After initiation of therapy, some increase the dose and monitor the urinary albumin. There is no benefit of intervention prior to onset of albuminuria or using a combination of an ACE inhibitor and an ARB. If use of either ACE inhibitors or ARBs is not possible or the blood pressure is not controlled, then diuretics, calcium channel blockers (nondihydropyridine class), or beta blockers (with caution in individuals at increased risk for experiencing hypoglycemia) may be used. Mineralocorticoid receptor antagonists can help reduce blood pressure and albuminuria in refractory cases but require close monitoring of the serum potassium. SGLT-2 inhibitors can reduce albuminuria and, after an initial decline (~3 mL/min per 1.73 m^2) in GFR, may slow further decline in kidney function in individuals with and without T2DM and CKD. The mechanism of action of SGLT-2 inhibitors is multifactorial and includes inducing natriuresis, reducing intraglomerular pressure through restored tubuloglomerular feedback, and potentially altering signaling pathways related to nutrient sensing (e.g., AMPK). Because of the elevated risk of euglycemic diabetic ketoacidosis with SGLT-2 inhibitors, use in individuals with type 1 DM and insulin-deficient type 2 DM is not recommended. Some glucagon-like peptide-1 (GLP-1) receptor agonists may also both improve glycemic control and reduce the progression of diabetic kidney disease in individuals with type 2 DM and established CVD **(Chap. 404)**. The ADA suggests a protein intake of 0.8 mg/kg of body weight/day in individuals with diabetic kidney disease.

Nephrology consultation should be considered when the estimated GFR is <30 mL/min per 1.743 m^2 or with atypical features such as hematuria, rapidly declining renal function, or proteinuria > 3 g/day. Complications of atherosclerosis are the leading cause of death in diabetic individuals with nephropathy and hyperlipidemia should be treated aggressively. Referral for transplant evaluation should be made when the GFR approaches 20 mL/min per 1.73 m^2. Preemptive (before dialysis) kidney transplantation from a living donor or simultaneous pancreas-kidney transplantation from a deceased donor both offer improved patient and kidney survival over waiting for a deceased donor kidney alone. A combined pancreas-kidney transplant offers the promise of normoglycemia and freedom from both insulin and dialysis. As compared with nondiabetic individuals, hemodialysis in patients with DM is associated with more frequent complications, such as hypotension (due to autonomic neuropathy or loss of reflex tachycardia), more difficult vascular access, and accelerated progression of retinopathy.

NEUROPATHY AND DIABETES MELLITUS

Diabetic neuropathy, which occurs in ~50% of individuals with long-standing type 1 and type 2 DM, manifests as a diffuse neuropathy (distal symmetrical polyneuropathy and/or autonomic neuropathy), a mononeuropathy, and/or a radiculopathy/polyradiculopathy. As with other complications of DM, the development of neuropathy correlates with the duration of diabetes and glycemic control. Additional risk factors are body mass index (BMI) (the greater the BMI, the greater the risk of neuropathy) and smoking. The presence of CVD, elevated triglycerides, and hypertension is also associated with diabetic peripheral neuropathy. Both myelinated and unmyelinated nerve fibers are lost. Because the clinical features of diabetic neuropathy are similar to those of other neuropathies, the diagnosis of diabetic neuropathy should be made only after other possible etiologies are excluded **(Chap. 446)**.

Distal Symmetric Polyneuropathy (DSPN) DSPN, the most common form of diabetic neuropathy, most frequently presents with distal sensory loss and pain, but up to 50% of patients do not have symptoms of neuropathy. Symptoms may include a sensation of numbness, tingling, sharpness, or burning that begins in the feet and spreads proximally. Hyperesthesia, paresthesia, and dysesthesia also may occur. Pain typically involves the lower extremities, is usually present at rest, and worsens at night. Both an acute (lasting <12 months) and a chronic form of painful diabetic neuropathy may occur. The acute form is sometimes treatment-related, occurring in the context of improved glycemic control. As diabetic neuropathy progresses, the pain subsides and eventually disappears, but a sensory deficit persists, and motor defects may develop. Physical examination **(Chap. 403)** often reveals sensory loss (to 10-g monofilament and/or vibration), loss of ankle deep-tendon reflexes, abnormal position sense, and muscular atrophy or foot drop. Annual screening for DSPN should begin 5 years after diagnosis of type 1 DM and at the time of diagnosis of type 2 DM and is aimed at detecting loss of protective sensation (LOPS). LOPS and DSPN are major risk factors for foot ulceration and falls due to small and large nerve fiber dysfunction and predispose to lower extremity amputation.

Autonomic Neuropathy Individuals with long-standing type 1 or 2 DM may develop signs of autonomic dysfunction involving the parasympathetic (cholinergic) and sympathetic (adrenergic) systems. DM-related autonomic neuropathy can affect multiple organ systems, including the cardiovascular, gastrointestinal (GI), genitourinary, sudomotor, and metabolic systems. Cardiovascular autonomic neuropathy, reflected by decreased heart rate variability, resting tachycardia, and orthostatic hypotension, is associated with an increase in CVD. Orthostatic hypotension, a late and unusual complication of diabetes, is sometimes seen in patients with associated DPN and severe parasympathetic dysfunction. Reports of sudden death in DM have also been attributed to autonomic neuropathy affecting the cardiovascular system and predisposing to severe hypoglycemia, both of which may prolong the QTc interval. Autonomic neuropathy may reduce counterregulatory hormone release (especially epinephrine), leading to an inability to sense hypoglycemia appropriately (hypoglycemia unawareness) **(Chap. 406)** and subjecting the patient to the risk of severe hypoglycemia. Gastroparesis and bladder-emptying abnormalities are often caused by the autonomic neuropathy seen in DM (discussed below). Hyperhidrosis of the upper extremities and anhidrosis of the lower extremities result from sympathetic nervous system dysfunction. Anhidrosis of the feet can promote dry skin with cracking, which increases the risk of foot ulcers.

Mononeuropathy and/or Radiculopathy/Polyradiculopathy Mononeuropathy (dysfunction of isolated cranial or peripheral nerves) is less common than polyneuropathy in DM and presents with pain

and motor weakness in the distribution of a single nerve. Mononeuropathies can occur at entrapment sites such as carpal tunnel or be noncompressive. Involvement of the third cranial nerve is most common and is heralded by diplopia. Physical examination reveals ptosis and ophthalmoplegia with normal pupillary constriction to light. Sometimes other cranial nerves, such as IV, VI, or VII (Bell's palsy), are affected. Peripheral mononeuropathies or simultaneous involvement of more than one nerve (mononeuropathy multiplex) may also occur. Diabetic radiculopathy or polyradiculopathy is a syndrome characterized by severe disabling pain in the distribution of one or more nerve roots. It may be accompanied by motor weakness. Intercostal or truncal radiculopathy causes pain over the thorax or abdomen. Involvement of the lumbar plexus or femoral nerve may cause severe pain in the thigh or hip and may be associated with muscle weakness in the hip flexors or extensors (diabetic amyotrophy). Fortunately, diabetic polyradiculopathies are usually self-limited and resolve over 6–12 months.

TREATMENT

Diabetic Neuropathy

Prevention of diabetic neuropathy is critical through improved glycemic control. Treatment of diabetic neuropathy is less than satisfactory. Lifestyle modifications (exercise, diet) have some efficacy in DSPN in type 2 DM and hypertension, and hypertriglyceridemia should be treated. Efforts to improve glycemic control in long-standing diabetes may be confounded by hypoglycemia unawareness. Patients should avoid neurotoxins (including alcohol) and smoking, and consider supplementation with vitamins for possible deficiencies (B_{12}, folate; **Chap. 333**). Metformin may reduce intestinal absorption of vitamin B_{12} in type 2 DM, and pernicious anemia is more common in type 1 DM where it is associated with anti–parietal cell autoantibodies and may require sublingual or parenteral B_{12} replacement. Patients should be educated that loss of sensation in the foot increases the risk for ulceration and its sequelae and that prevention of such problems is paramount. Patients with symptoms or signs of neuropathy or LOPS should check their feet daily and take precautions (footwear) aimed at preventing calluses or ulcerations. If foot deformities are present, a podiatrist should be involved.

Chronic, painful diabetic neuropathy is difficult to treat with only symptomatic treatment being available; evidence of the effectiveness of improved glycemic control in painful diabetic neuropathy is lacking. Two oral agents approved by the U.S. Food and Drug Administration (FDA), duloxetine and pregabalin, or gabapentin is usually initially used for pain associated with diabetic neuropathy. Diabetic neuropathy may respond to tricyclic antidepressants, venlafaxine, carbamazepine, tramadol, or topical capsaicin products. An 8% capsaicin patch requires application by a health care provider. Tapentadol, a centrally acting opioid, is also approved by the FDA, but has only modest efficacy and poses addiction risk, making it and other opioids less desirable and not a first-line therapy. No direct comparisons of agents are available, and it is reasonable to switch agents if there is no response or if side effects develop. Referral to a pain management center may be necessary.

Therapy of orthostatic hypotension secondary to autonomic neuropathy is also difficult. Nonpharmacologic maneuvers (adequate salt intake, avoidance of dehydration and diuretics, lower extremity support hose, and physical activity) may offer some benefit. A variety of agents have limited success (midodrine and droxidopa are approved by the FDA for orthostatic hypotension of any etiology). Patients with resting tachycardia may be considered for beta blocker therapy with caution exercised if there is hypoglycemia unawareness. Patients with type 1 DM and orthostatic hypotension should be evaluated for primary adrenal insufficiency (Addison's disease) that may be associated with anti-21-hydroxylase autoantibodies as part of an autoimmune polyendocrine syndrome **(Chap. 389)**.

GASTROINTESTINAL/GENITOURINARY DYSFUNCTION

Long-standing type 1 and 2 DM may affect the motility and function of the GI and genitourinary systems. The most prominent GI symptoms are delayed gastric emptying (gastroparesis) and altered small- and large-bowel motility (constipation or diarrhea). Gastroparesis may present with symptoms of anorexia, nausea, vomiting, early satiety, and abdominal bloating. Microvascular complications (retinopathy and neuropathy) are usually present. Nuclear medicine scintigraphy after ingestion of a radiolabeled meal may document delayed gastric emptying but may not correlate well with the patient's symptoms. Noninvasive "breath tests" following ingestion of a radiolabeled meal are emerging as a diagnostic tool. Although parasympathetic dysfunction secondary to chronic hyperglycemia is important in the development of gastroparesis, hyperglycemia itself also impairs gastric emptying. Nocturnal diarrhea, alternating with constipation, is a feature of DM-related GI autonomic neuropathy. In type 1 DM, these symptoms should also prompt evaluation for celiac disease that is associated with anti-tissue transglutaminase autoantibodies because of its increased frequency.

Diabetic autonomic neuropathy may lead to genitourinary dysfunction including cystopathy and female sexual dysfunction (reduced sexual desire, dyspareunia, reduced vaginal lubrication). Symptoms of diabetic cystopathy begin with an inability to sense a full bladder and a failure to void completely. As bladder contractility worsens, bladder capacity and the postvoid residual increase, leading to symptoms of urinary hesitancy, decreased voiding frequency, incontinence, and recurrent urinary tract infections.

Erectile dysfunction and retrograde ejaculation are very common in DM and may be one of the earliest signs of diabetic neuropathy **(Chap. 397)**. Erectile dysfunction, which increases in frequency with the age of the patient and the duration of diabetes, may occur in the absence of other signs of diabetic autonomic neuropathy.

TREATMENT

Gastrointestinal/Genitourinary Dysfunction

Current treatments for these complications of DM are inadequate and nonspecific. Improved glycemic control should be a goal but has not clearly shown benefit. Smaller, more frequent meals that are easier to digest (liquid) and low in fat and fiber may minimize symptoms of gastroparesis. Medications that slow gastric emptying (opioids, GLP-1 receptor agonists) should be avoided. Metoclopramide may be used with severe symptoms but is restricted to short-term treatment in both the United States and Europe. Symptoms of gastroesophageal reflux disease may require acid blocking therapy with a histamine-2 receptor antagonist or proton pump inhibitor. Gastric electrical stimulatory devices are available but not approved. Diabetic diarrhea in the absence of bacterial overgrowth is treated symptomatically **(Chap. 325)**.

Diabetic cystopathy should be treated with scheduled voiding or self-catheterization. Drugs that inhibit type 5 phosphodiesterase are effective for erectile dysfunction, but their efficacy in individuals with DM is slightly lower than in the nondiabetic population **(Chap. 397)**.

CARDIOVASCULAR MORBIDITY AND MORTALITY

CVD is increased in individuals with type 1 or type 2 DM. The Framingham Heart Study revealed a marked increase in PAD, coronary artery disease, MI, and CHF (risk increase from one- to fivefold) in DM. In addition, the prognosis for individuals with diabetes who have coronary artery disease or MI is worse than for nondiabetics. CHD is more likely to involve multiple vessels in individuals with DM. In addition to CHD, cerebrovascular disease is increased in individuals with DM (threefold increase in stroke). Thus, after controlling for all known cardiovascular risk factors, both type 1 and type 2 DM increases the cardiovascular death rate twofold in men and fourfold in women. CHF is common in long-standing DM.

The American Heart Association considers DM as a controllable risk factor for cardiovascular disease; in some studies, type 2 DM patients without a prior MI have a similar risk for coronary artery-related events as nondiabetic individuals who have had a prior MI. Cardiovascular risk assessment in type 2 DM should encompass a more nuanced approach. Cardiovascular risk is lower and not equivalent in a younger individual with a brief duration of type 2 DM compared to an older individual with long-standing type 2 DM. In individuals without a known diagnosis of diabetes, elevated HbA_{1c} is predictive not just of diabetes risk but also risk of CHD, stroke, and all-cause mortality. Because of the extremely high prevalence of underlying CVD in individuals with diabetes (especially in type 2 DM), evidence of atherosclerotic vascular disease (e.g., cardiac stress test) should be sought in an individual with diabetes who has symptoms, even if atypical, suggestive of cardiac ischemia or peripheral or carotid arterial disease. The screening of asymptomatic individuals with diabetes for CHD is not recommended or cost-effective. The absence of chest pain ("silent ischemia") is common in individuals with diabetes, and a thorough cardiac evaluation should be considered prior to major surgical procedures.

The increase in cardiovascular morbidity and mortality rates in diabetes appears to relate to the synergism of hyperglycemia with other cardiovascular risk factors such as dyslipidemia (elevated triglycerides, low high-density lipoprotein [HDL] cholesterol and small dense low-density lipoprotein [LDL]), hypertension, obesity, reduced physical activity, and cigarette smoking. Additional risk factors that are prevalent include CKD (albuminuria, reduced GFR), abnormal platelet function, increased markers of inflammation, and endothelial dysfunction. The results of the ACCORD trial and VADT trial, which demonstrated that tight glucose control had limited benefit on cardiovascular outcomes in individuals with established cardiovascular disease, suggesting the importance of insulin resistance and dyslipidemia.

TREATMENT

Cardiovascular Disease

Treatment of coronary disease in individuals with DM has substantial overlap with treatment in individuals without DM **(Chap. 273)**. Revascularization procedures for CHD, including percutaneous coronary interventions (PCIs) and coronary artery bypass grafting (CABG), may be less efficacious in individuals with DM. Initial success rates of PCI in individuals with DM are similar to those in the nondiabetic population, but higher rates of restenosis and lower long-term patency and survival rates have been reported. CABG plus optimal medical management likely has better outcomes than PCI for individuals with diabetes.

Aggressive cardiovascular risk modification in all individuals with DM and glycemic control should be individualized, as discussed in **Chap. 404**. In patients with known CHD and type 2 DM, an ACE inhibitor or ARB, a statin, and acetylsalicylic acid (ASA; aspirin) should be considered. Beta blockers can be used in individuals with diabetes after MI. In patients with CHF, thiazolidinediones should not be used **(Chap. 404)**. However, metformin can be used in patients with stable CHF if the renal function is normal. Some newer glucose-lowering therapies also have cardiovascular benefit, including the GLP-1 analogues liraglutide (LEADER trial), semaglutide (SUSTAIN-6 trial), and dulaglutide (REWIND trial) and the SGLT-2 inhibitors empagliflozin (EMPA-REG trial) and canagliflozin (CANVAS trial). All SGLT-2 inhibitors have been shown to exhibit benefits on prevention of CHF exacerbations. A possible increased risk of lower limb amputation and Fournier's gangrene has been reported with SGLT-2 inhibitor therapy.

Antiplatelet therapy reduces cardiovascular events in individuals with DM who have CHD and is recommended. The ADA recommends considering the use of aspirin for primary prevention of coronary events in individuals with diabetes with an increased cardiovascular risk (>50 years old with at least one risk factor such as hypertension, dyslipidemia, smoking, family history, or albuminuria). ASA is not recommended for primary prevention in those with a low cardiovascular risk (<50 years old with no risk factors). The aspirin dose is the same as in nondiabetic individuals.

Cardiovascular Risk Factors • DYSLIPIDEMIA Individuals with DM may have several forms of dyslipidemia **(Chap. 407)**. Because of the additive cardiovascular risk of hyperglycemia and hyperlipidemia, lipid abnormalities should be assessed aggressively and treated as part of comprehensive diabetes care **(Chap. 404)**. The most common pattern of dyslipidemia is hypertriglyceridemia and reduced HDL cholesterol levels. DM itself does not increase levels of LDL, but the small dense LDL particles found in type 2 DM are more atherogenic because they are more easily glycated and susceptible to oxidation.

Almost all treatment studies of diabetic dyslipidemia have been performed in individuals with type 2 DM because of the greater frequency of dyslipidemia in this form of diabetes. Interventional studies have shown that the beneficial effects of LDL reduction with statins are similar in the diabetic and nondiabetic populations. No prospective studies have addressed similar questions in individuals with type 1 DM. Because the frequency of CVD is low in children and young adults with diabetes, assessment of cardiovascular risk should be incorporated into the guidelines discussed below.

Based on the guidelines provided by the ADA, all individuals with diabetes should be advised about lifestyle modification, including diet, weight loss, and increased physical activity **(Chap. 404)**. If individuals with diabetes have elevated triglyceride levels (>1.7 mmol/L [150 mg/dL]) or low HDL cholesterol (<1 mmol/L [40 mg/dL] in men and <1.3 mmol/L [50 mg/dL] in women), lifestyle modification and improved glycemic control should be further emphasized. If triglycerides remain >5.7 mmol/L (500 mg/dL), treatment with fish oil, fibrate drugs, and icosapent may reduce the risk of pancreatitis. Icosapent additionally lowers CHD risk.

In terms of pharmacologic therapy, the ADA recommends the following: (1) all patients with diabetes and atherosclerotic cardiovascular disease should receive high-intensity statin therapy; (2) in patients aged 40–75 years without cardiovascular disease, consider moderate-intensity statin therapy to target LDL cholesterol <100 mg/dL (without additional risk factors) or high-intensity statin therapy to target LDL cholesterol <70 mg/dL (with additional risk factors); and (3) in patients aged 20–39 years with additional risk factors, consider moderate-intensity statin therapy. Screening for coronary artery calcification by electron beam computed tomography (CT) scan that noninvasively detects the presence of coronary artery atherosclerosis may help guide treatment initiation or intensity in equivocal cases or ambivalent patients. Atorvastatin and rosuvastatin are generally well tolerated if started at lower doses and titrated up to meet lipid goals. Atorvastatin is the statin of choice in patients with renal disease. If statin intolerant or the LDL cholesterol goal is not met, consider the addition of ezetimibe or a PCSK9 inhibitor **(Chap. 407)**. Icosapent results in cardiovascular risk reduction on top of statin treatment and may have a larger benefit in diabetic individuals. Statin usage is associated with a mild increase in the risk of developing type 2 DM. This risk is greatest in individuals with other risk factors for type 2 DM **(Chap. 403)**. However, the cardiovascular benefits of statin use outweigh the mildly increased risk of diabetes. Niacin use is associated with an even greater increased risk for type 2 DM or worsening glycemic control and is not recommended because of a lack of improvement in cardiovascular outcomes.

In individuals with type 2 DM and kidney disease or type 2 DM and atherosclerotic cardiovascular disease or multiple atherosclerotic risk factors, the ADA recommends an SGLT-2 inhibitor or GLP-1 receptor agonist as a second-line agent after metformin. In individuals with type 2 DM and heart failure (reduced ejection fraction), the ADA recommends an SGLT-2 inhibitor. Individuals with atherosclerotic

cardiovascular disease and type 1 or type 2 DM should be treated with an ACE inhibitor or angiotensin receptor blocker and beta blockers and antiplatelet therapy, as in the nondiabetic population **(Chap. 273)**.

HYPERTENSION Hypertension can accelerate other complications of DM, particularly CVD, nephropathy, and retinopathy. Blood pressure should be measured at every clinic visit. In targeting a goal of blood pressure of <140/90 mmHg, therapy should first emphasize lifestyle modifications such as weight loss, exercise, stress management, and sodium restriction. The blood pressure goal should be individualized. In some younger individuals or those with increased cardiovascular risk, the provider may target a blood pressure of <130/80 mmHg. Realizing that more than one agent is usually required to reach the blood pressure goal, the ADA recommends that all patients with diabetes and hypertension be treated with an ACE inhibitor or an ARB initially. Subsequently, agents that reduce cardiovascular risk (beta blockers, thiazide diuretics, and calcium channel blockers) should be incorporated into the regimen. ACE inhibitors and ARBs are likely equivalent in most patients with diabetes and renal disease but should not be combined. The addition of a potassium-sparing diuretic or mineralocorticoid receptor antagonist can help achieve blood pressure targets in refractory cases. Serum potassium and renal function should be monitored.

Because of the high prevalence of atherosclerotic disease in individuals with type 2 DM, the possibility of renovascular hypertension should be considered when the blood pressure is not readily controlled.

LOWER EXTREMITY COMPLICATIONS

DM is the leading cause of nontraumatic lower extremity amputation in the United States. Foot ulcers and infections are also a major source of morbidity in individuals with DM. The reasons for the increased incidence of these disorders in DM involve the interaction of several pathogenic factors: neuropathy, abnormal foot biomechanics, PAD, and poor wound healing. The peripheral sensory neuropathy interferes with normal protective mechanisms and allows the patient to sustain major or repeated minor trauma to the foot, often without knowledge of the injury. Disordered proprioception causes abnormal weight bearing while walking and subsequent formation of callus or ulceration. Motor and sensory neuropathy lead to abnormal foot muscle mechanics and to structural changes in the foot (hammer toe, claw toe deformity, prominent metatarsal heads, Charcot joint). Autonomic neuropathy results in anhidrosis and altered superficial blood flow in the foot, which promote drying of the skin and fissure formation. PAD and poor wound healing impede resolution of minor breaks in the skin, allowing them to enlarge and to become infected.

Many individuals with DM develop a foot ulcer (great toe or metatarsophalangeal areas are most common), and a significant subset who develop an ulceration will ultimately undergo amputation (14–24% risk with that ulcer or subsequent ulceration). Risk factors for foot ulcers or amputation include male sex, diabetes for >10 years, peripheral neuropathy, abnormal structure of foot (bony abnormalities, callus, thickened nails), PAD, smoking, history of previous ulcer or amputation, visual impairment, poor glycemic control, and diabetic nephropathy, especially dialysis. Large calluses are often precursors to or overlie ulcerations. Aggressive treatment of LDL cholesterol with the PCSK9 inhibitor evolocumab has been shown to reduce the risk of future major adverse limb events in patients with PAD.

TREATMENT

Lower Extremity Complications

The optimal therapy for foot ulcers and amputations is prevention through identification of high-risk patients, education of the patient, and institution of measures to prevent ulceration. High-risk patients should be identified during the routine, annual foot examination performed on all patients with DM (see "Ongoing Aspects of Comprehensive Diabetes Care" in **Chap. 404**). If the monofilament test or one of the other tests is abnormal, the patient is diagnosed with LOPS **(Chap. 403)**. Providers should consider screening for asymptomatic PAD in individuals >50 years of age who have diabetes and other risk factors using ankle-brachial index testing **(Chap. 281)**. Patient education should emphasize (1) careful selection of footwear, (2) daily inspection of the feet to detect early signs of poor-fitting footwear or minor trauma, (3) daily foot hygiene to keep the skin clean and moist, (4) avoidance of self-treatment of foot abnormalities and high-risk behavior (e.g., walking barefoot), and (5) prompt consultation with a health care provider if an abnormality arises. Calluses and nail deformities should be treated by a podiatrist. Interventions directed at risk factor modification include orthotic shoes and devices, callus management, nail care, and prophylactic measures to reduce increased skin pressure from abnormal bony architecture. Attention to other risk factors for vascular disease (smoking, dyslipidemia, hypertension) and improved glycemic control are also important.

Despite preventive measures, foot ulceration and infection are common and represent a serious problem. Due to the multifactorial pathogenesis of lower extremity ulcers, management of these lesions is multidisciplinary and often demands expertise in orthopedics, vascular surgery, endocrinology, podiatry, and infectious diseases. The plantar surface of the foot is the most common site of ulceration. Ulcers may be primarily neuropathic (no accompanying infection) or may have surrounding cellulitis or osteomyelitis. Cellulitis without ulceration should be treated with antibiotics that provide broad-spectrum coverage (see below).

An infected ulcer is a clinical diagnosis, because superficial culture of any ulceration will likely find multiple bacterial species of unknown significance. The infection surrounding the foot ulcer may be due to multiple organisms, with aerobic gram-positive cocci (staphylococci including methicillin-resistant *Staphylococcus aureus* [MRSA], group A and B streptococci) being most common and with aerobic gram-negative bacilli and/or obligate anaerobes as co-pathogens.

Gas gangrene may develop in the absence of clostridial infection. Cultures should be obtained from the debrided ulcer base or from purulent drainage or aspiration of the wound. Wound depth should be determined by inspection and probing with a blunt-tipped sterile instrument. A wound that probes to the bone represents clinical evidence of osteomyelitis. Plain radiographs of the foot should be performed to assess the possibility of osteomyelitis in chronic ulcers that have not responded to therapy. Magnetic resonance imaging (MRI) is the most specific modality, with nuclear medicine scans and labeled white cell studies as alternatives. Surgical debridement is often necessary.

Osteomyelitis is best treated by a combination of prolonged antibiotics and debridement of infected bone when possible. The possible contribution of vascular insufficiency should be considered in all patients. Peripheral arterial bypass procedures are often effective in promoting wound healing and in decreasing the need for amputation of the ischemic limb **(Chap. 281)**.

Interventions with demonstrated efficacy in diabetic foot ulcers or wounds include the following: (1) off-loading, (2) debridement, (3) wound dressings, (4) appropriate use of antibiotics, (5) revascularization, and (6) limited amputation. Off-loading is the complete avoidance of weight bearing on the ulcer, which removes the mechanical trauma that retards wound healing. Bed rest and a variety of orthotic devices or contact casting limit weight bearing on wounds or pressure points. Surgical debridement is important and effective, but the efficacy of other modalities for wound healing (enzymes, growth factors, cellular therapy, hyperbaric oxygen) is unclear. Dressings such as hydrocolloid dressings promote wound healing by creating a moist environment, controlling the exudate, and protecting the wound. Antiseptic agents should be avoided. Topical antibiotics are of limited value. Referral for physical therapy, orthotic evaluation, and rehabilitation should occur once the infection is controlled.

Mild or non-limb-threatening infections can be treated with oral antibiotics directed predominantly at methicillin-susceptible staphylococci and streptococci (e.g., dicloxacillin, cephalosporin, amoxicillin/clavulanate). However, in patients with a prior history of MRSA or in locations with a high prevalence of MRSA, treatment with clindamycin, doxycycline, or trimethoprim-sulfamethoxazole is preferred. Trimethoprim-sulfamethoxazole exhibits less reliable coverage of streptococci than the β-lactams, and individuals with diabetes may develop adverse effects including acute kidney injury and hyperkalemia. Surgical debridement of necrotic tissue, local wound care (avoidance of weight bearing over the ulcer), and close surveillance for progression of infection are crucial. More severe infections require IV antibiotics as well as offloading and local wound care. Urgent surgical debridement may be required. Optimization of glycemic control should be a goal. IV antibiotics should provide broad-spectrum coverage directed toward *S. aureus*, including MRSA, streptococci, gram-negative aerobes, and anaerobic bacteria. Initial antimicrobial regimens include vancomycin plus a β-lactam/β-lactamase inhibitor or carbapenem, or vancomycin plus a quinolone with metronidazole. In some cases, daptomycin, ceftaroline, or linezolid may be substituted for vancomycin in consultation with an Infectious Diseases expert. If the infection surrounding the ulcer is not improving with IV antibiotics, reassessment of antibiotic coverage and reconsideration of the need for surgical debridement or revascularization are indicated. With clinical improvement, oral antibiotics and local wound care can be continued on an outpatient basis with close follow-up.

INFECTIONS

Individuals with DM have a greater frequency and severity of infection. The reasons for this include incompletely defined abnormalities in cell-mediated immunity and phagocyte function associated with hyperglycemia, as well as diminished vascularization. Hyperglycemia aids the colonization and growth of a variety of organisms (*Candida* and other fungal species). Many common infections are more frequent and severe in the diabetic population, whereas several rare infections are seen almost exclusively in the diabetic population. Examples of this latter category include rhinocerebral mucormycosis, emphysematous infections of the gallbladder and urinary tract, and "malignant" or invasive otitis externa. Invasive otitis externa is usually secondary to *Pseudomonas aeruginosa* infection in the soft tissue surrounding the external auditory canal, usually begins with pain and discharge, and may rapidly progress to osteomyelitis and meningitis. These infections should be sought, in particular, in patients presenting with severe hyperglycemia **(Chap. 404)**.

Pneumonia, urinary tract infections, and skin and soft tissue infections are all more common in the diabetic population. In general, the organisms that cause pulmonary infections are similar to those found in the nondiabetic population; however, gram-negative organisms, *S. aureus*, and *Mycobacterium tuberculosis* are more frequent pathogens. Adults with DM should receive vaccination against pneumococcus, annually against influenza, and now also against the coronavirus SARS-CoV-2, which causes increased morbidity and mortality in obese individuals and patients with DM **(Chap. 199)**. In addition to early antibiotic therapy for presumed bacterial infections, patients with DM should be considered for early intervention with antiviral agents (e.g., against influenza in flu or varicella-zoster virus in shingles) or with monoclonal antibodies in COVID-19. Urinary tract infections (either lower tract or pyelonephritis) are the result of common bacterial agents such as *Escherichia coli*, although several yeast species (e.g., *Candida albicans* and *Candida glabrata*) are commonly observed. Complications of urinary tract infections include emphysematous pyelonephritis and emphysematous cystitis. Bacteriuria occurs frequently in individuals with diabetic cystopathy and does not require antibiotic therapy except in specific circumstances such as pregnancy or a planned urologic procedure. Susceptibility to furunculosis, superficial candidal infections, and vulvovaginitis are increased. Poor glycemic control is a common denominator in individuals with these infections. Individuals with diabetes have an increased rate of colonization of *S. aureus* in the skinfolds and nares. Individuals with diabetes also have a greater risk of postoperative wound infections that may be mitigated by perioperative protocols for insulin administration to maintain glycemic control.

DERMATOLOGIC MANIFESTATIONS

The most common skin manifestations of DM are xerosis and pruritus and are usually relieved by skin moisturizers. Protracted wound healing and skin ulcerations are also frequent complications. Diabetic dermopathy, sometimes termed *pigmented pretibial papules*, or "diabetic skin spots," begins as an erythematous macule or papule that evolves into an area of circular hyperpigmentation. These lesions result from minor mechanical trauma in the pretibial region and are more common in elderly men with DM. Bullous diseases, such as bullosa diabeticorum (shallow ulcerations or erosions in the pretibial region), are also seen. *Necrobiosis lipoidica diabeticorum* is an uncommon disorder, accompanying diabetes in predominantly young women. This usually begins in the pretibial region as an erythematous plaque or papules that gradually enlarge, darken, and develop irregular margins, with atrophic centers and central ulceration. They are often painful. Vitiligo and alopecia areata occur at increased frequency in individuals with type 1 DM. *Acanthosis nigricans* (hyperpigmented velvety plaques seen on the neck, axilla, or extensor surfaces) is sometimes a feature of severe insulin resistance and accompanying diabetes. Generalized or localized *granuloma annulare* (erythematous plaques on the extremities or trunk), *lichen planus* (violaceous papules on the cutaneous surface with or without erosions in the mouth and genitalia), and *scleredema* (areas of skin thickening on the back or neck at the site of previous superficial infections) are more common in the diabetic population. *Lipoatrophy* and *lipohypertrophy* can occur at insulin injection sites but are now unusual with the use of human insulin and avoided by rotating injection sites.

406 Hypoglycemia

Stephen N. Davis, Philip E. Cryer

Hypoglycemia is most commonly caused by insulin or insulin-producing drugs used to treat diabetes mellitus or by exposure to other drugs, including alcohol. However, a number of other disorders, including critical organ failure, sepsis and inanition, hormone deficiencies, non-β-cell tumors, insulinoma, and prior gastric surgery, can cause hypoglycemia (Table 406-1). Hypoglycemia may be documented by *Whipple's triad:* (1) symptoms consistent with hypoglycemia, (2) a low plasma glucose concentration measured with a precise method, and (3) relief of symptoms after the plasma glucose level is raised. The lower limit of the fasting plasma glucose concentration is normally ~70 mg/dL (~3.9 mmol/L), but lower venous glucose levels occur normally, late after a meal, during pregnancy, and during prolonged fasting (>24 h). Severe hypoglycemia can cause serious morbidity and increase the risk for serious cardiovascular events and mortality during and after the initial hypoglycemic episode. It should be considered in any patient with episodes of confusion, an altered level of consciousness, or a seizure.

SYSTEMIC GLUCOSE BALANCE AND GLUCOSE COUNTERREGULATION

Glucose is an obligate metabolic fuel for the brain under physiologic conditions. The brain cannot synthesize glucose or store more than a few minutes' supply as glycogen and therefore requires a continuous supply of glucose from the arterial circulation. As the arterial plasma glucose concentration falls below the physiologic range, blood-to-brain glucose transport becomes insufficient to support brain energy metabolism and function. However, multiple integrated glucose counterregulatory mechanisms normally prevent or rapidly correct hypoglycemia.

Plasma glucose concentrations are normally maintained within a relatively narrow range—roughly 70–110 mg/dL (3.9–6.1 mmol/L) in the fasting state, with transient higher excursions after a meal—despite wide variations in exogenous glucose delivery from meals and in endogenous glucose utilization by, for example, exercising muscle. Between meals and during fasting, plasma glucose levels are maintained by endogenous glucose production, hepatic glycogenolysis, and hepatic (and renal) gluconeogenesis (Fig. 406-1). Although hepatic glycogen stores are usually sufficient to maintain plasma glucose levels for ~8 h, this period can be shorter if glucose demand is increased by exercise or if glycogen stores are depleted by illness or starvation.

Gluconeogenesis normally requires low insulin levels and the presence of anti-insulin (counterregulatory) hormones together with a coordinated supply of precursors from muscle and adipose tissue to the liver and kidneys. Muscle provides lactate, pyruvate, alanine, glutamine, and other amino acids. Triglycerides in adipose tissue are broken down into fatty acids and glycerol, which is a gluconeogenic precursor. Fatty acids provide an alternative oxidative fuel to tissues other than the brain (which requires glucose).

Systemic glucose balance, maintenance of the normal plasma glucose concentration, is accomplished by a network of hormones, neural signals, and substrate effects that regulate endogenous glucose production and glucose utilization by tissues other than the brain (Chap. 403). Among the regulatory factors, insulin plays a dominant role (Table 406-2; Fig. 406-1). As plasma glucose levels decline within the physiologic range, pancreatic β-cell insulin secretion decreases, thereby increasing hepatic glycogenolysis and hepatic (and renal) gluconeogenesis. Low insulin levels also reduce glucose utilization in peripheral tissues, inducing lipolysis and proteolysis and consequently releasing gluconeogenic precursors. Thus, a decrease in insulin secretion is the first defense against hypoglycemia.

As plasma glucose levels decline just below the physiologic range, glucose counterregulatory (plasma glucose–raising) hormones are released (Table 406-2; Fig. 406-1). Among these, pancreatic α-cell glucagon and adrenomedullary epinephrine play a primary role. Glucagon stimulates hepatic glycogenolysis and gluconeogenesis. Adrenomedullary epinephrine also stimulates hepatic glycogenolysis and gluconeogenesis (and renal gluconeogenesis) but limits peripheral uptake of glucose and stimulates lipolysis with production of glycerol and fatty acids. Epinephrine becomes critical when glucagon is deficient. When hypoglycemia is prolonged beyond ~4 h, cortisol and growth hormone also support glucose production and restrict glucose utilization to a limited amount (both mechanisms are reduced by ~80% compared to epinephrine). Thus, cortisol and growth hormone play no role in defense against acute hypoglycemia.

As plasma glucose levels fall further, symptoms prompt behavioral defense against hypoglycemia, including the ingestion of food (Table 406-2; Fig. 406-1). The normal glycemic thresholds for these responses to decreasing plasma glucose concentrations are shown in Table 406-2. However, these thresholds are dynamic. They shift to higher-than-normal glucose levels in people with poorly controlled diabetes, who can experience symptoms of hypoglycemia when their glucose levels decline toward the normal range. On the other hand, thresholds shift to lower-than-normal glucose levels in people with recurrent hypoglycemia; i.e., patients with intensively treated diabetes or an insulinoma have symptoms at glucose levels lower than those that cause symptoms in healthy individuals.

Clinical Manifestations Neuroglycopenic manifestations of hypoglycemia are the direct result of central nervous system glucose deprivation. These features include behavioral changes, confusion, fatigue, seizure, loss of consciousness, cardiac arrhythmias, and, if hypoglycemia is severe, death. Neurogenic (or autonomic) manifestations of hypoglycemia result from the perception of physiologic changes caused by the central nervous system–mediated sympathoadrenal discharge that is triggered by hypoglycemia. They include *adrenergic* symptoms (mediated largely by norepinephrine released from

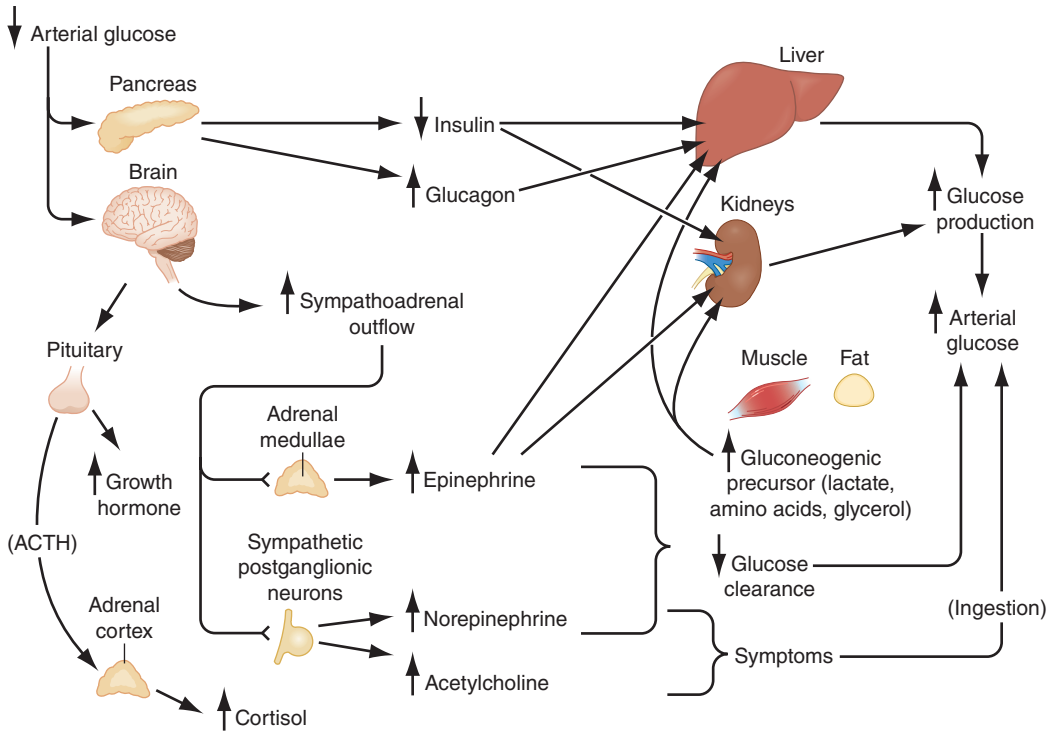

FIGURE 406-1 Physiology of glucose counterregulation: Mechanisms that normally prevent or rapidly correct hypoglycemia. In insulin-deficient diabetes, the key counterregulatory responses—suppression of insulin and increases in glucagon—are lost, and stimulation of sympathoadrenal outflow is attenuated. ACTH, adrenocorticotropic hormone.

sympathetic postganglionic neurons but perhaps also by epinephrine released from the adrenal medullae), such as palpitations, tremor, and anxiety, as well as *cholinergic* symptoms (mediated by acetylcholine released from sympathetic postganglionic neurons), such as sweating, hunger, and paresthesias. Clearly, these are nonspecific symptoms. Their attribution to hypoglycemia requires that the corresponding plasma glucose concentration be low and that the symptoms resolve after the glucose level is raised (as delineated by Whipple's triad).

Common signs of hypoglycemia include diaphoresis and pallor. Heart rate and systolic blood pressure are typically increased but may not be raised in an individual who has experienced repeated, recent episodes of hypoglycemia. Neuroglycopenic manifestations are often observable. Transient focal neurologic deficits occur occasionally. Permanent neurologic deficits are rare.

Etiology and Pathophysiology Hypoglycemia activates proinflammatory, procoagulant, and proatherothrombotic responses in type 1 diabetes mellitus (T1DM), type 2 diabetes mellitus (T2DM), and nondiabetic individuals. These responses increase platelet aggregation, reduce fibrinolytic balance (increase plasminogen activator inhibitor-1), and increase intravascular coagulation. Hypoglycemia also reduces protective nitric oxide–mediated arterial vasodilator mechanisms in healthy, T1DM, and T2DM individuals.

HYPOGLYCEMIA IN DIABETES

Impact and Frequency Hypoglycemia is the limiting factor in the glycemic management of diabetes mellitus. First, it causes recurrent morbidity in most people with T1DM and in many with advanced T2DM, and it is sometimes fatal. Second, it precludes maintenance of euglycemia over a lifetime of diabetes and, thus, full realization of the well-established microvascular benefits of glycemic control. Third, it causes a vicious cycle of recurrent hypoglycemia by producing hypoglycemia-associated autonomic failure—i.e., the clinical syndromes of defective glucose counterregulation and of hypoglycemia unawareness.

TABLE 406-2 Physiologic Responses to Decreasing Plasma Glucose Concentrations

RESPONSE	GLYCEMIC THRESHOLD, mmol/L (mg/dL)	PHYSIOLOGIC ↓ EFFECTS	ROLE IN PREVENTION OR CORRECTION OF HYPOGLYCEMIA (GLUCOSE COUNTERREGULATION)
↓ Insulin	4.4–4.7 (80–85)	↑ R_a (↓ R_d), increased lipolysis; ↑ FFA ↑ Glycerol	Primary glucose regulatory factor/first defense against hypoglycemia
↑ Glucagon	3.6–3.9 (65–70)	↑ R_a	Primary glucose counterregulatory factor/second defense against hypoglycemia
↑ Epinephrine	3.6–3.9 (65–70)	↑ R_a, ↓ R_c, increased lipolysis; ↑ FFA and glycerol	Third defense against hypoglycemia; critical when glucagon is deficient
↑ Cortisol and growth hormone	3.6–3.9 (65–70)	↑ R_a, ↓ R_c	Involved in defense against prolonged hypoglycemia; not critical
Symptoms	2.8–3.1 (50–55)	Recognition of hypoglycemia	Prompt behavioral defense against hypoglycemia (food ingestion)
↓ Cognition	<2.8 (<50)	—	Compromises behavioral defense against hypoglycemia

Note: R_a, rate of glucose appearance, glucose production by the liver and kidneys; R_c, rate of glucose clearance, glucose utilization relative to the ambient plasma glucose by insulin-sensitive tissues; R_d, rate of glucose disappearance, glucose utilization by insulin-sensitive tissues such as skeletal muscle. R_d by the brain is not altered by insulin, glucagon, epinephrine, cortisol, or growth hormone.

Abbreviation: FFA, free fatty acids.

Hypoglycemia is a fact of life for people with T1DM if treated with insulin, sulfonylurea, or glinides. They suffer an average of two episodes of symptomatic hypoglycemia per week and at least one episode of severe, at least temporarily disabling hypoglycemia each year. An estimated 6–10% of people with T1DM die as a result of hypoglycemia. The incidence of hypoglycemia is lower in T2DM than in T1DM. However, its prevalence in insulin-requiring T2DM is surprisingly high. Recent studies have revealed a hypoglycemia prevalence approaching 70%. In fact, as patients with T2DM outnumber those with T1DM by ten- to twentyfold, the prevalence of hypoglycemia is now greater in T2DM. Hypoglycemia can occur at any hemoglobin A_{1c} (HbA_{1C}) level. Although severe hypoglycemia occurs twice as frequently at lower HbA_{1C} levels in T1DM, it still occurs at HbA_{1C} levels >8%. In insulin-requiring T2DM, severe hypoglycemia can occur at lower HbA_{1C} values but also importantly at values of 8–10%. Severe hypoglycemia in T2DM carries an increased risk of severe cardiovascular and cerebrovascular morbidity and mortality for up to 1 year after the event. The risk of severe hypoglycemia and a subsequent cardiovascular adverse event is, in fact, relatively increased when trying to improve glucose control in some T2DM individuals with persistently raised HbA_{1C} values. Therefore, improvements in glycemic control in these individuals should be performed incrementally and carefully to avoid episodes of hypoglycemia. Insulin, sulfonylureas, or glinides can cause hypoglycemia in T2DM. Metformin, thiazolidinediones, α-glucosidase inhibitors, glucagon-like peptide 1 (GLP-1) receptor agonists, sodium-glucose cotransporter-2 inhibitors, and dipeptidyl peptidase IV (DPP-IV) inhibitors do not cause hypoglycemia. However, they increase the risk when combined with a sulfonylurea, glinide, or insulin. Notably, the frequency of hypoglycemia approaches that in T1DM as persons with T2DM develop absolute insulin deficiency and require more complex treatment with insulin.

Conventional Risk Factors The conventional risk factors for hypoglycemia in diabetes are identified on the basis of relative or absolute insulin excess. This occurs when (1) insulin (or insulin secretagogue) doses are excessive, ill-timed, or of the wrong type; (2) the influx of exogenous glucose is reduced (e.g., during an overnight fast, periods of temporary fasting, or after missed meals or snacks); (3) insulin-independent glucose utilization is increased (e.g., during exercise); (4) sensitivity to insulin is increased (e.g., with improved glycemic control, in the middle of the night, after exercise, or with increased fitness or weight loss); (5) endogenous glucose production is reduced (e.g., after alcohol ingestion); and (6) insulin clearance is reduced (e.g., in renal failure). However, these conventional risk factors alone explain a minority of episodes; other factors are typically involved.

Hypoglycemia-Associated Autonomic Failure (HAAF) While marked insulin excess alone can cause hypoglycemia, iatrogenic hypoglycemia in diabetes (T1DM and/or T2DM) is typically the result of the interplay of relative or absolute therapeutic insulin excess and compromised physiologic and behavioral defenses against falling plasma glucose concentrations (Table 406-2; Fig. 406-2). Defective glucose counterregulation compromises physiologic defense (particularly decrements in insulin and increments in glucagon and epinephrine), and hypoglycemia unawareness compromises behavioral defense (ingestion of carbohydrate).

DEFECTIVE GLUCOSE COUNTERREGULATION In the setting of absolute endogenous insulin deficiency, insulin levels do not decrease as plasma glucose levels fall; thus, the first defense against hypoglycemia is lost. After a few years of disease duration in T1DM, glucagon levels do not increase as plasma glucose levels fall; a second defense against hypoglycemia is lost. Reduced glucagon responses to hypoglycemia also occur in long-duration T2DM. However, pancreatic alpha cells that produce glucagon are present in the same number and size in T1DM as compared to age-matched nondiabetic individuals. Thus, the defect that restricts glucagon release during hypoglycemia in T1DM (and presumably in long-standing T2DM) appears to be a signaling defect, as glucagon responses to other physiologic stress in T1DM (e.g., exercise) are preserved. Finally, the increase in epinephrine levels, the third critical defense against acute hypoglycemia, is typically attenuated. The glycemic threshold for the sympathoadrenal (adrenomedullary epinephrine and sympathetic neural norepinephrine) response is shifted to lower plasma glucose concentrations. That shift is typically the result of recent antecedent iatrogenic hypoglycemia. In the setting of absent decrements in insulin and of absent increments in glucagon, the attenuated increment in epinephrine causes the clinical syndrome of defective glucose counterregulation. Affected patients are at ≥25-fold greater risk of severe iatrogenic hypoglycemia during intensive glycemic therapy for their diabetes than are patients with normal epinephrine responses. This functional—and potentially reversible—disorder is distinct from classic diabetic autonomic neuropathy, which also includes all of the above pathophysiologic defects, and is a structural and irreversible disorder.

HYPOGLYCEMIA UNAWARENESS The attenuated sympathoadrenal response (largely the reduced sympathetic neural response) to hypoglycemia causes the clinical syndrome of *hypoglycemia unawareness*—i.e., loss of the warning adrenergic and cholinergic symptoms that previously allowed the patient to recognize developing hypoglycemia and therefore to abort the episode by ingesting carbohydrates. Affected patients are at a sixfold increased risk of severe iatrogenic hypoglycemia during intensive glycemic therapy of their diabetes.

HAAF IN DIABETES The concept of HAAF in diabetes posits that recent antecedent iatrogenic hypoglycemia (or sleep or prior exercise)

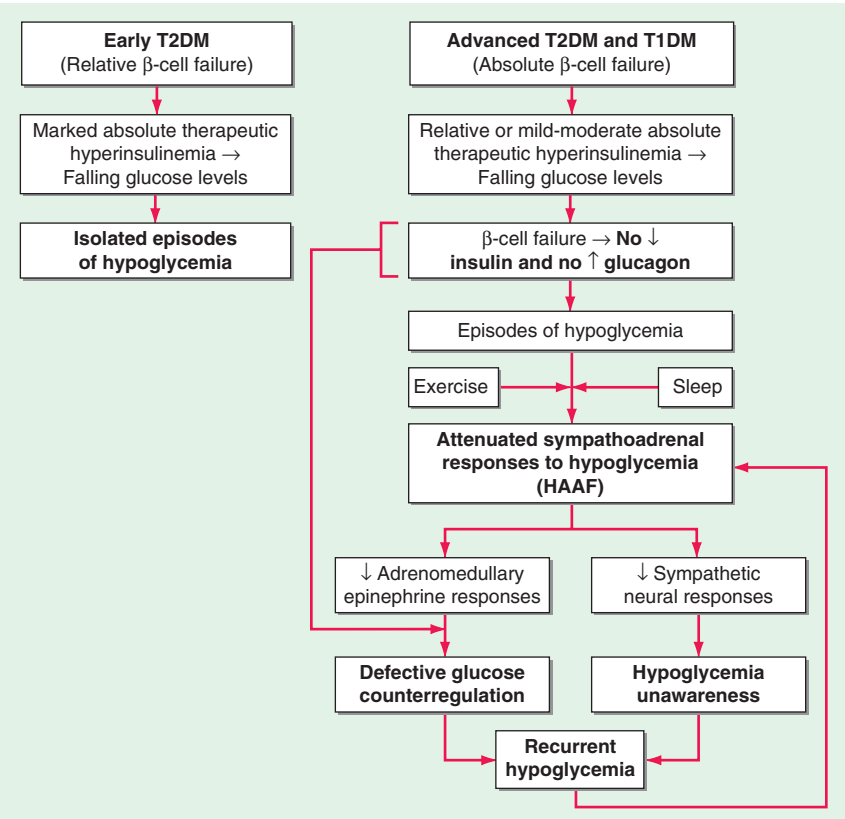

FIGURE 406-2 Hypoglycemia-associated autonomic failure (HAAF) in insulin-deficient diabetes. T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus. *(Modified from PE Cryer: Hypoglycemia in Diabetes. Pathophysiology, Prevalence, and Prevention, 2nd ed. © American Diabetes Association, 2012.)*

causes both defective glucose counterregulation (by reducing the epinephrine response to a given level of subsequent hypoglycemia in the setting of absent insulin and glucagon responses) and hypoglycemia unawareness (by reducing the sympathoadrenal response to a given level of subsequent hypoglycemia). These impaired responses, which can occur in individuals with either T1DM or T2DM, create a vicious cycle of recurrent iatrogenic hypoglycemia (Fig. 406-2). Hypoglycemia unawareness and, to some limited extent, the reduced epinephrine component of defective glucose counterregulation can be reversible by as little as 2–3 weeks of scrupulous avoidance of hypoglycemia in most affected patients.

On the basis of this pathophysiology, additional risk factors for hypoglycemia in diabetes include (1) absolute insulin deficiency, indicating that insulin levels will not decrease and glucagon levels will not increase as plasma glucose levels fall; (2) a history of severe hypoglycemia or of hypoglycemia unawareness, implying recent antecedent hypoglycemia, as well as prior exercise or sleep, indicating that the sympathoadrenal response will be attenuated; (3) impaired renal function resulting in reduced clearance of exogenous and endogenous insulin; (4) classical diabetic autonomic neuropathy; and (5) lower HbA_{1C} or lower glycemic goals even at elevated HbA_{1C} levels (8–10%), as they represent an increased probability of recent antecedent hypoglycemia.

Hypoglycemia Risk Factor Reduction Several recent, multicenter, randomized controlled trials investigating the potential benefits of tight glucose control in either inpatient or outpatient settings have reported a high prevalence of severe hypoglycemia. In the NICE-SUGAR study, attempts to control in-hospital plasma glucose values toward physiologic levels resulted in increased mortality risk. The ADVANCE and ACCORD studies and the Veterans Affairs Diabetes Trial (VADT) also found a significant incidence of severe hypoglycemia among T2DM patients. Severe hypoglycemia with accompanying serious cardiovascular morbidity and mortality also occurred in the standard (e.g., not receiving intensified treatment) control group in all of the above studies and in another large study in prediabetic and T2DM individuals (ORIGIN). Thus, as stated above, severe hypoglycemia can and does occur at HbA_{1c} values of 8–10% in both T1DM and T2DM. Somewhat surprisingly, all three studies found little or no benefit of intensive glucose control to reduce macrovascular events in T2DM. In fact, the ACCORD study was ended early because of the increased mortality rate in the intensive glucose control arm. Whether iatrogenic hypoglycemia was the cause of the increased mortality risk is not known. In light of these findings, some new recommendations and paradigms have been formulated. Whereas there is little debate regarding the need to reduce hyperglycemia in the hospital, the glycemic maintenance goals in critical care settings have been modified to stay between 140 and 180 mg/dL. Similar glycemic targets are also recommended in non–critically ill patients by a number of expert societies, although some recommend even more strict glucose control down to 108 mg/dL. Accordingly, the benefits of insulin therapy and reduced hyperglycemia can be obtained while the prevalence of hypoglycemia is reduced.

Similarly, evidence exists that intensive glucose control can reduce the prevalence of microvascular disease in both T1DM and T2DM. These benefits need to be weighed against the increased prevalence of hypoglycemia. Certainly, the level of glucose control (i.e., the HbA_{1c} value, symptoms of hyper- and hypoglycemia, and home glucose values) should be evaluated for each patient. Multicenter trials have demonstrated that individuals with recently diagnosed T1DM or T2DM can have better glycemic control with less hypoglycemia. In addition, there is still long-term benefit in reducing HbA_{1c} values from higher to lower, albeit still above recommended levels. Perhaps a reasonable therapeutic goal is the lowest HbA_{1c} level that does not cause severe hypoglycemia and that preserves awareness of hypoglycemia.

Pancreatic transplantation (both whole organ and islet cell) has been used in part as a treatment for severe hypoglycemia. Generally, rates of hypoglycemia are reduced after transplantation. This decrease appears to be due to increased physiologic insulin and glucagon responses during hypoglycemia.

The use of continuous glucose monitors (CGMs), either alone or in combination with continuous subcutaneous infusion via a wearable pump, offers promise as a method of reducing hypoglycemia while improving HbA_{1c}. Specifically, continuous glucose monitoring coupled with temporary discontinuation of subcutaneous insulin infusion when the monitor predicts a low glucose concentration is particularly promising. Studies investigating the use of CGM during inpatient care for both insulin-requiring pediatric and adult patients with diabetes are ongoing. Furthermore, progress utilizing a portable wearable "artificial pancreas" incorporating continuous glucose sensor modulation of either insulin alone or bi-hormonal delivery of both insulin and glucagon has been established. Additionally, stem cell–derived β cells also offer promise of novel therapeutic interventions to reduce hypoglycemia.

Other interventions to stimulate counterregulatory responses, such as selective serotonin reuptake inhibitors, β-adrenergic receptor antagonists, opiate receptor antagonists, and fructose, remain experimental and have not been assessed in large-scale clinical trials.

Thus, intensive glycemic therapy **(Chap. 404)** needs to be applied along with the patient's education and empowerment, frequent self-monitoring of blood glucose, flexible insulin (and other drug) regimens (including the use of insulin analogues, both short- and longer-acting), individualized glycemic goals, and ongoing professional guidance, support, and consideration of both the conventional risk factors and those indicative of compromised glucose counterregulation. Given a history of hypoglycemia unawareness, a 2- to 3-week period of scrupulous avoidance of hypoglycemia is indicated.

HYPOGLYCEMIA WITHOUT DIABETES

There are many causes of hypoglycemia (Table 406-1). Because hypoglycemia is common in insulin- or insulin secretagogue–treated diabetes, it is often reasonable to assume that a clinically suspicious episode is the result of hypoglycemia. On the other hand, because hypoglycemia is rare in the absence of relevant drug-treated diabetes (pregnancy and during severe episodes of morning sickness), it is reasonable to conclude that a hypoglycemic disorder is present only in patients in whom Whipple's triad can be demonstrated.

Particularly when patients are ill or medicated, the initial diagnostic focus should be on the possibility of drug involvement and then on critical illnesses, hormone deficiency, or non–islet cell tumor hypoglycemia. In the absence of any of these etiologic factors and in a seemingly well individual, the focus should shift to possible endogenous hyperinsulinism or accidental, surreptitious, or even malicious hypoglycemia.

Drugs Insulin and insulin secretagogues suppress glucose production and stimulate glucose utilization. Ethanol blocks gluconeogenesis but not glycogenolysis. Thus, alcohol-induced hypoglycemia typically occurs after a several-day ethanol binge during which the person eats little food, with consequent glycogen depletion. Ethanol is usually measurable in blood at the time of presentation, but its levels correlate poorly with plasma glucose concentrations. Because gluconeogenesis becomes the predominant route of glucose production during prolonged hypoglycemia, alcohol can contribute to the progression of hypoglycemia in patients with insulin-treated diabetes.

Many other drugs have been associated with hypoglycemia. These include commonly used drugs such as angiotensin-converting enzyme inhibitors and angiotensin receptor antagonists, β-adrenergic receptor antagonists, quinolone antibiotics, indomethacin, quinine, and sulfonamides.

Critical Illness Among hospitalized patients, serious illnesses such as renal, hepatic, or cardiac failure; sepsis; and inanition are second only to drugs as causes of hypoglycemia.

Rapid and extensive hepatic destruction (e.g., toxic hepatitis) causes fasting hypoglycemia because the liver is the major site of endogenous glucose production. The mechanism of hypoglycemia in patients with cardiac failure is unknown. Hepatic congestion and hypoxia may be involved. Although the kidneys are a source of glucose production, hypoglycemia in patients with renal failure is also caused by the reduced clearance of insulin (thereby inappropriately increasing

insulin relative to the prevailing glucose levels) and the reduced mobilization of gluconeogenic precursors in renal failure.

Sepsis is a relatively common cause of hypoglycemia. Increased glucose utilization is induced by cytokine production in macrophage-rich tissues such as the liver, spleen, and lung. Hypoglycemia develops if glucose production fails to keep pace. Cytokine-induced inhibition of gluconeogenesis in the setting of nutritional glycogen depletion, in combination with hepatic and renal hypoperfusion, may also contribute to hypoglycemia.

Hypoglycemia can be seen with starvation. Due to brain conversion and utilization of alternative substrates, such as lactate, pyruvate, and ketone bodies, there is only a modest counterregulatory neuroendocrine and autonomic nervous system response. During periods of prolonged starvation (fasting) plasma glucose levels are lower in women as compared to men, perhaps because of loss of whole-body fat stores and subsequent depletion of gluconeogenic precursors (e.g., amino acids), necessitating increased glucose utilization.

Hormone Deficiencies Neither cortisol nor growth hormone is critical to the prevention of hypoglycemia, at least in adults. Nonetheless, hypoglycemia can occur with prolonged fasting in patients with primary adrenocortical failure (Addison's disease) or hypopituitarism. Anorexia and weight loss are typical features of chronic cortisol deficiency and likely result in glycogen depletion. Cortisol deficiency is associated with impaired gluconeogenesis and low levels of gluconeogenic precursors; these associations suggest that substrate-limited gluconeogenesis, in the setting of glycogen depletion, is the cause of hypoglycemia. Growth hormone deficiency can cause hypoglycemia in young children. In addition to extended fasting, high rates of glucose utilization (e.g., during exercise or in pregnancy) or low rates of glucose production (e.g., after alcohol ingestion) can precipitate hypoglycemia in adults with previously unrecognized hypopituitarism.

Hypoglycemia is not a feature of the epinephrine-deficient state that results from bilateral adrenalectomy when glucocorticoid replacement is adequate, nor does it occur during pharmacologic adrenergic blockade when other glucoregulatory systems are intact. Combined deficiencies of glucagon and epinephrine play a key role in the pathogenesis of iatrogenic hypoglycemia in people with insulin-deficient diabetes, as discussed earlier. Otherwise, deficiencies of these hormones are not usually considered in the differential diagnosis of a hypoglycemic disorder.

Non–β-Cell Tumors Fasting hypoglycemia, often termed *non–islet cell tumor hypoglycemia*, occurs occasionally in patients with large mesenchymal or epithelial tumors (e.g., hepatomas, adrenocortical carcinomas, carcinoids). The glucose kinetic patterns resemble those of hyperinsulinism (see next), but insulin secretion is suppressed appropriately during hypoglycemia. In most instances, hypoglycemia is due to overproduction of an incompletely processed form of insulin-like growth factor II ("big IGF-II") that does not complex normally with circulating binding proteins and thus more readily gains access to target tissues. The tumors are usually apparent clinically, plasma ratios of IGF-II to IGF-I are high, and free IGF-II levels (and levels of pro-IGF-II [1–21]) are elevated. Curative surgery is seldom possible, but reduction of tumor bulk may ameliorate hypoglycemia. Therapy with a glucocorticoid, growth hormone, or both has also been reported to alleviate hypoglycemia. Hypoglycemia attributed to ectopic IGF-I production has been reported but is rare.

Endogenous Hyperinsulinism Hypoglycemia due to endogenous hyperinsulinism can be caused by (1) a primary β-cell disorder—typically a β-cell tumor (*insulinoma*), sometimes multiple insulinomas, or a functional β-cell disorder with β-cell hypertrophy or hyperplasia; (2) an antibody to insulin or to the insulin receptor; (3) a β-cell secretagogue such as a sulfonylurea; or perhaps (4) ectopic insulin secretion, among other very rare mechanisms. None of these causes are common.

The fundamental pathophysiologic feature of endogenous hyperinsulinism caused by a primary β-cell disorder or an insulin secretagogue is the failure of insulin secretion to fall to very low levels during hypoglycemia. This feature is assessed by measurement of plasma insulin, C-peptide (the connecting peptide that is cleaved from proinsulin to produce insulin), proinsulin, and glucose concentrations during hypoglycemia. Insulin, C-peptide, and proinsulin levels need not be high relative to normal, euglycemic values; rather, they are inappropriately high in the setting of a low plasma glucose concentration. Critical diagnostic findings are a plasma insulin concentration ≥3 μU/mL (≥18 pmol/L), a plasma C-peptide concentration ≥0.6 ng/mL (≥0.2 nmol/L), and a plasma proinsulin concentration ≥5.0 pmol/L when the plasma glucose concentration is <55 mg/dL (<3.0 mmol/L) with symptoms of hypoglycemia. A low plasma β-hydroxybutyrate concentration (≤2.7 mmol/L) and an increment in plasma glucose level of >25 mg/dL (>1.4 mmol/L) after IV administration of glucagon (1.0 mg) indicate increased insulin (or IGF) actions.

The diagnostic strategy is (1) to measure plasma glucose, insulin, C-peptide, proinsulin, and β-hydroxybutyrate concentrations and to screen for circulating oral hypoglycemic agents during an episode of hypoglycemia and (2) to assess symptoms during the episode and seek their resolution following correction of hypoglycemia by glucose (either oral or parenteral) or by IV injection of glucagon (i.e., to document Whipple's triad). This is straightforward if the patient is hypoglycemic when seen. Since endogenous hyperinsulinemic disorders usually, but not invariably, cause fasting hypoglycemia, a diagnostic episode may develop after a relatively short outpatient fast. Serial sampling during an inpatient diagnostic fast of up to 72 h or after a mixed meal is more problematic. An alternative is to give patients a detailed list of the required measurements and ask them to present to an ambulatory care center or emergency room, with the list, during a symptomatic episode. Obviously, a normal plasma glucose concentration during a symptomatic episode indicates that the symptoms are not the result of hypoglycemia.

An *insulinoma*—an insulin-secreting pancreatic islet β-cell tumor—is the prototypical cause of endogenous hyperinsulinism and therefore should be sought in patients with a compatible clinical syndrome. However, insulinoma is not the only cause of endogenous hyperinsulinism. Some patients with fasting endogenous hyperinsulinemic hypoglycemia have diffuse islet involvement with β-cell hypertrophy and sometimes hyperplasia. This pattern is commonly referred to as *nesidioblastosis*, although β-cells budding from ducts are not invariably found. Other patients have a similar islet pattern but with postprandial hypoglycemia, a disorder termed *noninsulinoma pancreatogenous hypoglycemia*. Post–gastric bypass postprandial hypoglycemia, which most often follows Roux-en-Y gastric bypass, is also characterized by diffuse islet involvement and endogenous hyperinsulinism. Multiple pathophysiologic mechanisms have been suggested including exaggerated GLP-1 responses to meals resulting in hyperinsulinemia, hypoglucagonemia, and hypoglycemia. However, other mechanisms may be responsible for the relative hyperinsulinemia, such as reduced insulin clearance and reduced glucagon responses to hypoglycemia. The relevant pathogenesis has not been clearly established. However, if medical treatment with agents such as an α-glucosidase inhibitor, diazoxide, or octreotide fail, partial pancreatectomy may be required. Autoimmune hypoglycemias include those caused by an antibody to insulin that binds postmeal insulin and then gradually disassociates, with consequent late postprandial hypoglycemia. Alternatively, an insulin receptor antibody can function as an agonist. The presence of an insulin secretagogue, such as a sulfonylurea or a glinide, results in a clinical and biochemical pattern similar to that of an insulinoma but can be distinguished by the presence of the circulating secretagogue. Finally, there are reports of very rare phenomena such as ectopic insulin secretion, a gain-of-function insulin receptor mutation, and exercise-induced hyperinsulinemia.

Insulinomas are uncommon, with an estimated yearly incidence of 1 in 250,000. Because >90% of insulinomas are benign, they are a treatable cause of potentially fatal hypoglycemia. The median age at presentation is 50 years in sporadic cases, but the tumor usually presents in the third decade when it is a component of multiple endocrine neoplasia type 1 **(Chap. 388)**. More than 99% of insulinomas are within the substance of the pancreas, and the tumors are usually small (<2.0 cm in diameter

in 90% of cases). Therefore, they come to clinical attention because of hypoglycemia rather than mass effects. CT or MRI detects ~70–80% of insulinomas. These methods detect metastases in the roughly 10% of patients with a malignant insulinoma. Transabdominal ultrasound often identifies insulinomas, and endoscopic ultrasound has a sensitivity of ~90%. Somatostatin receptor scintigraphy is thought to detect insulinomas in about half of patients. Selective pancreatic arterial calcium injections, with the endpoint of a sharp increase in hepatic venous insulin levels, regionalize insulinomas with high sensitivity, but this invasive procedure is seldom necessary except to confirm endogenous hyperinsulinism in the diffuse islet disorders. Intraoperative pancreatic ultrasonography almost invariably localizes insulinomas that are not readily palpable by the surgeon. Surgical resection of a solitary insulinoma is generally curative. Diazoxide, which inhibits insulin secretion, or the somatostatin analogue octreotide can be used to treat hypoglycemia in patients with unresectable tumors; everolimus, an mTOR (mammalian target of rapamycin) inhibitor, has also been successful in combination with the above approaches.

ACCIDENTAL, SURREPTITIOUS, OR MALICIOUS HYPOGLYCEMIA

Accidental ingestion of an insulin secretagogue (e.g., as the result of a pharmacy or other medical error) or even accidental administration of insulin can occur. Factitious hypoglycemia, caused by surreptitious or even malicious administration of insulin or an insulin secretagogue, shares many clinical and laboratory features with insulinoma. It is most common among health care workers, patients with diabetes or their relatives, and people with a history of other factitious illnesses. However, it should be considered in all patients being evaluated for hypoglycemia of obscure cause. Ingestion of an insulin secretagogue causes hypoglycemia with increased C-peptide levels, whereas exogenous insulin causes hypoglycemia with low C-peptide levels, reflecting suppression of insulin secretion.

Analytical error in the measurement of plasma glucose concentrations is rare. On the other hand, hand-held and continuous glucose monitors used to guide treatment of diabetes are not quantitative instruments, particularly at low glucose levels, and should not be used for the definitive diagnosis of hypoglycemia. Even with a quantitative method, low measured glucose concentrations can be artifactual—e.g., the result of continued glucose metabolism by the formed elements of the blood ex vivo, particularly in the presence of leukocytosis, erythrocytosis, or thrombocytosis or with delayed separation of the serum from the formed elements (pseudohypoglycemia).

INBORN ERRORS OF METABOLISM CAUSING HYPOGLYCEMIA

Nondiabetic hypoglycemia also results from inborn errors of metabolism. Such hypoglycemia most commonly occurs in infancy but can also occur in adulthood. Cases in adults can be classified into those resulting in fasting hypoglycemia, postprandial hypoglycemia, and exercise-induced hypoglycemia.

Fasting Hypoglycemia Although rare, disorders of glycogenolysis can result in fasting hypoglycemia. These disorders include glycogen storage disease (GSD) of types 0, I, III, and IV and Fanconi-Bickel syndrome (Chap. 419). Patients with GSD types I and III characteristically have high blood lactate levels before and after meals, respectively. Both groups have hypertriglyceridemia, but ketones are high in GSD type III. Defects in fatty acid oxidation also result in fasting hypoglycemia. These defects can include (1) defects in the carnitine cycle; (2) fatty-acid β-oxidation disorders; (3) electron transfer disturbances; and (4) ketogenesis disorders. Finally, defects in gluconeogenesis (fructose-1,6-biphosphatase) have been reported to result in recurrent hypoglycemia and lactic acidosis.

Postprandial Hypoglycemia Inborn errors of metabolism resulting in postprandial hypoglycemia are also rare. These errors include (1) glucokinase, SUR1, and Kir6.2 potassium channel mutations; (2) congenital disorders of glycosylation; and (3) inherited fructose intolerance.

Exercise-Induced Hypoglycemia Exercise-induced hypoglycemia, by definition, follows exercise. It results in hyperinsulinemia caused by increased activity of monocarboxylate transporter 1 in β cells.

APPROACH TO THE PATIENT

Hypoglycemia

In addition to the recognition and documentation of hypoglycemia as well as its treatment (often on an urgent basis), diagnosis of the hypoglycemic mechanism is critical for the selection of therapy that prevents, or at least minimizes, recurrent hypoglycemia.

RECOGNITION AND DOCUMENTATION

Hypoglycemia is suspected in patients with typical symptoms; in the presence of confusion, an altered level of consciousness, or a seizure; or in a clinical setting in which hypoglycemia is known to occur. Blood should be drawn, whenever possible, before the administration of glucose to allow documentation of a low plasma glucose concentration. Convincing documentation of hypoglycemia requires the fulfillment of Whipple's triad. Thus, the ideal time to measure the plasma glucose level is during a symptomatic episode. A normal glucose level excludes hypoglycemia as the cause of the symptoms. A low glucose level confirms that hypoglycemia is the cause of the symptoms, provided the latter resolve after the glucose level is raised. When the cause of the hypoglycemic episode is obscure, additional measurements—made while the glucose level is low and before treatment—should include plasma insulin, C-peptide, proinsulin, and β-hydroxybutyrate levels; also critical are screening for circulating oral hypoglycemic agents and assessment of symptoms before and after the plasma glucose concentration is raised.

When the history suggests prior hypoglycemia and no potential mechanism is apparent, the diagnostic strategy is to evaluate the patient as just described and assess for Whipple's triad during and after an episode of hypoglycemia. On the other hand, while it cannot be ignored, a distinctly low plasma glucose concentration measured in a patient without corresponding symptoms raises the possibility of an artifact (pseudohypoglycemia).

DIAGNOSIS OF THE HYPOGLYCEMIC MECHANISM

In a patient with documented hypoglycemia, a plausible hypoglycemic mechanism can often be deduced from the history, physical examination, and available laboratory data (Table 406-1). Drugs, particularly alcohol or agents used to treat diabetes, should be the first consideration—even in the absence of known use of a relevant drug—given the possibility of surreptitious, accidental, or malicious drug administration. Other considerations include evidence of a relevant critical illness, hormone deficiencies (less commonly), and a non-β-cell tumor that can be pursued diagnostically (rarely). Absent one of these mechanisms in an otherwise seemingly well individual, the care provider should consider endogenous hyperinsulinism and proceed with measurements and assessment of symptoms during spontaneous hypoglycemia or under conditions that might elicit hypoglycemia.

URGENT TREATMENT

If the patient is able and willing, oral treatment with glucose tablets or glucose-containing fluids, candy, or food is appropriate. A reasonable initial dose is 15–20 g of glucose. If the patient is unable or unwilling (because of neuroglycopenia) to take carbohydrates orally, parenteral therapy is necessary. IV administration of glucose (25 g) should be followed by a glucose infusion guided by serial plasma glucose measurements. If IV therapy is not practical, SC or IM glucagon (1.0 mg in adults) can be used, particularly in patients with T1DM. Because it acts by stimulating glycogenolysis, glucagon is ineffective in glycogen-depleted individuals (e.g., those with alcohol-induced hypoglycemia). Glucagon also stimulates insulin secretion and is therefore less useful in T2DM. The

somatostatin analogue octreotide can be used to suppress insulin secretion in sulfonylurea-induced hypoglycemia. These treatments raise plasma glucose concentrations only transiently, and patients should therefore be urged to eat as soon as is practical to replete glycogen stores.

PREVENTION OF RECURRENT HYPOGLYCEMIA

Prevention of recurrent hypoglycemia requires an understanding of the hypoglycemic mechanism. Offending drugs can be discontinued or their doses reduced. Hypoglycemia caused by a sulfonylurea can persist for hours or even days. Underlying critical illnesses can often be treated. Cortisol and growth hormone can be replaced if levels are deficient. Surgical, radiotherapeutic, or chemotherapeutic reduction of a non–islet cell tumor can alleviate hypoglycemia even if the tumor cannot be cured; glucocorticoid or growth hormone administration also may reduce hypoglycemic episodes in such patients. Surgical resection of an insulinoma is curative; medical therapy with diazoxide or octreotide can be used if resection is not possible and in patients with a nontumor β-cell disorder. Partial pancreatectomy may be necessary in the latter patients. The treatment of autoimmune hypoglycemia (e.g., with glucocorticoid or immunosuppressive drugs) is problematic, but these disorders are sometimes self-limited. Failing these treatments, frequent feedings and avoidance of fasting may be required. Administration of uncooked cornstarch at bedtime or even an overnight intragastric infusion of glucose may be necessary for some patients.

407 Disorders of Lipoprotein Metabolism

Daniel J. Rader

Lipoproteins are complexes of lipids and proteins that are essential for transport of cholesterol, triglycerides (TGs), and fat-soluble vitamins in the blood. Lipoproteins play essential roles in the absorption of dietary cholesterol, long-chain fatty acids, and fat-soluble vitamins; the transport of TGs, cholesterol, and fat-soluble vitamins from the liver to peripheral tissues; and the transport of cholesterol from peripheral tissues back to the liver and intestine for excretion. Disorders of lipoprotein metabolism can be primary (caused by genetic conditions) or secondary (to other medical conditions or environmental exposures) and involve either a substantial increase or decrease in specific circulating lipids or lipoproteins. Lipoprotein disorders can have a number of clinical consequences, most notably premature atherosclerotic cardiovascular disease (ASCVD), and are therefore important to appropriately diagnose and treat. This chapter reviews the etiology and pathophysiology of disorders of lipoprotein metabolism and clinical approaches to their diagnosis and management.

LIPOPROTEIN STRUCTURE AND METABOLISM

Lipoproteins contain an "oil droplet" core of hydrophobic lipids (TGs and cholesteryl esters) surrounded by a shell of hydrophilic lipids (phospholipids, unesterified cholesterol) and proteins (called apolipoproteins) that interact with body fluids **(Fig. 407-1)**. The plasma lipoproteins are divided into major classes based on their relative density: chylomicrons, very-low-density lipoproteins (VLDLs), intermediate-density lipoproteins (IDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs). Each lipoprotein class comprises a family of particles that vary in density, size, and protein composition. Because lipid is less dense than water, the density of a lipoprotein particle is primarily determined by the amount of lipid per particle. Chylomicrons are the most lipid-rich and therefore least dense lipoprotein particles, whereas HDLs have the least lipid and are therefore the most dense. Lipoprotein particles vary widely in size, with the largest particles being the most lipid-rich (chylomicrons) and the smallest particles being the most dense (HDL).

The proteins associated with lipoproteins, called *apolipoproteins* **(Table 407-1)**, are required for the assembly, structure, function, and metabolism of lipoproteins. Apolipoproteins provide a structural basis for lipoproteins, activate enzymes important in lipoprotein metabolism, and act as ligands for cell surface receptors. ApoB is the major structural protein of chylomicrons, VLDLs, IDLs, and LDLs (collectively known as apoB-containing lipoproteins). One molecule of apoB, either apoB-48 (chylomicrons) or apoB-100 (VLDL, IDL, or LDL), is present on each lipoprotein particle. The human liver synthesizes the full-length apoB-100 (one of the largest proteins in humans), whereas the intestine makes the shorter apoB-48, which is derived from transcription of the same *APOB* gene after posttranscriptional mRNA editing. HDLs lack apoB and have different apolipoproteins that define this lipoprotein class, most importantly apoA-I, which is synthesized in both the liver and intestine and is found on virtually all HDL particles. ApoA-II is the second most abundant HDL apolipoprotein and is on approximately two-thirds of the HDL particles. ApoC-II, apoC-III, and apoA-V regulate the metabolism of TG-rich lipoproteins. ApoE plays a critical role in the metabolism and clearance of TG-rich particles. Most apolipoproteins, other than apoB, exchange actively among lipoprotein particles in the blood. Apolipoprotein(a) [apo(a)] is a distinctive apolipoprotein that results in the formation of a lipoprotein known as lipoprotein(a) [Lp(a)] and is discussed more below.

TRANSPORT OF INTESTINALLY DERIVED DIETARY LIPIDS BY CHYLOMICRONS

The critical role of chylomicrons is the efficient transport of absorbed dietary lipids from the intestine to tissues that require fatty acids for energy or storage and then return of cholesterol to the liver **(Fig. 407-2)**. Dietary lipids are hydrolyzed by lipases within the intestinal lumen and emulsified with bile acids to form micelles. Dietary cholesterol, fatty acids, and fat-soluble vitamins are absorbed in the proximal small intestine. Cholesterol and retinol are esterified (by the addition of a fatty acid) in the enterocyte to form cholesteryl esters and retinyl esters, respectively. Longer-chain fatty acids (>12 carbons) are incorporated into TGs and packaged with apoB-48, phospholipids, cholesteryl esters, retinyl esters, and α-tocopherol (vitamin E) in a process that requires the action of the microsomal TG transfer protein (MTP) to form chylomicrons. Nascent chylomicrons are secreted into the intestinal lymph and delivered via the thoracic duct directly to the systemic circulation, where they are extensively processed by peripheral tissues before reaching the liver. The particles encounter lipoprotein lipase (LPL), which is anchored to the endothelial surfaces of capillaries in adipose tissue and heart and skeletal muscle (Fig. 407-2). ApoC-II and apoA-V are apolipoproteins that are transferred to circulating chylomicrons from HDL in the postprandial state; apoC-II acts as a required cofactor for LPL activation, and apoA-V serves as a facilitator of LPL activity. The TGs in chylomicrons

TABLE 407-1 Major Apolipoproteins

APOLIPOPROTEIN	PRIMARY SOURCE	LIPOPROTEIN ASSOCIATION	FUNCTION
ApoA-I	Intestine, liver	HDL, chylomicrons	Core structural protein for HDL, promotes cellular lipid efflux via ABCA1, activates LCAT
ApoA-II	Liver	HDL, chylomicrons	Structural protein for HDL
ApoA-V	Liver	VLDL, chylomicrons	Promotes LPL-mediated triglyceride lipolysis
Apo(a)	Liver	Lp(a)	Structural protein for Lp(a)
ApoB-48	Intestine	Chylomicrons, chylomicron remnants	Core structural protein for chylomicrons
ApoB-100	Liver	VLDL, IDL, LDL, Lp(a)	Core structural protein for VLDL, LDL, IDL, Lp(a); ligand for binding to LDL receptor
ApoC-II	Liver	Chylomicrons, VLDL, HDL	Cofactor for LPL
ApoC-III	Liver, intestine	Chylomicrons, VLDL, HDL	Inhibits LPL activity and lipoprotein binding to receptors
ApoE	Liver	Chylomicron remnants, IDL, HDL	Ligand for binding to LDL receptor and other receptors

Abbreviations: HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LDL, low-density lipoprotein; Lp(a), lipoprotein(a); LPL, lipoprotein lipase; VLDL, very-low-density lipoprotein.

are hydrolyzed by LPL, and free fatty acids are released and taken up by adjacent myocytes or adipocytes and are either oxidized to generate energy or reesterified and stored as TG. Some of the released free fatty acids bind albumin before entering cells and are transported to other tissues, especially the liver. The chylomicron particle progressively shrinks in size as the hydrophobic TG core is hydrolyzed and the excess hydrophilic lipids (cholesterol and phospholipids) and apolipoproteins on the particle surface are transferred to HDL, ultimately creating chylomicron remnants.

Chylomicron remnants contain apoB-48, which lacks the region in apoB-100 that binds to the LDL receptor. Nevertheless, they are rapidly removed from the circulation by the liver through a process that critically requires apoE as a ligand for receptors in the liver. Few, if any, chylomicrons or chylomicron remnants are generally present in the blood after a 12-h fast, except in patients with certain disorders of lipoprotein metabolism.

TRANSPORT OF HEPATICALLY DERIVED LIPIDS BY VLDL AND LDL

Another key role of lipoproteins is the transport of hepatic lipids from the liver to the periphery (Fig. 407-2) to provide an energy source during fasting. During the fasting state, lipolysis of adipose TGs generates fatty acids that are transported to the liver, and the liver is also capable of synthesizing fatty acids through de novo lipogenesis. These fatty acids are esterified by the liver into TGs, which are packaged into VLDL particles along with apoB-100, phospholipids, cholesteryl esters, and vitamin E in a process that also requires MTP. VLDL thus resemble chylomicrons in that they are "triglyceride-rich lipoproteins," but they contain apoB-100 rather than apoB-48, are smaller and less buoyant, and have a higher ratio of cholesterol to TG (~1 mg of cholesterol for every 5 mg of TG, whereas in chylomicrons, this ratio is closer to ~1:8). After secretion by the liver into the plasma, the circulating TGs in VLDL are hydrolyzed by LPL. After the relatively TG-depleted VLDL remnants dissociate from LPL, they are referred to as IDLs, which contain roughly similar amounts of cholesterol and TG by mass. The liver removes ~40–60% of IDL by receptor-mediated endocytosis via binding to apoE, which is acquired through transfer of this protein from HDL. The remainder of IDL is further remodeled by hepatic lipase (HL) to form LDL. During this process, phospholipids and TGs in the particle are hydrolyzed, and most of the remaining apolipoproteins except apoB-100 are transferred to other lipoproteins. LDL is primarily a by-product of fatty acid energy transport by VLDL with little true physiologic role; one exception is that LDL may be partially responsible for delivery of vitamin E to the retina and brain. LDL is ultimately removed from the circulation by receptor-mediated endocytosis (primarily via the LDL receptor) in the liver, with a region of apoB-100 serving as the specific ligand for binding to the LDL receptor. It should be noted that apoB-48 does not contain the LDL receptor-binding ligand region, and therefore, clearance of apoB-48-containing chylomicron remnants is dependent on apoE-mediated clearance as noted above. Some LDL particles are lipolytically processed to small dense LDL particles that are believed to be especially atherogenic.

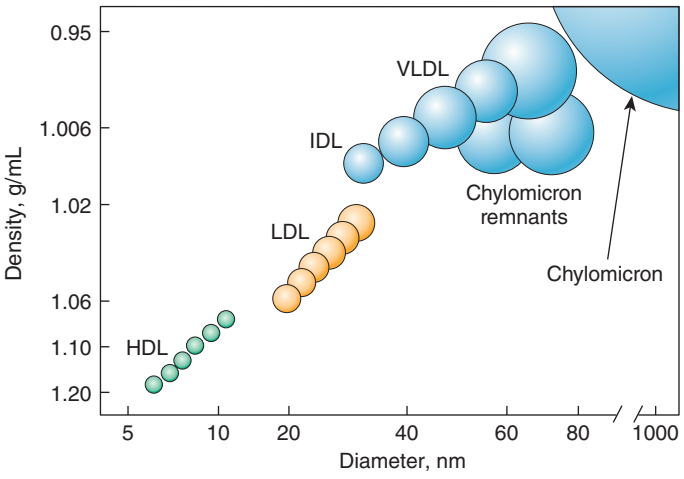

FIGURE 407-1 The density and size distribution of the major classes of lipoprotein particles. Lipoproteins are classified by density and size, which are inversely related. HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

Lp(a) is a lipoprotein similar to LDL in lipid and protein composition, but it contains an additional distinctive protein called apo(a). Apo(a) is synthesized in the liver and attached to apoB-100 by a disulfide linkage. The major site of clearance of Lp(a) is the liver, but the uptake pathway is not known. Lp(a) is now established as causal factor for ASCVD, and an elevated level of Lp(a) serves as an independent risk factor and merits more aggressive therapy to reduce LDL cholesterol levels (see below).

HDL METABOLISM AND REVERSE CHOLESTEROL TRANSPORT

All nucleated cells synthesize cholesterol, but only hepatocytes and enterocytes can effectively excrete cholesterol from the body, into either the bile or the gut lumen, respectively. In the liver, cholesterol is secreted into the bile, either directly or after conversion to bile acids. Cholesterol in peripheral cells is transported from the plasma membranes of peripheral cells to the liver and intestine by a process termed *reverse cholesterol transport* that is facilitated by HDL **(Fig. 407-3)**.

Nascent HDL particles are synthesized by the intestine and the liver. Newly secreted apoA-I rapidly acquires phospholipids and unesterified cholesterol from its site of synthesis (intestine or liver) via cellular efflux promoted by the membrane protein ATP-binding cassette protein A1 (ABCA1). This process results in the formation of discoidal HDL particles, which then recruit additional unesterified cholesterol from cells or circulating lipoproteins. Within the HDL particle, the cholesterol is esterified to cholesteryl ester (CE) through the addition of a fatty acid by lecithin-cholesterol acyltransferase (LCAT), a plasma enzyme associated with HDL; the hydrophobic CE forms the core

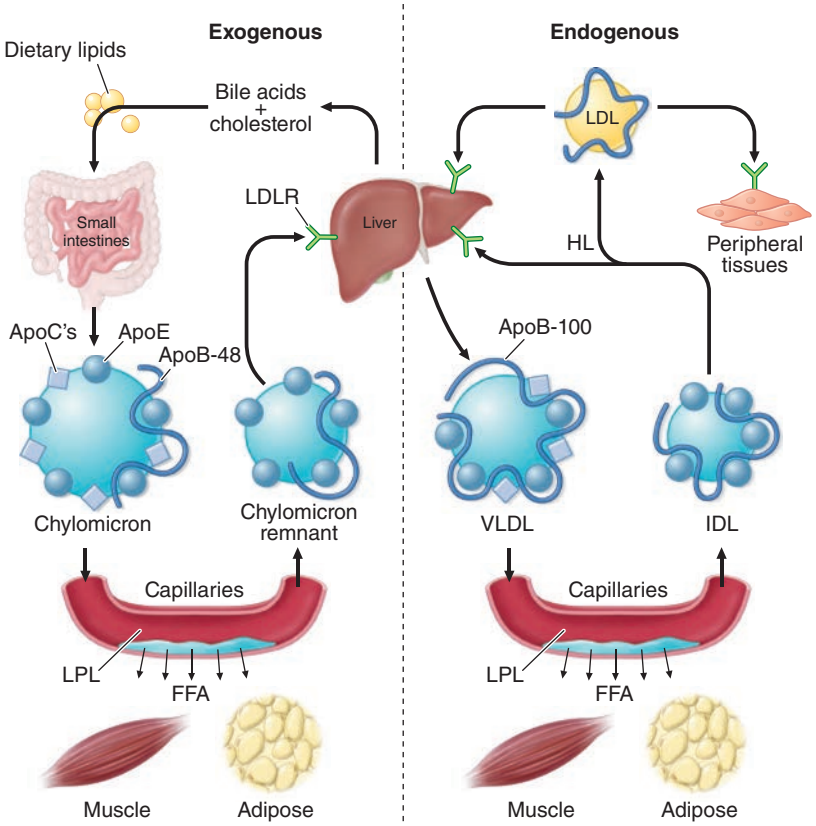

FIGURE 407-2 The exogenous and endogenous lipoprotein metabolic pathways. The exogenous pathway transports dietary lipids to the periphery and the liver. The endogenous pathway transports hepatic lipids to the periphery. FFA, free fatty acid; HL, hepatic lipase; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LDLR, low-density lipoprotein receptor; LPL, lipoprotein lipase; VLDL, very-low-density lipoprotein.

of the mature HDL particle. As HDL acquires more CE, it becomes spherical, and additional apolipoproteins and lipids are transferred to the particles from the surfaces of chylomicrons and VLDLs during lipolysis.

HDL cholesterol in the blood is transported to hepatocytes by two major pathways. HDL CE can be "selectively" taken up by hepatocytes via the scavenger receptor class B1 (SR-B1), a cell surface HDL receptor that mediates the selective transfer of CE from HDL with subsequent dissociation and "recycling" of the HDL particle. In addition, HDL CE can be transferred to apoB-containing lipoproteins in exchange for TG by the cholesteryl ester transfer protein (CETP). The CE esters are then removed from the circulation by LDL receptor–mediated endocytosis. HDL-derived CE taken up by the hepatocyte through these pathways is hydrolyzed, and much of the cholesterol is ultimately excreted directly into the bile or converted to bile acids with excretion to bile, providing a biliary route into the intestinal lumen. There is also evidence that, under certain conditions, HDL cholesterol can be transported directly into the intestinal lumen without requiring a transhepatobiliary route, a process known as *transintestinal cholesterol excretion*.

HDL particles undergo extensive remodeling within the plasma compartment by a variety of lipid transfer proteins and lipases. The phospholipid transfer protein (PLTP) transfers phospholipids from other lipoproteins to HDL or among different classes of HDL particles and is a regulator of HDL metabolism. After CETP- and PLTP-mediated lipid exchange, the TG-enriched HDL becomes a much better substrate for HL, which hydrolyzes the TGs and phospholipids to generate smaller HDL particles. A related enzyme called endothelial lipase (EL) hydrolyzes HDL phospholipids, generating smaller HDL particles that are catabolized faster. Remodeling of HDL influences the metabolism, function, and plasma concentrations of HDL.

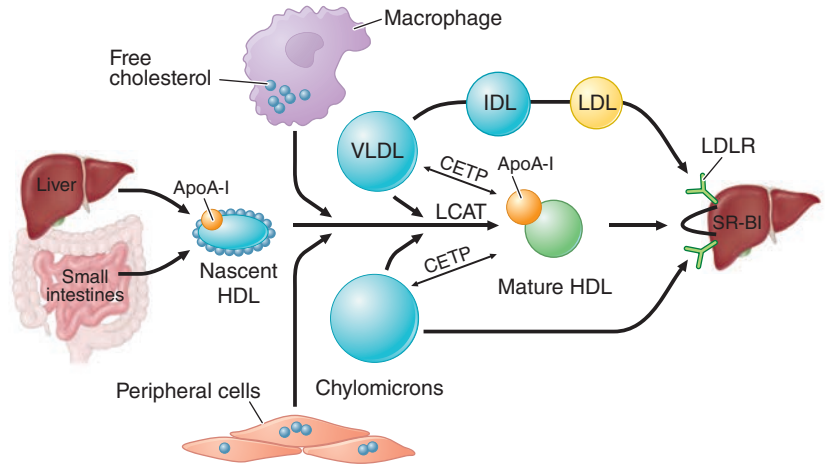

FIGURE 407-3 High-density lipoprotein (HDL) metabolism and reverse cholesterol transport. The HDL pathway transports excess cholesterol from the periphery back to the liver for excretion in the bile. The liver and the intestine produce nascent HDLs. Free cholesterol is acquired from macrophages and other peripheral cells and esterified by lecithin-cholesterol acyltransferase (LCAT), forming mature HDLs. HDL cholesterol can be selectively taken up by the liver via SR-BI (scavenger receptor class BI). Alternatively, HDL cholesteryl ester can be transferred by cholesteryl ester transfer protein (CETP) from HDLs to very-low-density lipoproteins (VLDLs) and chylomicrons, which can then be taken up by the liver. IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LDLR, low-density lipoprotein receptor.

SCREENING

Dyslipidemia is an important causal factor in ASCVD, and treatment has been proven to substantially reduce cardiovascular risk. Therefore, all adults (and many children) should be actively screened for plasma lipids. A lipid panel should be measured, preferably after an overnight fast. In most clinical laboratories, the total cholesterol and TGs in the plasma are measured enzymatically, and then after precipitation of apoB-containing lipoproteins, the cholesterol in the supernatant is measured to determine the HDL cholesterol (HDL-C). The LDL cholesterol (LDL-C) is then estimated using the following equation (the Friedewald formula):

$$\text{LDL-C} = \text{total cholesterol} - (\text{TG}/5) - \text{HDL-C}$$

(The VLDL cholesterol content is estimated by dividing the plasma TG by 5, reflecting the ratio of TG to cholesterol in VLDL particles.) This formula is reasonably accurate if test results are obtained on fasting plasma and if the TG level does not exceed ~200 mg/dL; by convention, it cannot be used if the TG level is >400 mg/dL. LDL-C can be directly measured by a number of methods. The non-HDL-C can be easily calculated by subtracting the HDL-C from the total cholesterol. It has the advantage of incorporating the cholesterol contained within VLDL and IDL, which in most cases is also atherogenic and associated with increased ASCVD risk. There is increasing evidence that measurement of plasma apoB levels may provide a better assessment of cardiovascular risk than the LDL-C level, and even the non-HDL-C level, and is recommended by some experts. While this has not yet become standard clinical practice, the data supporting the use of apoB as a risk marker and guide to therapeutic intervention are quite strong. There is also increasing interest in Lp(a), an independent ASCVD risk factor that is highly heritable and may be helpful

in risk stratification. In patients with evidence of dyslipidemia, further evaluation and treatment are based on evidence of preexisting ASCVD and clinical assessment of cardiovascular risk using risk calculators such as the American Heart Association (AHA)/American College of Cardiology (ACC) risk calculator as well as, in some cases, based on additional approaches to risk assessment such as apoB and Lp(a) (see "Approach to the Patient" for more detailed discussion).

DISORDERS ASSOCIATED WITH ELEVATED APOB-CONTAINING LIPOPROTEINS

Disorders of lipoprotein metabolism that cause elevated levels of apoB-containing lipoproteins are among the most common and clinically important of the dyslipoproteinemias. They are generally characterized by increased plasma levels of total cholesterol, accompanied by increased TGs, LDL-C, or both. Many patients with hyperlipidemia have some combination of genetic predisposition (often polygenic) and medical or environmental contribution (medical condition, diet, lifestyle, or drug). Many, but not all, patients with hyperlipidemia are at increased risk for ASCVD, which is the primary reason for making the diagnosis, as intervention can substantially reduce this risk. In addition, patients with severe hypertriglyceridemia may be at risk for acute pancreatitis and require intervention to reduce this risk.

Although hundreds of proteins influence lipoprotein metabolism, and genetic variants in most of the genes that encode them interact with each other and the environment to produce dyslipidemia, there are a limited number of discrete "nodes" or pathways that regulate lipoprotein metabolism and are dysfunctional in specific dyslipidemias. These include (1) lipolysis of TG-rich lipoproteins by LPL; (2) receptor-mediated uptake of apoB-containing lipoproteins by the liver; (3) cellular cholesterol metabolism in the hepatocyte and the enterocyte; (4) assembly and secretion of VLDLs by the liver; and (5) neutral lipid transfer and phospholipid hydrolysis in the plasma. Primary genetic disorders of lipoprotein metabolism caused by single-gene mutations **(Table 407-2)** have taught us a great deal about the physiologic roles of specific proteins in these pathways in humans and are clinically important to diagnose and treat.

SEVERE HYPERTRIGLYCERIDEMIA

Severe hypertriglyceridemia (HTG) is defined by fasting TG levels >500 mg/dL and is usually accompanied by moderately elevated total cholesterol levels and reduced levels of HDL-C, usually without important elevation in LDL-C or apoB. It is medically important because it is associated with risk of acute pancreatitis and, in some cases, is also associated with increased risk of ASCVD. Severe HTG is usually caused by impaired lipolysis of TGs in TG-rich lipoproteins (TRLs) by the enzyme LPL. LPL is synthesized by adipocytes, skeletal myocytes, and cardiomyocytes, and its posttranslational maturation and folding require the action of lipase maturation factor 1 (LMF1). After secretion, it is transported from the subendothelial to the vascular endothelial surfaces by GPIHPB1, which docks it to the endothelial surface. ApoC-II is a required cofactor for LPL, and apoA-V promotes LPL activity, and both are transported to the bound LPL on the TRLs. Single-gene Mendelian disorders that reduce LPL activity have been described **(Table 407-3)** as reviewed below; the majority of patients with severe HTG have a polygenic predisposition to secondary factors like obesity or insulin resistance.

Primary (Genetic) Causes of Severe Hypertriglyceridemia • **FAMILIAL CHYLOMICRONEMIA SYNDROME (FCS)** LPL is required for the hydrolysis of TGs in chylomicrons and VLDLs. Genetic deficiency or inactivity of LPL results in impaired lipolysis and profound elevations in plasma TGs, mostly in chylomicrons. While chylomicronemia predominates, in fact, these patients often have elevated plasma levels of VLDL as well. The fasting plasma is turbid, and if left undisturbed for several hours, the chylomicrons float to the top and form a creamy supernatant layer. Fasting TG levels are >500 mg/dL and usually >1000 mg/dL. Because chylomicrons contain cholesterol, fasting total cholesterol levels are also elevated. There are five genes in which mutations can result in FCS (Table 407-2). FCS has an estimated frequency of ~1 in 200,000–300,000, although its true prevalence is unknown. The most common molecular cause of FCS involves mutations in the *LPL* gene. *LPL deficiency* has autosomal recessive inheritance (loss-of-function mutations in both alleles). Heterozygotes with *LPL* mutations often have moderate elevations in plasma TG levels and increased risk for coronary heart disease (CHD). FCS can also be caused by mutations in genes that affect LPL processing or activity. For example, apoC-II is a required cofactor for LPL. *APOC2 deficiency* due to loss-of-function mutations in both *APOC2* alleles results in functional lack of LPL activity and severe hyperchylomicronemia that is indistinguishable from LPL deficiency. It is also recessive in inheritance pattern and much rarer than LPL deficiency. Another apolipoprotein, apoA-V, facilitates the association of TRLs with LPL and promotes hydrolysis of the TGs. Individuals harboring loss-of-function mutations in both *APOA5* alleles causing *APOA5 deficiency* develop a form of FCS. GPIHBP1 is required for transport and tethering of LPL to the endothelial luminal surface. Homozygosity for mutations in *GPIHBP1* that interfere with its synthesis or folding cause FCS. Autoantibodies to GPIHBP1 have also been reported to cause severe hyperchylomicronemia. Finally, *LMF1* is required for appropriate processing and folding of LPL, and bialleleic loss-of-function mutations can cause FCS.

FCS can present in childhood or adulthood with severe abdominal pain due to acute pancreatitis. In this setting, the diagnosis should be suspected if a fasting TG level is >500 mg/dL. Eruptive xanthomas, which are small, yellowish-white papules, may appear in clusters on the back, buttocks, and extensor surfaces of the arms and legs. On funduscopic examination, the retinal blood vessels may be opalescent (lipemia retinalis). Hepatosplenomegaly is sometimes noted as a result of uptake of circulating chylomicrons by reticuloendothelial cells in the liver and spleen. Premature ASCVD is not generally a feature of FCS.

The diagnosis of FCS is a clinical diagnosis based on persistence and severity of HTG, with a history of acute pancreatitis or eruptive xanthomas increasing the suspicion. While LPL activity can be measured in "postheparin plasma" obtained after an IV heparin injection to release the endothelial-bound LPL, this assay is not widely available. Genetic testing of a panel of candidate FCS genes can be used to confirm the diagnosis but is not required for making the clinical diagnosis.

Because of the risk of pancreatitis, it is important to consider the diagnosis and institute therapeutic interventions in FCS. The goal is to prevent pancreatitis by reducing fasting TG levels to <500 mg/dL. Consultation with a registered dietician familiar with this disorder is essential. Dietary fat intake should be markedly restricted (to as little as 15 g/d), often with fat-soluble vitamin supplementation. Strict adherence to dietary fat restriction can be successful at controlling the chylomicronemia; fish oils or fibrates (such as fenofibrate) may be tried but are unlikely to be effective. A new therapeutic approach involving the silencing of *APOC3* with an antisense oligonucleotide is approved in Europe for patients with FCS. In patients with *APOC2* deficiency, apoC-II can be provided exogenously by infusing fresh-frozen plasma to resolve the chylomicronemia in the setting of severe acute pancreatitis. Management of patients with FCS is particularly challenging during pregnancy when VLDL production is increased.

FAMILIAL PARTIAL LIPODYSTROPHY (FPLD) FPLD is a genetic condition in which the generation of adipose tissue in certain fat depots is impaired and in others is excessive. FPLD is an underrecognized monogenic cause of severe HTG, which is likely due to both increased lipid synthesis and VLDL production, as well as reduced LPL-mediated clearance of TRLs. FPLD is typically a dominantly inherited disorder caused by mutations in several different genes, including lamin A/C (*LMNA*), PPARγ (*PPARG*), perilipin (*PLIN1*), *AKT2*, and *ADRA2A* (Table 407-2). FPLD is characterized by loss of subcutaneous fat in the extremities and buttocks, often accompanied by increased visceral fat. Because of the reduced or absent subcutaneous fat in the arms and legs, patients are often described as having a "muscular" appearance. In addition to severe HTG, FPLD patients usually have insulin resistance, often quite severe, accompanied by type 2 diabetes and hepatosteatosis.

TABLE 407-2 Primary Dyslipoproteinemias Caused by Known Single-Gene Mutations

GENETIC DISORDER	GENES MUTATED	LIPOPROTEINS AFFECTED	CLINICAL FINDINGS	GENETIC TRANSMISSION	ESTIMATED PREVALENCE
Severe Hypertriglyceridemia					
Familial chylomicronemia syndrome (FCS)	Biallelic LoF mutations in: *LPL, APOC2, APOA5, GPIHBP1, LMF1*	Elevated: Chylomicrons, VLDL Reduced: HDL	Pancreatitis, eruptive xanthomas, hepatosplenomegaly	AR	~1/200,000–300,000
Familial partial lipodystrophy (FPLD)	Heterozygous LoF mutations in: *LMNA, PPARG, PLIN1, AKT2, ADRA2A*	Elevated: Chylomicrons, VLDL, LDL Reduced: HDL	Insulin resistance, fatty liver disease, pancreatitis, central obesity, lack of subcutaneous adipose in extremities	AD	<1/1,000,000
Hypercholesterolemia					
Familial hypercholesterolemia (FH)	Heterozygous LoF mutations in *LDLR*	Elevated: LDL	Tendon xanthomas, premature atherosclerotic cardiovascular disease (ASCVD)	AD	~1/250
Familial defective apoB-100 (FDB)	Heterozygous LoF receptor binding region mutations in *APOB*	Elevated: LDL	Tendon xanthomas, premature ASCVD	AD	~1/1500
Autosomal dominant hypercholesterolemia (ADH), type 3	Heterozygous GoF mutations in *PCSK9*	Elevated: LDL	Tendon xanthomas, premature ASCVD	AD	<1/1,000,000
Autosomal recessive hypercholesterolemia (ARH)	Biallelic LoF mutations in *LDLRAP1*	Elevated: LDL	Tendon xanthomas, premature ASCVD	AR	<1/1,000,000
Sitosterolemia	Biallelic LoF mutations in *ABCG5, ABCG8*	Elevated: LDL	Tendon xanthomas, premature ASCVD	AR	<1/1,000,000
Lysosomal acid lipase deficiency	Biallelic LoF mutations in *LIPA*	Elevated: LDL Reduced: HDL	Fatty liver disease, micronodular cirrhosis	AR	<1/1,000,000
Mixed Dyslipidemia					
Familial dysbetalipoproteinemia (FDBL)	Biallelic carriers of the *APOE2* variant	Elevated: Chylomicron remnants, IDL	Palmar and tuberoeruptive xanthomas, premature ASCVD	AR	~1/10,000
Hepatic lipase deficiency	Biallelic LoF mutations in *LIPC*	Elevated: Chylomicron remnants, IDL, HDL	Premature ASCVD	AR	<1/1,000,000
Hypolipidemic Syndromes					
Abetalipoproteinemia	Biallelic LoF mutations in *MTTP*	Absent: LDL Reduced: TG, HDL	Spinocerebellar degeneration, retinal degeneration	AR	<1/1,000,000
Familial hypobetalipoproteinemia	Heterozygous truncating mutations in *APOB*	Reduced: LDL	Fatty liver, reduced risk of ASCVD	AD	<1/1,000,000
Familial PCSK9 deficiency	Heterozygous LoF mutations in *PCSK9*	Reduced: LDL	Reduced risk of ASCVD	AD	~1/1,000
Familial combined hypolipidemia	Heterozygous LoF mutations in *ANGPTL3*	Reduced: TG, LDL, HDL	Reduced risk of ASCVD	AD	<1/1,000,000
Primary Low HDL Cholesterol Syndromes					
ApoA-I deletions/mutations	Heterozygous structural mutations in *APOA1*	Reduced: HDL	Variable depending on mutation: premature ASCVD, systemic amyloidosis	AD	<1/1,000,000
Tangier disease	Biallelic LoF mutations in *ABCA1*	Nearly absent: HDL Reduced: LDL Elevated: TG	Peripheral neuropathy, hepatosplenomegaly	AR	<1/1,000,000
Familial LCAT deficiency (FLD); fish eye disease (FED)	Biallelic LoF mutations in *LCAT*	Markedly reduced: HDL	Corneal opacities (both FLD and FED), progressive chronic kidney disease (FLD only)	AR	<1/1,000,000

Abbreviations: AD, autosomal dominant; apo, apolipoprotein; AR, autosomal recessive; ARH, autosomal recessive hypercholesterolemia; CHD, coronary heart disease; GoF, gain of function; HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LDL, low-density lipoprotein; LoF, loss of function; LPL, lipoprotein lipase; PVD, peripheral vascular disease; TG, triglyceride; VLDL, very-low density lipoprotein.

Pancreatitis secondary to HTG can be a complication; in addition, ASCVD risk is increased in FPLD patients. The diagnosis of FPLD is a clinical diagnosis based on the constellation of metabolic findings accompanied by the distinctive distribution of adipose tissue. Genetic testing of a panel of candidate FPLD genes can be used to confirm the diagnosis but is not required for making the clinical diagnosis. Because FPLD is a dominant disorder, the finding of a causal mutation should lead to family-based screening.

The dyslipidemia of FPLD can be difficult to manage clinically. Patients should be treated aggressively not only to reduce TG levels but also with statins and, if necessary, additional LDL-lowering therapies to reduce atherogenic lipoproteins. The insulin-resistant diabetes often requires aggressive management as well. Some patients have progression of fatty liver disease to nonalcoholic steatohepatitis and fibrosis. A different group of very rare patients have congenital generalized lipodystrophy, a recessive disorder caused by mutations in the *AGPAT2*

TABLE 407-3 Secondary Causes of Altered Lipid and Lipoprotein Levels

	LDL-C		HDL-C		LP(a) ELEVATED
TG ELEVATED	ELEVATED	REDUCED	ELEVATED	REDUCED	
High-carbohydrate diet	Hypothyroidism	Vegan diet	High-fat diet	Hypertriglyceridemia	Chronic kidney disease
Alcohol	Cholestasis	Malabsorption	Alcohol	Vegan diet	Nephrotic syndrome
Obesity	Nephrotic syndrome	Malnutrition	Exercise	Malabsorption	Inflammation
Insulin resistance	Cushing's syndrome	Severe liver disease	Drugs: estrogen	Malnutrition	Menopause
Type 2 diabetes	Acute intermittent porphyria	Gaucher's disease		Sedentary lifestyle	Orchidectomy
Lipodystrophy	Drugs: corticosteroids, cyclosporin, sirolimus, carbamazepine	Chronic infectious disease		Smoking	Hypothyroidism
Chronic kidney disease		Hyperthyroidism		Obesity	Acromegaly
Nephrotic syndrome				Gaucher's disease	Drugs: growth hormone, isotretinoin
Viral hepatitis				LAL deficiency	
Sepsis				Drugs: anabolic steroids, testosterone, beta blockers	
Cushing's syndrome					
Acromegaly					
Glycogen storage disease					
Pregnancy					
Drugs: estrogen, glucocorticoids, isotretinoin, bexarotene, other retinoids, beta blockers, bile acid binding resins					

Abbreviations: HDL-C, high-density lipoprotein cholesterol; LAL, lysosomal acid lipase; LDL-C, low-density lipoprotein cholesterol; Lp(a), lipoprotein(a); TG, triglyceride.

and *BSCL2* genes. These patients have nearly complete absence of subcutaneous fat, accompanied by profound leptin deficiency, insulin resistance, severe HTG, and accumulation of TGs in multiple tissues including the liver. Patients with generalized lipodystrophy can be effectively treated with recombinant leptin administration, which often manages the multiple metabolic issues in these patients.

Multifactorial Severe Hypertriglyceridemia Most patients with severe HTG do not have a single-gene mutation but instead have a multifactorial etiology that includes genetics and environment. The prevalence of this phenotype is ~1 in 1000. HTG often runs in families, and the term *familial HTG* has been employed; however, except for the genes in which mutations cause FCS or FPLD, reviewed above, no other classic Mendelian causes of HTG have been identified to date. Instead, extensive human genetic studies have clearly established a polygenic basis to this phenotype that consists of two categories: (1) rare heterozygous variants in the five genes discussed earlier that cause FCS in the homozygous state, and (2) a high burden of common variants that have small individual effects at raising TGs. Patients who inherit some combination of rare and common TG-raising alleles often have environmental factors that exacerbate their HTG. These "secondary" factors are reviewed in detail below, but the quantitatively most important factors promoting HTG include obesity, type 2 diabetes, insulin resistance, and alcohol use. Multifactorial HTG is characterized by elevated fasting TGs but average to below average LDL-C levels and low HDL-C levels; apoB levels are not generally elevated. This condition is not generally associated with a significantly increased risk of ASCVD. However, if the HTG is exacerbated by environmental factors, medical conditions, or drugs, the TGs can rise to a level at which acute pancreatitis is a risk. Indeed, management of patients with this condition is mostly focused on reduction of TGs to prevent pancreatitis. It is important to consider and rule out secondary causes of the HTG. Patients who are at high risk for ASCVD due to other risk factors should be treated with statin therapy. In patients who are otherwise not at high risk for ASCVD, lipid-lowering drug therapy can frequently be avoided with appropriate dietary and lifestyle changes. Patients with plasma TG levels >500 mg/dL after a trial of diet and exercise should be considered for drug therapy with a fibrate or fish oil to reduce TGs in order to prevent pancreatitis. These patients should also be carefully evaluated for ASCVD risk and may be candidates for statin therapy to further reduce cholesterol and cardiovascular risk.

HYPERCHOLESTEROLEMIA (ELEVATED LDL-C)

Elevated LDL-C is common and is medically important because it is associated with risk of premature ASCVD. Elevated LDL-C is often caused by impaired uptake of LDL by the liver. As discussed above, the LDL receptor is the major receptor responsible for uptake of LDL, and most causes of elevated LDL-C converge on reduced expression or activity of the LDL receptor in the liver. One major environmental factor that reduces LDL receptor activity is a diet high in saturated and trans fats. Other medical conditions that reduce LDL receptor activity include hypothyroidism and estrogen deficiency. Single-gene Mendelian disorders involving several genes that influence LDL clearance should be considered in patients with LDL-C levels >190 mg/dL (Table 407-2). However, the majority of patients with elevated LDL-C have a polygenic predisposition exacerbated by secondary factors like a diet high in saturated and trans fats.

Primary (Genetic) Causes of Elevated LDL-C • FAMILIAL HYPERCHOLESTEROLEMIA (FH) FH is an autosomal dominant disorder characterized by elevated plasma levels of LDL-C usually with relatively normal TG levels. FH is caused by mutations that lead to reduced function of the LDL receptor, with the most common being mutations in the *LDLR* gene itself. The reduction in LDL receptor activity in the liver results in a reduced rate of clearance of LDL from the circulation. The plasma level of LDL increases to a level such that the rate of LDL production equals the rate of LDL clearance by residual LDL receptor as well as non-LDL receptor mechanisms. Individuals with two mutated *LDLR* alleles (homozygotes or compound heterozygotes) have much higher LDL-C levels than those with one mutant allele, causing a condition known as *homozygous FH*.

Although mutations in *LDLR* are the most common cause of FH (and originally the term *FH* was used specifically for patients with *LDLR* mutations), mutations in at least two other genes, *APOB* and *PCSK9*, can also cause FH. ApoB-100 is the critical structural protein in LDL and contains a domain that serves as the ligand for binding to the LDL receptor. Mutations in the LDL receptor–binding domain of apoB-100 reduce the affinity of apoB/LDL binding to the LDL receptor, such that LDL is removed from the circulation at a reduced rate. This condition has also been termed *familial defective apoB* (FDB). Of note, truncating mutations in *APOB* cause *low* LDL-C levels (see below). The proprotein convertase subtilisin/kexin type 9 (PCSK9) is a secreted protein that binds to the LDL receptor and targets it for lysosomal degradation. Normally, after LDL binds to the LDL receptor, it is internalized along with the receptor, and in the low pH of the endosome, the LDL receptor dissociates from the LDL and recycles to the cell surface. When circulating PCSK9 binds the receptor, the complex is internalized and the receptor is directed to the lysosome, rather than to the cell surface, reducing the number of active LDL receptors. *Gain-of-function*

mutations in *PCSK9* that enhance the activity of PCSK9 cause a form of FH, also known as ADH type 3. Of note, loss-of-function mutations in *PCSK9 reduce* LDL-C levels (see below).

The population frequency of heterozygous FH was originally estimated to be 1 in 500 individuals, but recent data suggest it may be as high as ~1 in 250 individuals, making it one of the most common single-gene disorders in humans. FH has a much higher prevalence in certain founder populations, such as South African Afrikaners, Christian Lebanese, French Canadians, and Lancaster County Amish. Heterozygous FH is characterized by elevated plasma levels of LDL-C (usually >190 mg/dL) and relatively normal levels of TGs. Patients with FH have hypercholesterolemia from birth, and FH diagnosis is often based on detection of hypercholesterolemia on routine lipid screening; this serves as the basis for the recommendation to screen children between the ages of 9 and 11. A family history of hypercholesterolemia or premature ASCVD should prompt targeted screening. Inheritance of FH is dominant, meaning that the condition is inherited from one parent, and ~50% of the patient's siblings and children can be expected to have FH. For this reason, family-based "cascade screening" can be very effective in identifying additional persons with FH. Physical findings in some, but not all, patients with FH may include corneal arcus and/or tendon xanthomas, particularly involving the dorsum of the hands and the Achilles tendons. Untreated heterozygous FH is associated with a markedly increased risk of cardiovascular disease; untreated men with heterozygous FH have an ~50% chance of having a myocardial infarction before age 60 years, and women with heterozygous FH are at substantially increased risk as well. The age of onset of cardiovascular disease is highly variable and depends on the specific molecular defect, the level of LDL-C, and coexisting cardiovascular risk factors.

The diagnosis of FH is generally a clinical diagnosis based on hypercholesterolemia with LDL-C >190 mg/dL in the absence of a secondary etiology and ideally with a family history of hypercholesterolemia and/or premature ASCVD. Secondary causes of significant hypercholesterolemia such as hypothyroidism, nephrotic syndrome, and obstructive liver disease should be excluded. Sequencing of an FH gene panel (*LDLR*, *APOB*, *PCSK9*) to confirm the diagnosis is widely available and worthy of consideration; persons with molecularly confirmed FH are at higher risk of ASCVD and therefore may benefit from more aggressive treatment, and the finding of a specific causal variant has implications for family-based cascade screening.

FH patients should be actively treated to lower plasma levels of LDL-C, preferably starting in childhood. Initiation of a diet low in saturated and trans fats is recommended, but heterozygous FH patients almost always require pharmacologic therapy for effective control of their LDL-C levels. Statins are the initial drug class of choice, and usually "high-intensity" statin therapy is needed. Many FH patients cannot achieve adequate control of their LDL-C levels even with high-intensity statin therapy, and a cholesterol absorption inhibitor (ezetimibe), a PCSK9 inhibitor, an ACL inhibitor (bempedoic acid), and a bile acid sequestrant are other classes of drugs that can be added to statins **(Table 407-4)**. Some patients with severe heterozygous FH cannot be adequately managed using existing therapies and are candidates for LDL apheresis, a physical method of purging the blood of LDL in which the LDL particles are selectively removed from the circulation. Other novel approaches for these patients are under development.

Homozygous FH (HoFH) is caused by loss-of-function mutations in both alleles of the LDL receptor or double heterozygosity for mutations in two FH genes. Patients with HoFH have been classified into those with virtually no detectable LDL receptor activity (*receptor negative*) and patients with markedly reduced but detectable LDL receptor activity (*receptor defective*). Untreated LDL-C levels in patients with HoFH range from ~400 to >1000 mg/dL, with receptor-defective patients at the lower end and receptor-negative patients at the higher end of the range. TGs are usually relatively normal. Some patients with HoFH, particularly receptor-negative patients, present in childhood with cutaneous planar xanthomas on the hands, wrists, elbows, knees, heels, or buttocks. The devastating consequence of HoFH is accelerated ASCVD, which often presents in childhood or early adulthood. Atherosclerosis often develops first in the aortic root, where it can cause aortic valvular or supravalvular stenosis, and typically extends into the coronary ostia, which become stenotic. Symptoms can be atypical, and sudden death is not uncommon. Untreated, receptor-negative patients with HoFH rarely survive beyond the second decade; patients with receptor-defective LDL receptor defects have a better prognosis but almost invariably develop clinically apparent atherosclerotic vascular disease by age 30 and often much sooner.

HoFH should be suspected in a child or young adult with LDL >400 mg/dL without secondary cause. Cutaneous xanthomas, evidence of ASCVD, and/or hypercholesterolemia in both parents all are supportive of the diagnosis. While the diagnosis is usually made on clinical grounds, genetic testing should be performed to identify specific causal variants. Patients with HoFH must be treated aggressively to delay the onset and progression of CVD. Although receptor-negative patients have no response to statins and PCSK9 inhibitors, receptor-defective patients can have modest responses to these medicines, and they should be tried in patients with HoFH. Two drugs that reduce the hepatic production of VLDL and thus LDL, a small-molecule inhibitor of the microsomal TG transfer protein (MTP) and an antisense oligonucleotide to apoB, and an antibody that inhibits ANGPLT3 are approved for the treatment of patients with HoFH and should be considered in patients who have insufficient response to statins and PCSK9 inhibitors. LDL apheresis should be considered in HoFH patients who have persistently elevated LDL-C levels despite drug therapy. Liver transplantation is effective in decreasing plasma LDL-C levels in this disorder and is sometimes used as a last resort. Liver-directed gene therapy is under development for HoFH, as are other new therapeutic approaches intended to address the remaining unmet medical need.

FH is an autosomal dominant disorder. There are a few rare conditions that cause an FH-like phenotype in an autosomal recessive manner and should be considered in patients with severe hypercholesterolemia who do not report a family history of hypercholesterolemia or premature CHD.

AUTOSOMAL RECESSIVE HYPERCHOLESTEROLEMIA (ARH) ARH is a very rare autosomal recessive disorder that was originally reported in individuals of Sardinian descent. The disease is caused by mutations in the gene *LDLRAP1* encoding the protein LDLR adaptor protein (also called the ARH protein), which is required for LDL receptor–mediated endocytosis in the liver. LDLRAP1 binds to the cytoplasmic domain of the LDL receptor and links the receptor to the endocytic machinery. In the absence of LDLRAP1, LDL binds to the extracellular domain of the LDL receptor, but the lipoprotein-receptor complex fails to be internalized. ARH, like HoFH, is characterized by hypercholesterolemia, tendon xanthomas, and premature coronary artery disease (CAD). The levels of plasma LDL-C tend to be intermediate between the levels present in FH homozygotes and FH heterozygotes, and CAD is not usually symptomatic until the third decade. LDL receptor function in cultured fibroblasts is normal or only modestly reduced in ARH, whereas LDL receptor function in the liver is negligible. Unlike FH homozygotes, the hyperlipidemia responds to treatment with statins, but these patients often require additional therapy to lower plasma LDL-C to acceptable levels.

SITOSTEROLEMIA Sitosterolemia is a rare autosomal recessive disease that is caused by biallelic loss-of-function mutations in either of two members of the ATP-binding cassette (ABC) half transporter family, *ABCG5* and *ABCG8*. These genes are expressed in both enterocytes and hepatocytes. The proteins heterodimerize to form a functional complex that transports plant sterols such as sitosterol and campesterol, and animal sterols, predominantly cholesterol, across the apical biliary membrane of hepatocytes into the bile and across the apical luminal membrane of enterocytes into the gut lumen, thus reducing their (re)absorption and promoting their excretion. In normal individuals, <5% of dietary plant sterols are absorbed by the proximal small intestine. The small amounts of plant sterols that enter the circulation are preferentially excreted into the bile, and thus, levels of plant sterols are kept very low in tissues. In sitosterolemia, the intestinal absorption of sterols is increased and biliary and fecal excretion of the sterols is reduced, resulting in increased plasma and tissue levels of both plant sterols and cholesterol. The increase in hepatic sterol

TABLE 407-4 Drugs Used to Treat Dyslipidemia

DRUG	MAJOR INDICATIONS	STARTING DOSE	MAXIMAL DOSE	MECHANISM	ADVERSE EFFECTS
LDL-Lowering Drugs					
HMG-CoA reductase inhibitors (statins)	Elevated LDL-C; increased CV risk			↓ Inhibition of cholesterol synthesis → ↑ Hepatic LDL receptors	Myalgias and myopathy, ↑ transaminases, ↑ diabetes risk
Lovastatin		20–40 mg daily	80 mg daily		
Pravastatin		40–80 mg daily	80 mg daily		
Simvastatin		20–40 mg daily	80 mg daily		
Fluvastatin		20–40 mg daily	80 mg daily		
Atorvastatin		20–40 mg daily	80 mg daily		
Rosuvastatin		5–20 mg daily	40 mg daily		
Pitavastatin		1–2 mg daily	4 mg daily		
Cholesterol absorption inhibitor	Elevated LDL-C			↓ Cholesterol absorption→ ↑ LDL receptors	Elevated transaminases
Ezetimibe		10 mg daily	10 mg daily		
Bile acid sequestrants	Elevated LDL-C			↑ Bile acid excretion → ↑ LDL receptors	Bloating, constipation, elevated triglycerides
Cholestyramine		4 g daily	32 g daily		
Colestipol		5 g daily	40 g daily		
Colesevelam		3750 mg daily	4375 mg daily		
PCSK9 inhibitors	Elevated LDL-C	140 mg SC every 2 weeks	420 mg SC every 1 month (HoFH)	↓ PCSK9 activity due to Ab inhibition → ↑ LDL receptors	Injection site reactions
Evolocumab (Ab)		75 mg SC every 2 weeks	150 mg SC every 2 weeks		
Alirocumab (Ab)					
Inclisiran (siRNA)		300 mg SC every 6 months	300 mg SC every 6 months	↓ PCSK9 synthesis due to siRNA silencing → ↑ LDL receptors	Injection site reactions
ATP citrate lyase inhibitor	Elevated LDL-C	180 mg daily	180 mg daily	↓ Inhibition of cholesterol synthesis → ↑ LDL receptors	↑ uric acid and gout
Bempedoic acid					Tendon rupture
MTP inhibitor	HoFH	5 mg daily	60 mg daily	MTP inhibition → ↓ VLDL assembly and secretion	Nausea, diarrhea, increased hepatic fat
Lomitapide					
ApoB inhibitor (ASO)	HoFH	200 mg SC weekly	200 mg SC weekly	↓ ApoB synthesis due to ASO silencing → ↓ ApoB/VLDL secretion	Injection site reactions, flu-like symptoms, increased hepatic fat
Mipomersen					
ANGPTL3 inhibitor (Ab)	HoFH	15 mg/kg IV q 4 weeks	15 mg/kg IV q 4 weeks	↓ ANGPTL3 activity due to Ab inhibition → ↑ LPL activity, ↑ LDL catabolism	Reduced HDL-C levels
Evinacumab					
TG-Lowering Drugs					
Fibric acid derivatives (fibrates)	Elevated TG	600 mg bid	600 mg bid	↑ LPL, ↓ VLDL synthesis	Dyspepsia, myalgia, gallstones, elevated transaminases
Gemfibrozil		40–160 mg daily depending on product	40–160 mg daily depending on product		
Fenofibrate					
Omega-3 fatty acids	Elevated TG	4 g daily	4 g daily	↑ TG catabolism	Dyspepsia, fishy odor to breath
Acid ethyl esters					
Icosapent ethyl		4 g daily	4 g daily		

Abbreviations: Ab, antibody; GI, gastrointestinal; HDL-C, high-density lipoprotein cholesterol; HoFH, homozygous familial hypercholesterolemia; LDL, low-density lipoprotein; LDL-C, LDL cholesterol; LPL, lipoprotein lipase; TG, triglyceride; VLDL, very-low-density lipoprotein.

levels results in transcriptional suppression of the expression of the LDL receptor, resulting in reduced uptake of LDL and substantially increased LDL-C levels. In addition to the clinical picture of severe hypercholesterolemia, often accompanied by tendon xanthomas and premature ASCVD, these patients also have anisocytosis and poikilocytosis of erythrocytes and megathrombocytes due to the incorporation of plant sterols into cell membranes. Episodes of hemolysis and splenomegaly are a distinctive clinical feature of this disease compared to other genetic forms of hypercholesterolemia and can be a clue to the diagnosis. Sitosterolemia should be suspected in a patient with severe hypercholesterolemia without a family history of such or who fails to respond to statin therapy. Sitosterolemia can be diagnosed by a laboratory finding of a substantial increase in plasma sitosterol and/or other plant sterols and should be confirmed by gene sequencing of *ABCG5* and *ABCG8*. It is important to make the diagnosis, because diet, bile acid sequestrants, and cholesterol-absorption inhibitors are the most effective agents to reduce LDL-C and plasma plant sterol levels in these patients. Of note, heterozygosity for mutations in *ABCG5* or *ABCG8* is now recognized to cause a moderate form of hypercholesterolemia.

LYSOSOMAL ACID LIPASE DEFICIENCY (LALD) LALD, also known as *cholesteryl ester storage disease*, is an autosomal recessive disorder caused by loss-of-function variants in both alleles of the gene *LIPA* encoding the enzyme lysosomal acid lipase (LAL). LAL is responsible for hydrolyzing neutral lipids, particularly TGs and CEs, after delivery to the lysosome by cell surface receptors such as the LDL receptor. It is particularly important in the liver, which clears large amounts of lipoproteins from the circulation. LALD is characterized by elevated LDL-C, usually in association with low HDL-C and with variably elevated TG levels, together with progressive fatty liver ultimately leading to hepatic fibrosis. Genetic deficiency of LAL results in accumulation

of neutral lipid in the hepatocytes, leading to hepatosplenomegaly, microvesicular steatosis, and ultimately fibrosis and end-stage liver disease. The most severe form of this disorder, Wolman's disease, presents in infancy and is rapidly fatal. The etiology of the elevated LDL-C levels is primarily due to impaired LDL receptor–mediated clearance of LDL. LALD should be suspected in nonobese patients with elevated LDL-C, low HDL-C, and evidence of fatty liver in the absence of overt insulin resistance. The diagnosis can be made with a dried blood spot assay of LAL activity and confirmed by DNA genotyping for the most common mutation, followed if necessary by sequencing of the gene to find the second mutation. Liver biopsy is required to assess the degree of inflammation and fibrosis. LALD is underdiagnosed; it is critically important to suspect it and make the diagnosis because enzyme replacement therapy with sebelipase alfa is now available and is highly effective in treating this condition.

The above conditions primarily cause elevations in LDL due to impaired catabolism of LDL from the blood. There are a few forms of primary dyslipidemia that impair the catabolism of "remnant" TRLs (after their processing by LPL) and therefore cause elevations in both cholesterol and TGs due to remnant accumulation.

Multifactorial Hypercholesterolemia Most patients with elevated LDL-C do not have a single-gene disorder, as described above, but instead have a multifactorial etiology that includes genetics and environment. Genetic variation contributes substantially to elevated LDL-C levels in the general population. It has been estimated that at least 50% of variation in LDL-C is genetically determined. Many patients with elevated LDL-C have *polygenic hypercholesterolemia* due to multiple common genetic variants exerting modest LDL-raising effects. Individuals at the tail of the highest burden of polygenic risk score for LDL-C often have LDL-C levels that are similar to those with FH. In patients who are genetically predisposed to higher LDL-C levels, diet plays a key exacerbating role; indeed, increased saturated and trans fats in the diet shift the entire distribution of LDL-C levels in the population to the right. As described in more detail below, patients with elevated LDL-C should be carefully assessed for their risk of ASCVD and managed with lifestyle modification and LDL-lowering medications as needed to reduce LDL-C and risk of ASCVD.

MIXED HYPERLIPIDEMIA (ELEVATED TG AND LDL-C)

Mixed hyperlipidemia can be defined as fasting TGs >150 mg/dL and evidence of elevated cholesterol-containing lipoproteins (such as LDL-C >130 mg/dL or non-HDL-C >160 mg/dL). It is one of the most common types of lipid disorders seen in clinical practice, due both to genetic predisposition and influence of medical conditions and environmental factors (see below). It is generally associated with elevated risk of ASCVD, and therefore, patients with mixed hyperlipidemia should be carefully evaluated and managed to reduce this risk.

Primary (Genetic) Causes of Mixed Hyperlipidemia • **FAMILIAL DYSBETALIPOPROTEINEMIA (FDBL)** FDBL (also known as *type III hyperlipoproteinemia*) is a recessive disorder characterized by a mixed hyperlipidemia due to the accumulation of remnant lipoprotein particles (chylomicron remnants and VLDL remnants, or IDL). ApoE is present in multiple copies on chylomicron remnants and IDL and mediates their removal via hepatic lipoprotein receptors (Fig. 407-2). The *APOE* gene is polymorphic in sequence, resulting in the expression of three common isoforms: apoE3, which is the most common (~78% global allele frequency [AF]), apoE4 (~14% global AF), and apoE2 (~8% global AF). The apoE4 allele, which has an arginine instead of a cysteine at position 112, is widely known for being the major genetic risk factor for Alzheimer's disease. It is associated with slightly higher LDL-C levels and increased ASCVD risk but is not associated with FDBL. The apoE2 allele, which has a cysteine at position 158 instead of an arginine, is the cause of FDBL when present on both alleles. ApoE2 has a lower affinity for the LDL receptor; therefore, chylomicron remnants and IDL containing apoE2 are removed from plasma at a slower rate, leading to their accumulation in blood.

Approximately 0.5% of the general population are apoE2/E2 homozygotes, but only a small minority of these individuals actually develop hyperlipidemia characteristic of FDBL (which has a prevalence of ~1 in 10,000). Thus, an additional, sometimes identifiable, factor precipitates the development of overt dysbetalipoproteinemia in apoE2/E2 homozygotes. The most common precipitating factors are a high-fat diet, sedentary lifestyle, obesity, alcohol use, menopause, diabetes mellitus, hypothyroidism, renal disease, HIV infection, or certain drugs. Certain dominant-negative mutations in apoE can cause a dominant form of FDBL where the hyperlipidemia is fully manifest in the heterozygous state, but these mutations are very rare.

Patients with FDBL usually present in adulthood with hyperlipidemia, xanthomas, or premature coronary or peripheral vascular disease. In FDBL, in contrast to other disorders of elevated TGs, the plasma levels of cholesterol and TG are often elevated to a similar degree, and the level of HDL-C is usually normal. Two distinctive types of xanthomas, tuberoeruptive and palmar, are seen in FDBL patients. Tuberoeruptive xanthomas begin as clusters of small papules on the elbows, knees, or buttocks and can grow to the size of small grapes. Palmar xanthomas (alternatively called *xanthomata striata palmaris*) are orange-yellow discolorations of the creases in the palms and wrists. Both of these xanthoma types are virtually pathognomonic for FDBL. Subjects with FDBL have premature ASCVD and tend to have more peripheral vascular disease than is typically seen in FH.

The definitive diagnosis of FDBL can be made either by the documentation of very high levels of remnant lipoproteins or by identification of the apoE2/E2 genotype. A variety of methods are used to identify remnant lipoproteins in the plasma, including "β-quantification" by ultracentrifugation (ratio of directly measured VLDL cholesterol to total plasma TG >0.30), lipoprotein electrophoresis (broad β band), or nuclear magnetic resonance lipoprotein profiling. The Friedewald formula for calculation of LDL-C is not valid in FDBL because the VLDL particles are depleted in TG and enriched in cholesterol. The plasma levels of LDL-C are actually low in this disorder due to defective metabolism of VLDL to LDL. DNA-based apoE genotyping can be performed to confirm homozygosity for apoE2, which is diagnostic for FDBL. However, absence of the apoE2/E2 genotype does not strictly rule out the diagnosis of FDBL, because other mutations in apoE can (rarely) cause this condition.

Because FDBL is associated with increased risk of premature ASCVD, it should be treated aggressively. Other metabolic conditions that can exacerbate the hyperlipidemia (see above) should be managed. Patients with FDBL are typically diet-responsive and can respond favorably to low-cholesterol, low-fat diets and weight reduction. Alcohol intake should be curtailed. Pharmacologic therapy is often required, and statins are the first line in management. In the event of statin intolerance or insufficient control of hyperlipidemia, cholesterol absorption inhibitors, PCSK9 inhibitors, and fibrates are also effective in the treatment of FDBL.

HEPATIC LIPASE DEFICIENCY Hepatic lipase (HL; gene name *LIPC*) is a member of the same gene family as LPL and hydrolyzes TGs and phospholipids in remnant lipoproteins and HDL. Hydrolysis of lipids in remnant particles by HL contributes to their hepatic uptake via an apoE-mediated process. HL deficiency is a very rare autosomal recessive disorder caused by biallelic loss-of-function mutations in *LIPC*. It is characterized by elevated plasma levels of cholesterol and TGs (mixed hyperlipidemia) due to the accumulation of lipoprotein remnants, accompanied by elevated plasma level of HDL-C. The diagnosis is confirmed by confirmation of pathogenic mutations in both alleles of *LIPC*. Due to the small number of patients with HL deficiency, the association of this genetic defect with ASCVD is not entirely clear, although anecdotally, patients with HL deficiency who have premature CVD have been described. As with FDBL, statin therapy is recommended to reduce remnant lipoproteins and cardiovascular risk.

FAMILIAL COMBINED HYPERLIPIDEMIA (FCHL) FCHL is one of the most common familial lipid disorders; it is estimated to occur in ~1 in 100–200 individuals. FCHL is characterized by elevations in plasma levels of TGs (VLDL) and LDL-C (including especially a small dense

form of LDL) and reduced plasma levels of HDL-C. This disorder is an important contributor to premature CHD; ~20% of patients who develop CHD under age 60 have FCHL. FCHL can manifest in childhood but is usually not fully expressed until adulthood. The disease clusters in families, and affected family members typically have one of three possible phenotypes: (1) elevated plasma levels of LDL-C, (2) elevated plasma levels of TGs due to elevation in VLDL, or (3) elevated plasma levels of both LDL-C and TG. The lipoprotein profile can switch among these three phenotypes in the same individual over time and may depend on factors such as diet, exercise, weight, and insulin sensitivity. Patients with FCHL have substantially elevated plasma levels of apoB, often disproportionately high relative to the plasma LDL-C concentration, indicating the presence of small dense LDL particles, which are characteristic of this syndrome.

Individuals with this phenotype generally share the same metabolic defect, namely overproduction of VLDL and apoB by the liver. The molecular etiology of this condition remains poorly understood, and no single gene has been identified in which mutations convincingly cause this disorder in a simple Mendelian fashion. It is likely that defects in a combination of genes can cause the condition, suggesting that a more appropriate term for the disorder might be *polygenic combined hyperlipidemia.*

The presence of a mixed dyslipidemia (plasma TG levels between 150 and 500 mg/dL and total cholesterol levels between 200 and 400 mg/dL, usually with HDL-C levels <40 mg/dL in men and <50 mg/dL in women) and a family history of mixed dyslipidemia and/or premature CHD suggests the diagnosis. Measurement of plasma apoB levels can help support the diagnosis if they are substantially elevated, particularly relative to the LDL-C level. Individuals with this disorder should be treated aggressively due to significantly increased risk of premature CHD, often disproportionate to the LDL-C level. Decreased dietary intake of simple carbohydrates, increased aerobic exercise, and weight loss can all have beneficial effects on the lipid profile. Patients with type 2 diabetes should be aggressively treated to maintain good glucose control. Virtually all patients with FCHL merit lipid-lowering drug therapy to reduce apoB-containing lipoprotein levels and lower the risk of ASCVD. High-intensity statins are first line, but many patients with FCHL require combination therapy that includes ezetimibe, a PCSK9 inhibitor, and/or bempedoic acid.

SECONDARY CONTRIBUTORS TO ELEVATED LEVELS OF APOB-CONTAINING LIPOPROTEINS

There are many "secondary" factors that contribute to dyslipidemia (Table 407-3), often acting in concert with polygenic predisposition as reviewed above. Some primarily affect TGs, some primarily affect LDL-C, and some influence both, with a great deal of variability. Here the major secondary contributors are reviewed.

Secondary Factors That Primarily Elevate TG Levels

• HIGH-CARBOHYDRATE DIET Dietary carbohydrates are utilized as a substrate for fatty acid synthesis in the liver. Some of the newly synthesized fatty acids are esterified, forming TGs, and secreted in VLDL. Thus, excessive intake of calories as carbohydrates, which is frequent in Western societies, leads to increased hepatic VLDL-TG secretion and elevated TG levels. Reduction in carbohydrate consumption can have a substantial effect in reducing TG levels, although replacing carbohydrates with saturated fat can elevate LDL-C levels.

OBESITY, INSULIN RESISTANCE, AND TYPE 2 DIABETES (See also Chaps. 401–403) Obesity, insulin resistance, and type 2 diabetes mellitus are the most frequent contributors to dyslipidemia, primarily by influencing TGs. The increase in adipocyte mass and accompanying decreased insulin sensitivity associated with obesity have multiple effects on lipid metabolism, with one of the major effects being excessive hepatic VLDL production. More free fatty acids are delivered from the expanded and insulin-resistant adipose tissue to the liver, where they are reesterified in hepatocytes to form TGs, which are packaged into VLDLs for secretion into the circulation. In addition, the increased insulin levels promote increased fatty acid synthesis in the liver. In insulin-resistant patients who progress to type 2 diabetes mellitus, dyslipidemia remains common, even when the patient is under relatively good glycemic control. In addition to increased VLDL production, insulin resistance can also result in decreased LPL activity, resulting in reduced catabolism of chylomicrons and VLDLs and more severe HTG. This may be due in part to the effects of tissue insulin resistance leading to reduced transcription of LPL in skeletal muscle and adipose, as well as to increased production of the LPL inhibitor apoC-III by the liver. This reduction in LPL activity often exacerbates the effects of increased VLDL production and contributes to the dyslipidemia seen in these patients. The dyslipidemia in this setting is almost invariable associated with low HDL-C levels as well. A cluster of metabolic risk factors are often found together, including obesity, insulin resistance, hypertension, high TGs, and low HDL-C (the so-called "metabolic syndrome," Chap. 408).

ALCOHOL CONSUMPTION Excessive alcohol consumption inhibits hepatic oxidation of free fatty acids, thus promoting hepatic TG synthesis and VLDL secretion and leading to increased plasma TG levels. Regular alcohol use also raises plasma levels of HDL-C and should be considered in patients with the relatively unusual combination of elevated TGs and normal or elevated HDL-C. A careful history of alcohol use should be taken in patients with elevated TGs. Reduction in alcohol consumption can often have a substantial effect in reducing TG levels.

CHRONIC KIDNEY DISEASE (See also Chap. 311) Chronic kidney disease (CKD) is often associated with mild HTG (150–400 mg/dL) due to the accumulation of VLDLs and remnant lipoproteins in the circulation. TG lipolysis and remnant clearance are both reduced in patients with renal failure. Because the risk of ASCVD is increased in CKD, patients should usually be treated with lipid-lowering agents, particularly statins.

ESTROGEN AND OTHER DRUGS Many drugs have an impact on lipid metabolism and can result in significant alterations in the lipoprotein profile (Table 407-3). Estrogens often elevate TG levels, and TG levels can also increase during pregnancy. In women with HTG, plasma TG levels should be monitored when birth control pills or postmenopausal estrogen therapy is initiated and during pregnancy. Use of low-dose preparations of estrogen or the estrogen patch can minimize the effect of exogenous estrogen on lipids. Isotretinoin therapy for acne can cause substantial elevations in TGs, and TG levels should be checked at baseline and after initiation of therapy. Bexarotene therapy for cutaneous T-cell lymphoma often causes substantial increases in TGs, and patients should be monitored accordingly.

Secondary Factors That Elevate LDL-C Levels

• DIET HIGH IN SATURATED AND TRANS FATS Dietary saturated and trans fats act to downregulate LDL receptor expression in the liver, leading to elevation in LDL-C levels and increased ASCVD risk. A careful dietary history should be taken in individuals with elevated LDL-C with a focus on sources of saturated and trans fats. Reduction in consumption of saturated and trans fats can sometimes have a substantial effect in reducing LDL-C levels and is a cornerstone of the initial nonpharmacologic management of hypercholesterolemia.

HYPOTHYROIDISM (See also Chap. 382) Hypothyroidism is the most important secondary factor causing elevated LDL-C levels. It causes elevated plasma LDL-C levels due to downregulation of the hepatic LDL receptor, which is normally increased by the action of thyroid hormone. Because hypothyroidism is often subtle and therefore easily overlooked, all patients presenting with elevated plasma levels of LDL-C, especially if there has been an unexplained increase in LDL-C, should be screened for hypothyroidism by measuring thyroid-stimulating hormone (TSH). Thyroid replacement therapy usually reduces LDL-C levels; if not, the patient probably has a primary lipoprotein disorder and may require lipid-lowering drug therapy with a statin.

LIVER DISORDERS (See also Chap. 336) Cholestasis is almost invariably associated with hypercholesterolemia due to elevated LDL-C levels and sometimes particles called Lp-X. A major pathway by which cholesterol is excreted from the body is via secretion into bile, either directly or after conversion to bile acids, and cholestasis blocks this

critical excretory pathway. The increase in hepatocellular cholesterol results in downregulation of the LDL receptor, leading to increased plasma LDL-C levels. In severe cholestasis, excess free cholesterol, coupled with phospholipids, is shed into the plasma as a constituent of a lamellar particle called Lp-X. These unusual particles, which are not lipoproteins, lack apoB, and have an aqueous and not neutral lipid core, are rich in free cholesterol, and can deposit in the skin, producing xanthomas sometimes seen in patients with cholestasis. Some liver disorders can affect plasma lipid levels in other ways. Viral hepatitis can increase TGs, and liver failure can result in reduction in plasma cholesterol and TGs.

NEPHROTIC SYNDROME (See also Chap. 311) Nephrotic syndrome is a classic cause of excessive VLDL production leading to elevation in both TGs and LDL-C. The molecular mechanism of VLDL overproduction remains poorly understood but has been attributed to the effects of hypoalbuminemia leading to increased hepatic protein synthesis. Effective treatment of the underlying renal disease may normalize the lipid profile, but many patients with chronic nephrotic syndrome require lipid-lowering drug therapy with statins and sometimes additional drugs.

CUSHING'S SYNDROME (See also Chap. 386) Endogenous glucocorticoid excess in Cushing's syndrome is associated with increased VLDL synthesis and secretion leading to dyslipidemia characterized by HTG and elevated LDL-C. Treatment of the underlying cause is often sufficient to manage the dyslipidemia, but sometimes lipid-lowering drug therapy is needed.

IMMUNOSUPPRESSIVE THERAPY AND CORTICOSTEROIDS Several of the immunosuppressants used after solid organ transplantation, including cyclosporin and sirolimus, can cause substantial elevation in LDL-C and TG levels. These patients can present a difficult clinical management problem. Chronic corticosteroid use, whether after transplant or in other inflammatory conditions, can also result in elevations in LDL-C and TG levels, sometimes producing a substantial mixed dyslipidemia. When the immunosuppressant or steroid must be continued, which is often the case, drug therapy with statins may be indicated in certain patients, with careful attention to the potential for untoward muscle-related side effects.

DISORDERS ASSOCIATED WITH REDUCED APOB-CONTAINING LIPOPROTEINS

Plasma concentrations of LDL-C <60 mg/dL are unusual. Although in some cases, LDL-C levels in this range may be reflective of malnutrition or serious chronic illness, LDL-C <60 mg/dL in an otherwise healthy individual suggests an inherited condition. The major inherited causes of low LDL-C are reviewed here and listed in Table 407-2.

Abetalipoproteinemia The synthesis and secretion of apoB-containing lipoproteins in the enterocytes of the proximal small bowel and in the hepatocytes of the liver involve a complex series of events that coordinate the coupling of various lipids with apoB-48 and apoB-100, respectively. Abetalipoproteinemia is a rare autosomal recessive disease caused by loss-of-function mutations in the gene encoding microsomal TG transfer protein (MTP; gene name *MTTP*), a protein that transfers lipids to nascent chylomicrons and VLDLs in the intestine and liver, respectively. Plasma levels of cholesterol and TG are extremely low in this disorder, and chylomicrons, VLDLs, LDLs, and apoB are undetectable in plasma. The parents of patients with abetalipoproteinemia (obligate heterozygotes) have normal plasma lipid and apoB levels. Abetalipoproteinemia usually presents in early childhood with diarrhea and failure to thrive due to fat malabsorption. The initial neurologic manifestations are loss of deep tendon reflexes, followed by decreased distal lower extremity vibratory and proprioceptive sense, dysmetria, ataxia, and the development of a spastic gait, often by the third or fourth decade. Patients with abetalipoproteinemia also develop a progressive pigmented retinopathy presenting with decreased night and color vision, followed by reductions in daytime visual acuity and ultimately progressing to near-blindness. The presence of spinocerebellar degeneration and pigmented retinopathy in this disease has resulted in some patients with abetalipoproteinemia being misdiagnosed as having Friedreich's ataxia.

Most of the clinical manifestations of abetalipoproteinemia result from defects in the absorption and transport of fat-soluble vitamins. Vitamin E and retinyl esters are normally transported from enterocytes to the liver by chylomicrons, and vitamin E is dependent on VLDL for transport out of the liver and into the circulation. As a consequence of the inability of these patients to secrete apoB-containing particles, patients with abetalipoproteinemia are markedly deficient in vitamin E and are also mildly to moderately deficient in vitamins A and K. Patients with abetalipoproteinemia should be referred to specialized centers for confirmation of the diagnosis and appropriate therapy. Treatment consists of a low-fat, high-caloric, vitamin-enriched diet accompanied by large supplemental doses of vitamin E. It is imperative that treatment be initiated as soon as possible to prevent development of neurologic sequelae, which can progress even with high-dose vitamin E therapy. New therapies for this serious, albeit rare, disease are needed. The discovery that genetic loss of MTP causes absent LDL-C led to the development of an MTP inhibitor to treat homozygous FH (see below).

Familial Hypobetalipoproteinemia (FHBL) FHBL generally refers to a condition of low total cholesterol, LDL-C, and apoB due to mutations in the *APOB* gene. Most of the mutations causing FHBL result in a truncated apoB protein, resulting in impaired assembly and secretion of chylomicrons from enterocytes and VLDL from the liver. Any secreted VLDL particles containing a truncated apoB protein are cleared from the circulation at an accelerated rate, which also contributes to the low levels of LDL-C and apoB. Individuals heterozygous for these mutations usually have LDL-C levels <60–80 mg/dL and also tend to have low levels of plasma TG. Many FHBL patients have elevated levels of hepatic fat (due to reduced VLDL export) and sometimes have increased levels of liver transaminases, although it appears that these patients infrequently develop associated hepatic inflammation and fibrosis.

Truncating mutations in both apoB alleles cause homozygous FHBL, an extremely rare disorder resembling abetalipoproteinemia with nearly undetectable LDL-C and apoB. The neurologic defects in homozygous hypobetalipoproteinemia are similar to those seen in abetalipoproteinemia, but tend to be less severe. Homozygous hypobetalipoproteinemia can be distinguished from abetalipoproteinemia by examining the inheritance pattern of the plasma LDL-C level. The levels of LDL-C and apoB are normal in the parents of patients with abetalipoproteinemia, a classic recessive condition, and low in those of patients with homozygous hypobetalipoproteinemia, a co-dominant condition. The discovery that truncating mutations in apoB reduce LDL-C led to the development of an antisense oligonucleotide to treat HoFH (see below).

Familial PCSK9 Deficiency Another inherited cause of low LDL-C results from loss-of-function mutations in *PCSK9*. PCSK9 is a secreted protein that binds to the extracellular domain of the LDL receptor in the liver and promotes the degradation of the receptor. Heterozygosity for nonsense mutations in *PCSK9* that interfere with the synthesis of the protein are associated with increased hepatic LDL receptor activity and reduced plasma levels of LDL-C. Such mutations are more frequent in individuals of African descent. Individuals who are heterozygous for a loss-of-function mutation in *PCSK9* have an ~30–40% reduction in plasma levels of LDL-C and have a substantial protection from CHD relative to those without a *PCSK9* mutation, presumably due to having lower plasma cholesterol levels since birth. Homozygotes for these nonsense mutations have been reported and have extremely low LDL-C levels (<20 mg/dL) but appear otherwise healthy. A sequence variation of somewhat higher frequency (R46L) is found predominantly in individuals of European descent. This mutation impairs, but does not completely destroy, PCSK9 function. As a consequence, the plasma levels of LDL-C in individuals carrying this mutation are more modestly reduced (~15–20%); individuals with these mutations have a 45% reduction in CHD risk. The discovery of this condition led to the development of therapies that antagonize or silence PCSK9, thus reducing LDL-C levels and risk of CHD (see below).

Familial Combined Hypolipidemia Nonsense mutations in both alleles of the gene angiopoietin-like 3 (*ANGPTL3*) lead to low plasma levels of all three major lipid fractions—TG, LDL-C, and HDL-C—a phenotype termed *familial combined hypolipidemia*. ANGPTL3 is a protein synthesized by the liver and secreted into the bloodstream. It inhibits LPL, thus delaying clearance of TRLs from the blood and increasing TRL blood concentrations. Deficiency of ANGPTL3, therefore, raises LPL activity and lowers blood TG; it also lowers LDL-C and raises HDL-C levels apparently related to the effects of ANGPTL3 on endothelial lipase. ANGPTL3 deficiency is associated with a reduced risk for CHD. The discovery of this condition led to the development of therapies that antagonize or silence ANGPTL3 to reduce LDL-C and TG levels (see below).

DISORDERS ASSOCIATED WITH REDUCED HIGH-DENSITY LIPOPROTEINS

Low levels of HDL-C, generally defined as <50 mg/dL in women and <40 mg/dL in men, are very common in clinical practice. Low HDL-C is an important independent predictor of increased cardiovascular risk and has been used regularly in standardized risk calculators. As an independent risk factor, it has clinical value in the assessment of cardiovascular risk, and a patient with low HDL-C should generally be considered at higher risk of ASCVD. However, it is now considered doubtful that low HDL-C is directly *causal* for the development of ASCVD. Thus, while HDL-C remains an important biomarker for assessing cardiovascular risk, it is not considered a particularly attractive target for therapeutic intervention to raise HDL-C levels in order to reduce cardiovascular risk. HDL-targeted therapies that, remain in clinical development include a CETP inhibitor and an intravenous infusion of a lipidated apoA-I particle.

HDL metabolism is strongly influenced by TG metabolism, insulin resistance, and inflammation, among other environmental and medical factors. Thus, the HDL-C measurement integrates a number of cardiovascular risk factors, potentially explaining its strong inverse association with ASCVD. The majority of patients with low HDL-C have some combination of genetic predisposition and secondary factors. Variants in hundreds of genes have been shown to influence HDL-C levels. Even more important quantitatively, obesity and insulin resistance have strong suppressive effects on HDL-C, and low HDL-C in these conditions is widely observed. Furthermore, the vast majority of patients with elevated TGs have reduced levels of HDL-C due to the substantial interplay between the metabolism of TRLs and HDL (see above). Most patients with low HDL-C who have been studied in detail have accelerated catabolism of HDL and its associated apoA-I protein as the physiologic basis for the low HDL-C. Single-gene Mendelian disorders that reduce HDL-C activity have been described (Table 407-2) but are rare; the vast majority of patients with low HDL-C have a polygenic predisposition with secondary factors like obesity, insulin resistance, or HTG.

PRIMARY (GENETIC) CAUSES OF LOW HDL-C

Mutations in three key genes encoding proteins that play critical roles in HDL synthesis and catabolism result in hypoalphalipoproteinemia (primary low levels of HDL-C). Unlike the genetic forms of hypercholesterolemia, which are invariably associated with premature coronary atherosclerosis, genetic forms of hypoalphalipoproteinemia are usually not associated with clearly increased risk of ASCVD. Nevertheless, in the clinical setting of an HDL-C level <20 mg/dL without accompanying severe HTG, these rare conditions should be considered.

Gene Deletions and Missense Mutations in *APOA1* Complete genetic deficiency of apoA-I due to a complete deletion of the *APOA1* gene results in the virtual absence of circulating HDL, proving the critical role of apoA-I in HDL biogenesis. The *APOA1* gene is part of a gene cluster on chromosome 11 that includes *APOA5*, *APOC3*, and *APOA4*. Some patients with no apoA-I have large genomic deletions that include other genes in the cluster. The rare patient lacking apoA-I can have cholesterol deposits in the cornea and in the skin, and in contrast to the other genetic disorders of low HDL-C, premature CHD has been reported. Heterozygotes for apoA-I deletions have reduced HDL-C levels but no obvious clinical sequelae.

More common, but still rare, are heterozygous missense mutations in the *APOA1* gene associated with low plasma levels of HDL-C. The first example reported, and still the best known, is an Arg173Cys substitution in apoA-I (so-called apoA-I_{Milano}), found in multiple residents of a town in northern Italy. Heterozygotes for this mutation have very low plasma levels of HDL-C (<25 mg/dL) due to impaired LCAT activation and accelerated clearance of the HDL particles containing the abnormal apoA-I. Despite having very low plasma levels of HDL-C, these individuals do not appear have an increased risk of premature CHD (neither are they protected against CHD as was initially believed). Multiple other rare *APOA1* missense mutations causing low HDL-C have been reported. A few of these mutations in *APOA1* (as well as some mutations in *APOA2*) promote the formation of amyloid fibrils, causing systemic amyloidosis.

Tangier Disease (*ABCA1* Deficiency) Tangier disease is a rare autosomal co-dominant form of extremely low plasma HDL-C levels that is caused by mutations in the *ABCA1* gene encoding ABCA1, a cellular transporter that facilitates efflux of unesterified cholesterol and phospholipids from cells to apoA-I as an acceptor (Fig. 407-3). Through transporting cellular lipids, ABCA1 in the hepatocytes and intestinal enterocytes promotes the extracellular lipidation of the apoA-I secreted from the basolateral membranes of these tissues. In the genetic absence of ABCA1, the nascent, poorly lipidated apoA-I is rapidly cleared from the circulation. Thus, patients with Tangier disease (both *ABCA1* alleles mutated) have extremely low circulating plasma levels of HDL-C (<5 mg/dL) and apoA-I (<5 mg/dL). Cholesterol accumulates in the reticuloendothelial system of these patients, resulting in hepatosplenomegaly and pathognomonic enlarged, grayish yellow or orange tonsils. An intermittent peripheral neuropathy (mononeuritis multiplex) or a sphingomyelia-like neurologic disorder can also be seen in this disorder. Tangier disease may be associated with some increased risk of ASCVD, although the association is not as robust as might have been anticipated, given the extremely low levels of HDL-C in these patients. Patients with Tangier disease also have low plasma levels of LDL-C, which may attenuate the atherosclerotic risk. Heterozygotes for *ABCA1* mutations have moderately reduced plasma HDL-C levels (~15–40 mg/dL), and the effect on risk of ASCVD remains uncertain.

Familial LCAT Deficiency This rare autosomal recessive disorder is caused by mutations in LCAT, an enzyme synthesized in the liver and secreted into the plasma, where it circulates associated with lipoproteins (Fig. 407-3). As reviewed above, the enzyme is activated by apoA-I and mediates the esterification of cholesterol to form CEs. Consequently, in familial LCAT deficiency, the proportion of free cholesterol in circulating lipoproteins is greatly increased (from ~25% to >70% of total plasma cholesterol). Deficiency in this enzyme interferes with the maturation of HDL particles and results in rapid catabolism of circulating apoA-I.

Two genetic forms of familial LCAT deficiency have been described in humans: complete deficiency (also called *classic LCAT deficiency*) and partial deficiency (also called *fish eye disease*). Progressive corneal opacification due to the deposition of free cholesterol in the cornea, very low plasma levels of HDL-C (usually <10 mg/dL), and variable HTG are characteristic of both disorders. In partial LCAT deficiency, there are no other known clinical sequelae. In contrast, patients with complete LCAT deficiency have hemolytic anemia and progressive renal insufficiency that eventually leads to end-stage renal disease. Remarkably, despite the extremely low plasma levels of HDL-C and apoA-I, premature ASCVD is not a consistent feature of either LCAT deficiency or fish eye disease. The diagnosis can be confirmed in a specialized laboratory by assaying plasma LCAT activity or by sequencing the *LCAT* gene.

Primary Hypoalphalipoproteinemia Primary hypoalphalipoproteinemia is defined as a plasma HDL-C level below the tenth percentile in the setting of relatively normal cholesterol and TG levels, no apparent secondary causes of low plasma HDL-C, and no clinical signs of LCAT deficiency or Tangier disease. This syndrome is often referred

to as *isolated low HDL*. A family history of low HDL-C suggests an inherited condition and may trigger an evaluation of one of the Mendelian causes of hypoalphalipoproteinemia. However, most patients with isolated low HDL do not have an identifiable single-gene disorder and likely have a polygenic etiology, possibly exacerbated by a secondary factor. The physiologic defect appears to be accelerated catabolism of HDL and its apolipoproteins. Several kindreds with primary hypoalphalipoproteinemia and an increased incidence of premature CHD have been described, although it is not clear if the low HDL-C level is the cause of the accelerated atherosclerosis in these families.

SECONDARY FACTORS THAT REDUCE HDL-C LEVELS

Hypertriglyceridemia Low HDL-C is very commonly found in association with elevated TG levels. The lipolysis of TRLs generates lipids that transfer to HDL, and therefore, any impairment of lipolysis (the most common cause of elevated TGs) leads to reduced HDL biosynthesis. In settings of elevated TGs, where the HDL-C is not reduced, alternative explanations (e.g., FDBL, alcohol, estrogens) should be considered. Conversely, an isolated low HDL-C in the presence of normal TGs should prompt consideration of a primary genetic etiology (as above) or specific secondary factors (see below).

Very-Low-Fat Diet Dietary fat is positively associated with HDL-C levels. Individuals who eat very-low-fat vegan diets or who have anorexia or severe fat malabsorption often have low levels of HDL-C that are secondary to low dietary fat. In this setting, LDL-C levels are also usually low as well. There is no known harm to low HDL-C levels in this setting and no indication for liberalizing the diet solely for the purpose of raising the HDL-C.

Sedentary Lifestyle and Obesity Physical activity is known to have a (generally modest) effect in raising HDL-C levels, and conversely, a sedentary lifestyle is often associated with low HDL-C levels. Concordant with that observation, obesity is frequently associated with low HDL-C levels even when overt insulin resistance or HTG is not present. Increased physical activity and weight loss usually have some effect in raising HDL-C, which is not the primary reason for recommending these interventions but can have a motivating influence on the patient.

ANABOLIC STEROIDS AND TESTOSTERONE Anabolic steroids have a well-established effect on lowering HDL-C levels, sometimes quite dramatically. Testosterone supplementation can also reduce HDL-C levels, although not to the degree caused by anabolic steroids. In a young male patient who presents with unexplained very low HDL-C, a careful history of medication and supplement use should be taken.

APPROACH TO THE PATIENT

Lipoprotein Disorders

The major goals in the diagnosis and clinical management of lipoprotein disorders are (1) prevention of acute pancreatitis in patients with severe HTG and (2) prevention of CVD and related cardiovascular events. Given the high prevalence of dyslipidemia and the proven clinical benefits of early diagnosis and initiation of therapy, it is essential that physicians screen lipids systematically, rule out secondary causes of dyslipidemia, suspect inherited disorders of lipoprotein metabolism where appropriate, actively promote family-based cascade screening, carefully assess risk for ASCVD and consider additional risk stratification approaches, and be knowledgeable about the wide range of existing therapeutic options for dyslipidemia. The field of clinical lipidology has matured and is moving toward a more systematic clinical application of genomic medicine. Diagnostic DNA sequencing or genotyping in patients with suspected FCS, FPLD, FH, and FDBL has the potential to enhance molecular diagnosis, facilitate appropriate therapeutic interventions, and promote family-based cascade screening.

DIAGNOSIS

A critical first step in managing a lipoprotein disorder is to attempt to determine the class or classes of lipoproteins that are increased or decreased in the patient. Once the dyslipidemia is accurately classified, efforts should be directed to identify or rule out any possible secondary causes (Table 407-3). A careful social, medical, and family history should be obtained. In patients with elevated TG levels (>150 mg/dL), a fasting glucose and/or hemoglobin A_{1c} should be obtained to rule out diabetes. In patients with elevated LDL-C levels (>160 mg/dL), a TSH should be obtained to rule out hypothyroidism and consideration should be given to the possibility of liver or kidney disease. Once secondary causes have been ruled out, attempts should be made to diagnose a primary lipid disorder, because the underlying genetic defect can provide important prognostic information regarding the risk of pancreatitis in severe HTG and the risk of ASCVD in other dyslipidemias, as well as impact on the choice of drug therapy and the screening of other family members. Obtaining the correct diagnosis often requires a detailed family history, lipid analyses in family members, and sometimes specialized or genetic testing.

Severe Hypertriglyceridemia If the fasting plasma TG level is >500 mg/dL, the patient has severe HTG and may be at risk for pancreatitis. If the TG levels are persistently severely elevated, especially if they are >1000 mg/dL, and the total cholesterol-to-TG ratio is >8, FCS should be considered, and genetic testing of an FCS gene panel may be indicated (Table 407-2). If central obesity, insulin resistance, and/or fatty liver disease are also present, consideration should be given to the possibility of FPLD, and an FPLD gene panel may be indicated (Table 407-2). However, most individuals with severe HTG do not have a single-gene disorder but have increased polygenic risk for high TGs often exacerbated by secondary factors (diet, alcohol, obesity, insulin resistance, medications). Such patients are still at risk for acute pancreatitis and should be treated to reduce their TG levels and thus their risk of pancreatitis (see below).

Hypercholesterolemia If the LDL-C levels are >190 mg/dL, the patient has severe hypercholesterolemia and is at risk for premature ASCVD. In absence of secondary causes, FH should be considered, particularly if there is a family history of hypercholesterolemia and/or premature CHD, and genetic testing of an FH gene panel may be indicated (Table 407-2). While FH is a clinical diagnosis, a finding of a causal mutation may appropriately result in earlier and more aggressive therapy to lower LDL-C and should also promote family-based cascade screening as per the Centers for Disease Control and Prevention guidelines labeling FH as a Tier 1 condition. Recessive forms of severe hypercholesterolemia are rare, but if a patient with severe hypercholesterolemia has parents with normal cholesterol levels, ARH, sitosterolemia, and LALD should be considered, and genetic testing may be indicated (Table 407-2). Patients without an identified genetic variant or who have more moderate hypercholesterolemia are likely to have polygenic hypercholesterolemia but should still be considered at risk and eligible for treatment (see below).

Mixed Hyperlipidemia Elevations in fasting plasma levels of both TGs (>150 mg/dL) and LDL-C (>130 mg/dL), often accompanied by reduced levels of HDL-C (<40 mg/dL in men and <50 mg/dL in women), are common, and such patients are often diagnosed as having "mixed hyperlipidemia." Most such patients are at increased risk of ASCVD and merit consideration of lifestyle and/or pharmacologic interventions. Secondary factors, particularly obesity, insulin resistance, and type 2 diabetes, are common in such patients, who often also have increased polygenic risk for dyslipidemia. The presence of palmar or tuberous xanthomas or an unusual lipid profile of total cholesterol and TG levels in the same range with an HDL-C that is not reduced should prompt consideration of FDBL, or type III hyperlipidemia, and can be diagnosed by a nuclear magnetic

resonance (NMR) lipoprotein profile or genetic testing for the *APOE2* genotype. FDBL patients should be managed aggressively due to substantially increased risk of ASCVD. More commonly, patients with mixed hyperlipidemia, particularly those with family histories of dyslipidemia or premature ASCVD, have familial combined hyperlipidemia (FCHL). ApoB should be measured in such patients, and the finding of substantially elevated apoB levels can help identify patients with FCHL, who are at especially increased risk of ASCVD and require more aggressive treatment.

TREATMENT

Severe Hypertriglyceridemia

There is a well-established observational relationship between severe HTG, particularly chylomicronemia, and acute pancreatitis; however, there has never been a clinical trial designed or powered to definitively prove that intervention to reduce TGs reduces the risk of pancreatitis. Nevertheless, it is generally considered appropriate medical practice to intervene in patients with TGs >500 mg/dL in order to reduce the risk of pancreatitis. It remains uncertain whether chylomicronemia increases risk for ASCVD per se. Importantly, moderate HTG (TG 150–500 mg/dL) is associated with increased ASCVD risk; management of these patients is focused on reducing risk of ASCVD and on reducing LDL-C, non-HDL-C, and apoB.

LIFESTYLE AND MODIFIABLE FACTORS

In patients with severe HTG, lifestyle modification can be associated with a significant reduction in plasma TG level. Patients who drink alcohol should be encouraged to decrease or preferably eliminate their intake. Patients with severe HTG often benefit from a formal dietary consultation with a dietician intimately familiar with counseling patients on the dietary management of high TGs. Dietary fat intake should be restricted to reduce the formation of chylomicrons in the intestine. The excessive intake of simple carbohydrates should be discouraged because insulin drives TG production in the liver. Aerobic exercise and even increase in regular physical activity can have a positive effect in reducing TG levels and should be strongly encouraged. For patients who are overweight, weight loss can help to reduce TG levels. In extreme cases, bariatric surgery has been shown to not only produce effective weight loss but also substantially reduce plasma TG levels. Many patients with diabetes have HTG, and better control of diabetes can result in lowering of TGs. Finally, certain medications can exacerbate HTG (Table 407-3).

PHARMACOLOGIC THERAPY

Despite lifestyle interventions, many patients with severe HTG require pharmacologic therapy (Table 407-4). Patients who persist in having fasting TG >500 mg/dL despite active lifestyle management are candidates for pharmacologic therapy. The two major classes of drugs used for management of these patients are fibrates and omega-3 fatty acids (fish oils). In addition, statins can reduce plasma TG levels and also reduce ASCVD risk and should be used in patients with severe HTG who are at increased risk of ASCVD.

Fibrates Fibric acid derivatives, or fibrates, are agonists of PPARα, a nuclear receptor involved in the regulation of lipid metabolism. Fibrates stimulate LPL activity (enhancing TG hydrolysis), reduce apoC-III synthesis (enhancing lipoprotein remnant clearance), promote β-oxidation of fatty acids, and may reduce VLDL TG production. Fibrates reduce TG levels by ~30% in individuals with severe HTG and are often used as first-line therapy. They sometimes modestly raise LDL-C levels. Fibrates are generally well tolerated but can cause myopathy, especially when combined with statins, can raise creatinine, and are associated with an increase in gallstones. Fibrates can potentiate the effect of warfarin and certain oral hypoglycemic agents.

Omega-3 Fatty Acids (Fish Oils) Omega-3 fatty acids, or omega-3 polyunsaturated fatty acids (n-3 PUFAs), commonly known as fish oils, are present in high concentration in fish and in flaxseed. The n-3 PUFAs used for the treatment of HTG are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). n-3 PUFAs have been concentrated into capsules and in doses of 3–4 g/d are effective at lowering fasting TG levels by ~30%. Fish oils can cause an increase in plasma LDL-C levels in some patients. Icosapent ethyl is an EPA-only product that has been shown to reduce cardiovascular events in patients with HTG. In general, fish oils are well tolerated, with the major side effect being dyspepsia. They appear to be safe, at least at doses up to 3–4 g, but can be associated with a prolongation in the bleeding time. Fish oils can be first-line therapy for the treatment of severe HTG or can be used in combination with fibrates.

APOC3 Silencing ApoC-III inhibits LPL and TRL uptake, and genetic variants in the *APOC3* gene reduce TG levels and risk of ASCVD. Volanesorsen is an antisense oligonucleotide targeted to the *APOC3* mRNA in the liver; it significantly reduces plasma apoC-III and TG levels and is approved in Europe for patients with FCS. It has been associated with severe thrombocytopenia. Additional therapeutic approaches to APOC3 and other targets for TG lowering are in development.

Hypercholesterolemia (Elevated LDL-C with or without Elevated TG)

There are abundant and compelling data that intervention to reduce LDL-C substantially reduces the risk of ASCVD, including myocardial infarction and stroke, as well as total mortality. Thus, it is imperative that patients with hypercholesterolemia be carefully assessed for cardiovascular risk and need for intervention. It is also worth emphasizing that patients with or at high risk for ASCVD who have plasma LDL-C levels in the "normal" or average range also benefit from intervention to reduce LDL-C levels.

LIFESTYLE AND MODIFIABLE FACTORS

In patients with elevated LDL-C, lifestyle modifications can be effective but are often less effective than in HTG. Patients should receive dietary counseling to reduce the content of saturated fats and trans fats in the diet. Obese patients should make an effort to lose weight. Regular aerobic exercise has relatively little impact on reducing plasma LDL-C levels, although it has cardiovascular benefits independent of LDL-C lowering. Patients with hypothyroidism should be optimally controlled. Finally, certain medications can elevate LDL-C levels (Table 407-3).

PHARMACOLOGIC THERAPY

The decision to use LDL-lowering drug therapy (Table 407-4)—with a statin being first-line therapy—depends on the presence of ASCVD or, if absent, the level of LDL-C as well as the level of cardiovascular risk. In patients with established ASCVD, drug therapy to reduce LDL-C is well supported by clinical trial data to reduce LDL-C as long as it remains >70 mg/dL, using combination drug therapy if necessary. In the absence of ASCVD, patients with FH must be treated to reduce the very high lifetime risk of ASCVD, and treatment should be initiated as early as possible, ideally during childhood. Otherwise, the decision to initiate LDL-lowering drug therapy is generally determined by the level of cardiovascular risk. For patients >40 years old without clinical CVD, the AHA/ACC risk calculator can be used to determine the 10-year absolute risk for CVD, and current guidelines suggest that a 10-year risk >7.5% merits consideration of statin therapy regardless of plasma LDL-C level. For younger patients, the assessment of lifetime risk of CVD may help inform the decision to start a statin, as well as a careful assessment of family history of ASCVD. In patients for whom the decision to start a statin is uncertain due to borderline ASCVD risk and/or borderline LDL-C levels, additional risk stratification might be considered. Blood tests that predict ASCVD risk beyond

traditional risk factors include apoB, Lp(a), and high-sensitivity C-reactive protein (hs-CRP). In patients who are of a sufficient age (men >40 years and women >50 years), a coronary artery calcium (CAC) score has been shown to provide independent information about risk of CAD. Elevated levels of one or more of these biomarkers or an elevated CAC score might be used to justify initiation of statin therapy in primary prevention for patients who are in a borderline zone with regard to treatment. Finally, given the strong polygenic contribution to ASCVD, there is increasing interest in the concept that a polygenic risk score for CAD might eventually be of clinical utility in lifetime risk assessment and decision-making regarding statin therapy in primary prevention.

HMG-CoA Reductase Inhibitors (Statins) Statins inhibit HMG-CoA reductase, a key enzyme in cholesterol biosynthesis. By inhibiting cholesterol synthesis in the liver, statins lead to a counter-regulatory increase in the expression of the LDL receptor and thus accelerated clearance of circulating LDL, resulting in a dose-dependent reduction in plasma levels of LDL-C. The magnitude of LDL-C lowering associated with statin treatment (~30–55%) varies by statin and among individuals, but once a patient is on a statin, the doubling of the statin dose produces a ~6% further reduction in the level of plasma LDL-C. An extensive body of randomized clinical trials has clearly established that statin therapy significantly reduces major cardiovascular events (and in some cases total mortality) in both primary and secondary prevention settings. The seven statins currently available differ in their LDL-C–reducing potency (Table 407-4). Current recommendations are to use high-intensity statin therapy in patients with ASCVD or deemed at high risk of ASCVD. Statins also reduce plasma TGs in a dose-dependent fashion, which is roughly proportional to their LDL-C–lowering effects.

Statins, taken in tablet form once a day, are remarkably safe and well tolerated. The most important side effect associated with statin therapy is muscle pain, or myalgia, which occurs in 3–5% of patients, some of whom are unable to tolerate any statin. Severe myopathy (associated with an increase in plasma creatine kinase [CK]) and even rhabdomyolysis can occur rarely with statin treatment. The risk of statin-associated myalgia or myopathy is increased by the presence of older age, frailty, renal insufficiency, and coadministration of drugs that interfere with the metabolism of statins, such as erythromycin and related antibiotics, antifungal agents, immunosuppressive drugs, and fibric acid derivatives (particularly gemfibrozil). In the event of muscle symptoms, a plasma CK level may be obtained to differentiate myopathy from myalgia. Serum CK levels need not be monitored on a routine basis in patients taking statins because an elevated CK in the absence of symptoms does not predict the development of myopathy and does not necessarily suggest the need for discontinuing the drug. Statins can result in elevation in liver transaminases (alanine aminotransferase [ALT] and aspartate aminotransferase [AST]), but it is usually mild and transient and generally does not require discontinuation. Finally, meta-analyses of large randomized controlled clinical trials with statins indicate a slight excess in incident type 2 diabetes, an observation as yet not fully understood. However, the cardiovascular benefits associated with statin therapy far outweigh the slight increase in incident diabetes. Based on their safety and extensively documented benefit with regard to cardiovascular outcomes, statins are the clear drug class of choice for LDL-C reduction and are by far the most widely used class of lipid-lowering drugs.

Cholesterol Absorption Inhibitor Cholesterol within the lumen of the small intestine is derived from the diet (about one-third) and the bile (about two-thirds) and is actively absorbed by the enterocyte through a process that involves the protein NPC1L1. Ezetimibe (Table 407-4) is a cholesterol absorption inhibitor that binds directly to and inhibits NPC1L1 and blocks the intestinal absorption of cholesterol. Ezetimibe (10 mg taken once daily) inhibits cholesterol absorption by almost 60%, resulting in a reduction in delivery of dietary sterols in the liver and a compensatory increase in hepatic LDL receptor expression. The mean reduction in plasma LDL-C on ezetimibe (10 mg) is 18%, and the effect is additive when used in combination with a statin. Effects on TG and HDL-C levels are negligible. Ezetimibe added to a statin has been shown to significantly reduce major cardiovascular events compared with statin alone. It is generally considered the second-line option for adding to a statin in order to achieve further LDL-C reduction. Ezetimibe is very safe and well-tolerated. When used in combination with a statin, monitoring of liver transaminases is recommended. The only roles for ezetimibe in monotherapy are in patients who do not tolerate statins and in some patients with sitosterolemia.

PCSK9 Inhibitors Circulating PCSK9 targets the LDL receptor for lysosomal degradation, thus reducing its recycling and abundance at the surface of the hepatocyte. Genetic loss of function of *PCSK9* results in low levels of LDL-C and protection from CAD. Antibodies to PCSK9 (Table 407-4) sequester it and functionally increase the number of LDL receptors available to remove LDL from the blood. They are highly effective in lowering LDL-C, with an ~60% reduction in LDL-C. They also reduce plasma levels of Lp(a) modestly. Both PCSK9 antibodies have been shown to significantly reduce cardiovascular events when added to a statin in patients with existing CAD. These antibodies are administered subcutaneously every 2 weeks. They are generally well tolerated, with the major side effect being injection site reactions. They are generally indicated as second-line (added to statin) or third-line (added to statin plus ezetimibe) therapy in patients with FH or ASCVD in whom LDL-C is not reduced to acceptable levels with a statin (with or without ezetimibe) alone. An alternative approach to silencing *PCSK9*, inclisiran, is a therapeutic siRNA molecule that targets the *PCSK9* mRNA in the liver. In contrast to the antibodies, it is administered subcutaneously every 6 months. It is effective in reducing LDL-C by ~60% and appears to be well tolerated and safe; a cardiovascular outcomes trial is ongoing.

ATP Citrate Lyase Inhibitor Bempedoic acid is a first-in-class competitive inhibitor of ATP citrate lyase (ACL), which acts on mitochondrial-derived citrate to generate production of acetyl-CoA, which is subsequently used for cholesterol synthesis. Thus, it reduces cholesterol synthesis through a different mechanism than statins, ultimately upregulating the hepatic LDL receptor. In phase 3 trials, bempedoic acid 180 mg daily reduced LDL-C by ~18% when added to a statin and by ~23% as monotherapy. A cardiovascular outcomes trial is ongoing. Bempedoic acid is a prodrug that requires activation by very-long-chain acyl-CoA synthetase-1 (ASCVL1), which is not expressed in skeletal muscle, potentially explaining why it has less association with myalgias than statins; indeed, it has been shown to be relatively well tolerated in patients with statin intolerance. It is available in a fixed-dose combination with ezetimibe, which reduced LDL-C by ~36%, for patients who are statin intolerant. It can be used in combination with statins but should not be used with simvastatin in a dose >20 mg. Bempedoic acid is associated with increased uric acid levels and incidence of gout; it was also associated with increased incidence of tendon rupture in phase 3 trials. Unlike statins, it was not associated with increased incidence of diabetes.

Bile Acid Sequestrants (Resins) Bile acid sequestrants (BAS) bind bile acids in the intestine and promote their excretion rather than reabsorption in the ileum. To maintain the bile acid pool size, the liver diverts cholesterol to bile acid synthesis. The decreased hepatic intracellular cholesterol content results in upregulation of the LDL receptor and enhanced LDL clearance from the plasma. BAS, including cholestyramine, colestipol, and colesevelam (Table 407-4), primarily reduce plasma LDL-C levels but can cause an increase in plasma TGs. Therefore, patients with HTG generally should not be treated with bile acid–binding resins. Cholestyramine and colestipol are insoluble resins that must be suspended in liquids. Colesevelam is available as tablets but generally requires up to six to seven tablets per day for effective LDL-C lowering. BAS are effective

in combination with statins and in combination with ezetimibe. Side effects of resins are limited to the gastrointestinal tract and include bloating and constipation. Because BAS are not systemically absorbed, they are very safe and are the cholesterol-lowering drug of choice in children and in women who are pregnant, lactating, or actively trying to conceive. However, they are otherwise fourth- or fifth-line drugs for LDL-C reduction in other settings.

Specialized Drugs for HoFH Three "orphan" drugs are approved specifically for the management of HoFH, a rare condition caused by biallelic mutations in the major genes causing FH in which patients respond poorly to traditional LDL-lowering medications. Lomitapide is a small-molecule inhibitor of MTP that reduces LDL-C by ~50%, and mipomersen is an antisense oligonucleotide against apoB tgat reduces LDL-C by ~25%. Both of these drugs reduce hepatic VLDL production and thus LDL-C levels; however, due to their mechanism of action, each drug causes an increase in hepatic fat, the long-term consequences of which are unknown. In addition, lomitapide is associated with gastrointestinal-related side effects, and mipomersen is associated with skin reactions and flulike symptoms. Finally, an antibody inhibitor of ANGPTL3, evinacumab, was approved in 2021 for the treatment of HoFH. In a phase 3 trial, an intravenous infusion every 4 weeks reduced LDL-C levels in patients with HoFH by ~50% and was well tolerated. One of these three drugs should be considered in HoFH patients after a trial of a high-intensity statin, and possibly a PCSK9 inhibitor, is shown to be insufficient to reduce LDL-C levels.

LDL Apheresis Patients with severe hypercholesterolemia who cannot reduce their LDL-C to acceptable levels despite optimally tolerated combination drug therapy are candidates for LDL apheresis. In this process, the patient's plasma is passed over a column that selectively removes the LDL, and the LDL-depleted plasma is returned to the patient. LDL apheresis is indicated for patients on maximally tolerated combination drug therapy (including a PCSK9 inhibitor) who have CHD and a plasma LDL-C level >200 mg/dL or no CHD and a plasma LDL-C level >300 mg/dL; LDL apheresis could be considered in high-risk patients who have an LDL-C >160 mg/dL on maximal therapy.

408 The Metabolic Syndrome

Robert H. Eckel

The metabolic syndrome (syndrome X, insulin resistance syndrome) consists of a constellation of metabolic abnormalities that confer increased risk of cardiovascular disease (CVD) and diabetes mellitus. Evolution of the criteria for the metabolic syndrome since the original definition by the World Health Organization in 1998 reflects growing clinical evidence and analysis by a variety of consensus conferences and professional organizations. The major features of the metabolic syndrome include central obesity, hypertriglyceridemia, low levels of high-density lipoprotein (HDL) cholesterol, hyperglycemia, and hypertension **(Table 408-1)**.

GLOBAL HEALTH/EPIDEMIOLOGY

The most challenging feature of the metabolic syndrome to define is waist circumference. Intraabdominal circumference (visceral adipose tissue) is most strongly related to insulin resistance and risk of diabetes and CVD, and for any given waist circumference, the distribution of adipose tissue between subcutaneous (SC) and visceral depots varies substantially. Thus, within and between populations, there is a lesser versus greater risk at the same waist circumference. These differences in populations reflect the range of waist circumferences considered to confer risk in different geographic locations (Table 408-1).

The prevalence of the metabolic syndrome varies around the world, in part reflecting the age and ethnicity of the populations studied and the diagnostic criteria applied. In general, the prevalence of the metabolic syndrome increases with age. The prevalence of metabolic syndrome in the U.S. adult population meeting the criteria of the National Cholesterol Education Program (NCEP) and Adult Treatment Panel III (ATPIII) is ~35%. Greater global industrialization is associated with rising rates of obesity and expected increase in the prevalence of the metabolic syndrome, especially as the population ages. Moreover, the rising prevalence and severity of obesity among children reflect features of the metabolic syndrome in a younger population, now estimated to be 12 and 30% among obese and overweight children, respectively.

Using National Health and Nutrition Examination Survey (NHANES) data from 2012–2016, the prevalence of metabolic syndrome in the United States was 34.7% and not different between men (35.1%) and women (34.3%). The highest prevalence was in "other" race/ethnicity (39.0%) followed by Hispanic (36.3%) and non-Hispanic white (36.0%). Although increased from 32.5% in 2010–2012, the increase was not significant; however, the prevalence did increase significantly among those aged 20–39 years (from 16.2 to 21.3%) and in women (from 31.7 to 36.6%), Asian participants (from 19.9 to 26.2%), and Hispanic participants (from 32.9 to 40.4%). As in previous data, prevalence of metabolic syndrome increased with increasing age among all subgroups, i.e., from 19.5% among those aged 20–39 years to 48.6% among those aged ≥60 years.

The frequency distribution of the five components of the syndrome for the U.S. population (NHANES III) is summarized in **Fig. 408-1**. Increases in waist circumference predominate among women, whereas increases in fasting plasma triglyceride levels (i.e., >150 mg/dL), reductions in HDL cholesterol levels, and hyperglycemia are more likely in men.

RISK FACTORS

Overweight/Obesity The metabolic syndrome was first described in the early twentieth century; however, the worldwide overweight/obesity epidemic has recently been the force driving its increasing recognition. Central adiposity is a key feature of the syndrome, and the syndrome's prevalence reflects the strong relationship between waist circumference and increasing adiposity. However, despite the importance of obesity, patients who are of normal weight may also be

TABLE 408-1 NCEP:ATPIII[a] 2001 and Harmonizing Definition Criteria for the Metabolic Syndrome

NCEP:ATPIII 2001	HARMONIZING DEFINITION[b]		
Three or more of the following: • Central obesity: waist circumference >102 cm (males), >88 cm (females) • Hypertriglyceridemia: triglyceride level ≥150 mg/dL or specific medication • Low HDL[c] cholesterol: <40 mg/dL and <50 mg/dL for men and women, respectively, or specific medication • Hypertension: blood pressure ≥130 mmHg systolic or ≥85 mmHg diastolic or specific medication • Fasting plasma glucose level ≥100 mg/dL or specific medication or previously diagnosed type 2 diabetes	**Three of the following:** Waist circumference (cm)		
	Men	**Women**	**Ethnicity**
	≥94	≥80	Europid, sub-Saharan African, Eastern and Middle Eastern
	≥90	≥80	South Asian, Chinese, and ethnic South and Central American
	≥85	≥90	Japanese
	• Fasting triglyceride level >150 mg/dL or specific medication • HDL cholesterol level <40 mg/dL and <50 mg/dL for men and women, respectively, or specific medication • Blood pressure >130 mm systolic or >85 mm diastolic or previous diagnosis or specific medication • Fasting plasma glucose level ≥100 mg/dL (alternative indication: drug treatment of elevated glucose levels)		

[a]National Cholesterol Education Program and Adult Treatment Panel III. [b]In this analysis, the following thresholds for waist circumference were used: white men, ≥94 cm; African-American men, ≥94 cm; Mexican-American men, ≥90 cm; white women, ≥80 cm; African-American women, ≥80 cm; Mexican-American women, ≥80 cm. For participants whose designation was "other race—including multiracial," thresholds that were once based on Europid cutoffs (≥94 cm for men and ≥80 cm for women) and on South Asian cutoffs (≥90 cm for men and ≥80 cm for women) were used. For participants who were considered "other Hispanic," the International Diabetes Federation thresholds for ethnic South and Central Americans were used. [c]High-density lipoprotein.

insulin-resistant and may have the metabolic syndrome. This phenotype is particularly evident for populations in India, Southeast Asia, and Central America.

Sedentary Lifestyle Physical inactivity and less cardiorespiratory fitness are predictors of CVD events and the related risk of death. Many components of the metabolic syndrome are associated with a sedentary lifestyle, including increased adipose tissue (predominantly central), reduced HDL cholesterol, and increased triglycerides, blood pressure, and glucose in genetically susceptible persons. Compared with individuals who watch television or videos or use the computer <1 h daily, those who do so for >4 h daily have a twofold increased risk of the metabolic syndrome.

Genetics No single gene explains the complex phenotype called the metabolic syndrome. However, using genome-wide association and candidate gene approaches, several genetic variants are associated with the metabolic syndrome. Although many of the loci have unknown function, many others relate to body weight and composition, insulin resistance, and unfavorable disturbances in lipid and lipoprotein metabolism.

Aging The metabolic syndrome affects nearly 50% of the U.S. population aged >60, and at >60 years of age, women are more often affected. The age dependency of the syndrome's prevalence is seen in most populations around the world.

Diabetes Mellitus Diabetes mellitus can be included in both the NCEP and the harmonizing definitions of the metabolic syndrome, but the greatest value of the metabolic syndrome, and especially fasting glucose, is predicting type 2 diabetes. The great majority (~75%) of patients with type 2 diabetes or impaired glucose tolerance have the metabolic syndrome. The presence of the metabolic syndrome in these populations relates to a higher prevalence of CVD than in patients who have type 2 diabetes or impaired glucose tolerance but do not have the syndrome.

Cardiovascular Disease Individuals with the metabolic syndrome are twice as likely to die of CVD as those who do not, and their risk of an acute myocardial infarction or stroke is threefold higher. The approximate prevalence of the metabolic syndrome among patients with coronary heart disease (CHD) is 60%, with a prevalence of ~35% among patients with premature coronary artery disease (age ≤45) and a particularly high prevalence among women. With appropriate cardiac rehabilitation and changes in lifestyle (e.g., nutrition, physical activity, weight reduction, and—in some cases—pharmacologic therapy), the prevalence of the syndrome can be reduced.

Lipodystrophy Lipodystrophic disorders in general are associated with the metabolic syndrome. Moreover, it is quite common for such patients to present with the metabolic syndrome. Both genetic lipodystrophy (e.g., Berardinelli-Seip congenital lipodystrophy, Dunnigan familial partial lipodystrophy) and acquired lipodystrophy (e.g., HIV-related lipodystrophy and in HIV patients receiving certain antiretroviral therapies) may give rise to severe insulin resistance and many of the components of the metabolic syndrome.

ETIOLOGY

Insulin Resistance The most accepted and unifying hypothesis to describe the pathophysiology of the metabolic syndrome is insulin resistance, caused systemically by an incompletely understood defect in insulin action **(Chap. 403)**. The onset of insulin resistance is heralded by postprandial hyperinsulinemia, which is followed by fasting hyperinsulinemia and ultimately by hyperglycemia.

An early major contributor to the development of insulin resistance is an overabundance of circulating fatty acids **(Fig. 408-2)**. Plasma albumin-bound free fatty acids are derived predominantly from adipose-tissue triglyceride stores released by intracellular lipolytic enzymes. The lipolysis of triglyceride-rich lipoproteins in tissues by lipoprotein lipase also produces free fatty acids. Insulin mediates both anti-lipolysis and the stimulation of lipoprotein lipase in adipose tissue. Of note, the inhibition of lipolysis in adipose tissue is the most sensitive pathway of insulin action. Thus, when insulin resistance develops, increased lipolysis produces more fatty acids, which further decrease the anti-lipolytic effect of insulin. Excessive fatty acids enhance substrate availability and create insulin resistance by modifying downstream signaling. Fatty acids impair insulin-mediated glucose uptake and accumulate as triglycerides in both skeletal and cardiac muscle, whereas increased fatty acid flux increases glucose production and triglyceride production and accumulation in the liver.

Leptin resistance also may be a pathophysiologic mechanism to explain the metabolic syndrome. Physiologically, leptin reduces appetite, promotes energy expenditure, and enhances insulin sensitivity when insulin resistance is associated with leptin deficiency. In addition, leptin may regulate cardiac and vascular function through a nitric oxide–dependent mechanism. However, when obesity develops, hyperleptinemia ensues, with evidence of leptin resistance in the brain and other tissues resulting in inflammation, insulin resistance, hyperlipidemia, and a plethora of cardiovascular disorders, such as hypertension, atherosclerosis, CHD, and heart failure.

The oxidative stress hypothesis provides a unifying theory for aging and the predisposition to the metabolic syndrome. In studies of insulin-resistant individuals with obesity or type 2 diabetes, the offspring of patients with type 2 diabetes, and the elderly, a defect in mitochondrial oxidative phosphorylation leads to the accumulation of triglycerides and related lipid molecules in muscle, liver, and perhaps other tissues, i.e., β-cells.

Recently, the gut microbiome has emerged as an important contributor to the development of obesity and related metabolic disorders,

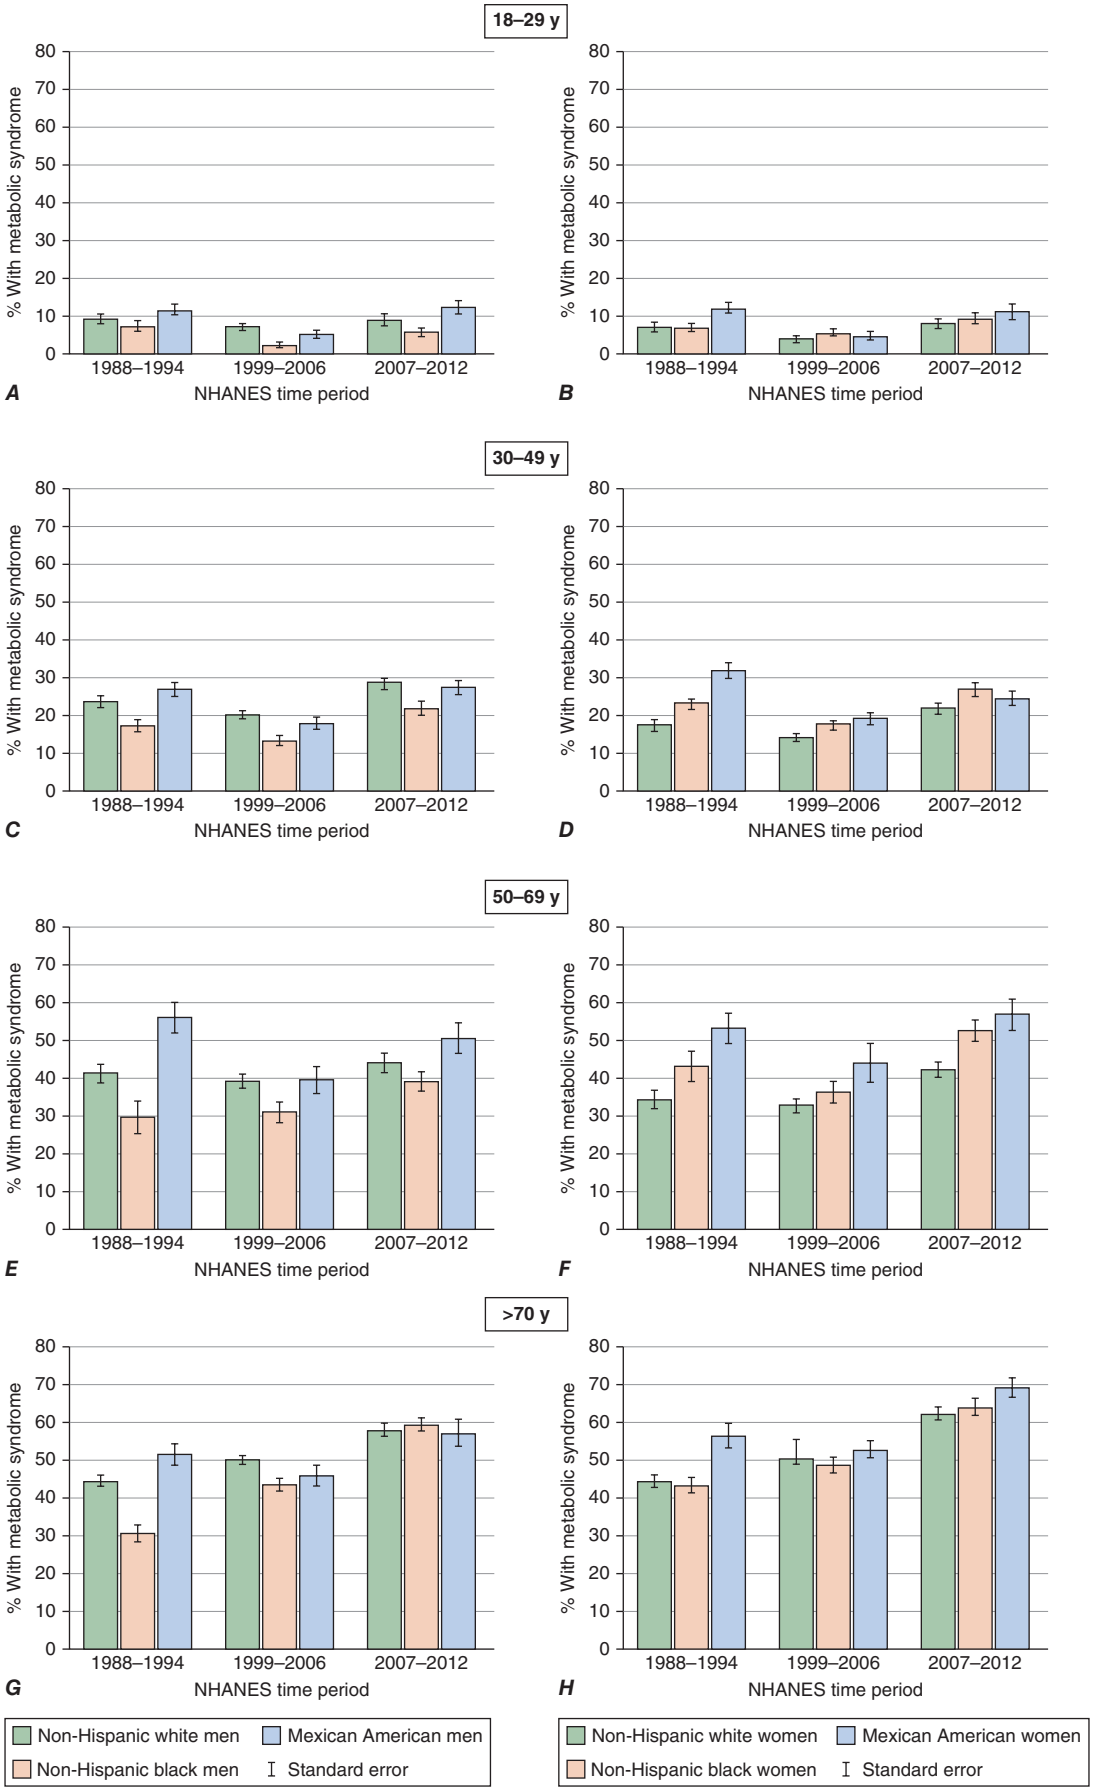

FIGURE 408-1 Prevalence of metabolic syndrome among US adults over time by race/ethnicity-sex and age group, National Health and Nutrition Examination Survey (NHANES), 1988-2012. Metabolic syndrome was defined by using the criteria agreed to jointly by the International Diabetes Federation; the US National Heart, Lung, and Blood Institute in the United States; American Heart Association; World Heart Federation; International Atherosclerosis Society; and International Association for the Study of Obesity SE, standard error. *(Reproduced with permission from JX Moore, N Chaudhary, T Akinyemiju. Metabolic syndrome prevalence by race/ethnicity and sex in the United States, National Health and Nutrition Examination Survey, 1988-2012. Prev Chronic Dis 14:E24, 2017.)*

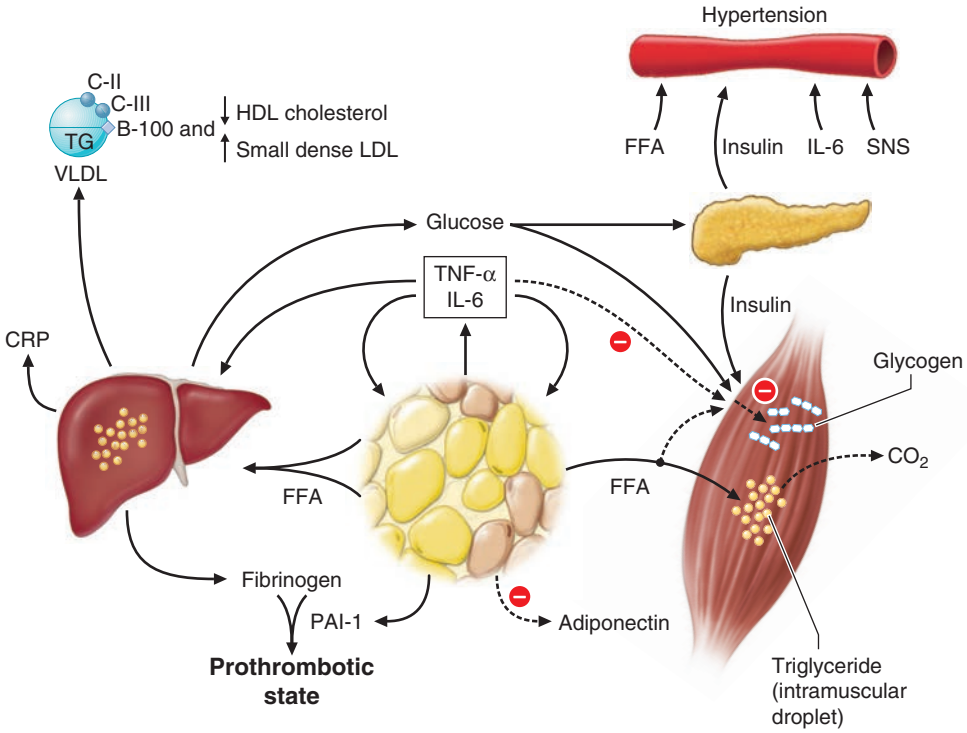

FIGURE 408-2 Pathophysiology of the metabolic syndrome. Free fatty acids (FFAs) are released in abundance from an expanded adipose tissue mass. In the liver, FFAs result in increased production of glucose and triglycerides and secretion of very-low-density lipoproteins (VLDLs). Associated lipid/lipoprotein abnormalities include reductions in high-density lipoprotein (HDL) cholesterol and an increased low-density lipoprotein (LDL) particle number. FFAs also reduce insulin sensitivity in muscle by inhibiting insulin-mediated glucose uptake. Associated defects include a reduction in glucose partitioning to glycogen and increased lipid accumulation in triglyceride (TG). The increase in circulating glucose, and to some extent FFAs, increases pancreatic insulin secretion, resulting in hyperinsulinemia. Hyperinsulinemia may result in enhanced sodium reabsorption and increased sympathetic nervous system (SNS) activity and contribute to hypertension, as might higher levels of circulating FFAs. The proinflammatory state is superimposed and contributory to the insulin resistance produced by excessive FFAs. The enhanced secretion of interleukin 6 (IL-6) and tumor necrosis factor α (TNF-α) produced by adipocytes and monocyte-derived macrophages results in more insulin resistance and lipolysis of adipose tissue triglyceride stores to circulating FFAs. IL-6 and other cytokines also enhance hepatic glucose production, VLDL production by the liver, hypertension, and insulin resistance in muscle. Insulin resistance also contributes to increased triglyceride accumulation in the liver (nonalcoholic fatty liver disease). Cytokines and FFAs also increase hepatic production of fibrinogen and adipocyte production of plasminogen activator inhibitor 1 (PAI-1), resulting in a pro-thrombotic state. Higher levels of circulating cytokines stimulate hepatic production of C-reactive protein (CRP). Reduced production of the anti-inflammatory and insulin-sensitizing cytokine adiponectin is also associated with the metabolic syndrome. *(Reproduced with permission from RH Eckel et al: The metabolic syndrome. Lancet 365:1415, 2005.)*

including inflammation and components of the metabolic syndrome. Although the mechanisms remain uncertain, interaction among genetic predisposition, diet, bile acid metabolism, and the intestinal flora is important.

Increased Waist Circumference Waist circumference is an important component of the most recent and frequently applied diagnostic criteria for the metabolic syndrome. However, measuring waist circumference does not reliably distinguish increases in SC abdominal adipose tissue from that in visceral fat; this distinction requires CT or MRI. With increases in visceral adipose tissue, adipose tissue–derived free fatty acids reach the liver more readily. In contrast, increases in abdominal SC fat release lipolysis products into the systemic circulation and therefore have fewer direct effects on hepatic metabolism. Relative increases in visceral versus SC adipose tissue with increasing waist circumference in Asians and Asian Indians may explain the greater prevalence of the syndrome in those populations than in African-American men, in whom SC fat predominates. It is also possible that visceral fat is a marker for—but not the source of—excess postprandial free fatty acids in obesity.

Dyslipidemia (See also Chap. 407) In general, free fatty acid flux to the liver results in increased production of apolipoprotein (apo) B–containing, triglyceride-rich, very-low-density lipoproteins (VLDLs). The effect of insulin on this process is complex, but *hypertriglyceridemia* is an excellent marker of the insulin-resistant condition. Not only is hypertriglyceridemia a feature of the metabolic syndrome, but patients with the metabolic syndrome have elevated levels of apoC-III carried on VLDLs and other lipoproteins. This increase in apoC-III is inhibitory to lipoprotein lipase, reduces triglyceride-rich lipoprotein remnant removal further contributing to hypertriglyceridemia, and confers more risk for atherosclerotic cardiovascular disease (ASCVD).

The other major lipoprotein disturbance in the metabolic syndrome is a *reduction in HDL cholesterol*. This reduction is a consequence of changes in HDL composition and metabolism. In the presence of hypertriglyceridemia, a decrease in the cholesterol content of HDL is a consequence of reduced cholesteryl ester content of the lipoprotein core in combination with cholesteryl ester transfer protein–mediated alterations in triglycerides that make the HDL particle small and dense. This change in lipoprotein composition also results in increased clearance of HDL from the circulation. These changes in HDL have a relationship to insulin resistance that is probably indirect, occurring in concert with the changes in triglyceride-rich lipoprotein metabolism.

In addition to HDLs, low-density lipoproteins (LDLs) have alterations in composition in the metabolic syndrome. With fasting serum triglycerides at >2.0 mM (~180 mg/dL), there is usually a predominance of small dense LDLs, which are thought to be more atherogenic, although their association with hypertriglyceridemia and low HDLs make their independent contribution to ASCVD difficult to assess. Individuals with hypertriglyceridemia often have increases in cholesterol content of both VLDL1 and VLDL2 subfractions and in LDL particle number. Both lipoprotein changes may contribute to atherogenic risk in patients with the metabolic syndrome.

Glucose Intolerance (See also Chap. 403) Defects in insulin action in the metabolic syndrome lead to impaired suppression of glucose production by the liver (and kidney) and reduced glucose uptake and metabolism in insulin-sensitive tissues—i.e., muscle and adipose tissue. There is a strong relationship between impaired fasting

glucose or impaired glucose tolerance and insulin resistance in studies of humans, nonhuman primates, and rodents. To compensate for defects in insulin action, insulin secretion and/or clearance increases or decreases, respectively, so that euglycemia remains. Ultimately, this compensatory mechanism fails because of defects in insulin secretion, resulting in progression from impaired fasting glucose and/or impaired glucose tolerance to type 2 diabetes mellitus.

Hypertension The relationship between insulin resistance and hypertension is well established. Paradoxically, under normal physiologic conditions, insulin is a vasodilator with secondary effects on sodium reabsorption in the kidney. However, in the setting of insulin resistance, the vasodilatory effect of insulin is lost but the renal effect on sodium reabsorption is preserved. Sodium reabsorption is increased in Caucasians with the metabolic syndrome but not in Africans or Asians. Insulin also increases the activity of the sympathetic nervous system, an effect that is preserved in the setting of insulin resistance. Insulin resistance is also associated with pathway-specific impairment in phosphatidylinositol-3-kinase signaling. In the endothelium, this impairment may cause an imbalance between the production of nitric oxide and the secretion of endothelin 1, with a consequent decrease in blood flow. In addition, increases in angiotensinogen gene expression in adipose tissue of obese subjects results in increases in circulating angiotensin II and vasoconstriction. Although these mechanisms are provocative, the inadequate evaluation of insulin action by measurement of fasting insulin levels or by homeostasis model assessment shows that insulin resistance contributes only partially to the increased prevalence of hypertension in the metabolic syndrome.

Another possible mechanism underlying hypertension in the metabolic syndrome is the vasoactive role of perivascular adipose tissue. Reactive oxygen species released by NADPH oxidase impair endothelial function and result in local vasoconstriction. Other paracrine effects such as leptin or other proinflammatory cytokines released from adipose tissue, such as tumor necrosis factor α (TNF-α) may also be important.

Hyperuricemia is another consequence of insulin resistance in the metabolic syndrome. There is growing evidence not only that uric acid is associated with hypertension but also that reduction of uric acid normalizes blood pressure in hyperuricemic adolescents with hypertension. The mechanism appears to be in part related to an adverse effect of uric acid on nitric oxide synthase in the macula densa of the kidney and stimulation of the renin-angiotensin-aldosterone system.

Proinflammatory Cytokines The increases in proinflammatory cytokines—including interleukins 1, 6, and 18; resistin; TNF-α; and the systemic biomarker C-reactive protein—reflect overproduction by the expanded adipose tissue mass (Fig. 408-2). Adipose tissue–derived macrophages may be the primary source of proinflammatory cytokines locally and in the systemic circulation. It remains unclear, however, how much of the insulin resistance is caused by the paracrine effects of these cytokines and how much by the endocrine effects.

Adiponectin Adiponectin is an anti-inflammatory cytokine produced exclusively by adipocytes. Adiponectin enhances insulin sensitivity and inhibits many steps in the inflammatory process. In the liver, adiponectin inhibits the expression of gluconeogenic enzymes and the rate of glucose production. In muscle, adiponectin increases glucose transport and enhances fatty acid oxidation, partially through the activation of AMP kinase. Reductions in adiponectin levels are common in the metabolic syndrome. The relative contributions of adiponectin deficiency and overabundance of the proinflammatory cytokines are unclear.

CLINICAL FEATURES

Symptoms and Signs The metabolic syndrome typically is not associated with symptoms. On physical examination, waist circumference and blood pressure are often elevated. The presence of either or both signs should prompt the clinician to search for other biochemical abnormalities that may be associated with the metabolic syndrome. Much less frequently, lipoatrophy or acanthosis nigricans is present on examination. Because these physical findings characteristically are associated with severe insulin resistance, other components of the metabolic syndrome are much more common.

Associated Diseases • **CARDIOVASCULAR DISEASE** The relative risk for new-onset CVD in patients with the metabolic syndrome who do not have diabetes averages 1.5- to 3-fold. However, in INTERHEART, a study of 26,903 subjects from 52 countries, the risk for acute myocardial infarction in subjects with the metabolic syndrome (World Health Organization or International Diabetes Federation definition) is comparable to that conferred by some, but not all, of the component risk factors. Diabetes mellitus (odds ratio [OR], 2.72) and hypertension (OR, 2.60) are stronger than other risk factors. Although congestive heart failure and the metabolic syndrome can occur together, typically this consequence is secondary to metabolic syndrome–related ASCVD or hypertension. Metabolic syndrome is also associated with increases in the risk for stroke, peripheral vascular disease, and Alzheimer's disease. However, as for myocardial infarction, the risk beyond the additive role of the components of the metabolic syndrome remains debatable. In the Reasons for Geographic and Racial Differences in Stroke (REGARDS) cohort, an observational study of black and white adults ≥45 years old across the United States, there were 9741 participants, and 41% had the metabolic syndrome. After adjustment for multiple confounders, metabolic syndrome was associated with increases in high-sensitivity C-reactive protein (hsCRP), and this relationship was associated with a 1.34 relative risk for all-cause mortality, but <50% of deaths were from CVD. The population-attributable risk was 9.5% for the metabolic syndrome alone and 14.7% for both metabolic syndrome and increased hsCRP. The relationship of metabolic syndrome and hsCRP to mortality was greater for whites than blacks.

TYPE 2 DIABETES Overall, the risk for type 2 diabetes among patients with the metabolic syndrome is increased three- to fivefold. In the Framingham Offspring Study's 8-year follow-up of middle-aged participants, the population-attributable risk of the metabolic syndrome for developing type 2 diabetes was 62% among men and 47% among women, yet increases in fasting plasma glucose explained most, if not all, of this increased risk.

Other Associated Conditions In addition to the features specifically used to define the metabolic syndrome, other metabolic alterations are secondary to or accompany insulin resistance. Those alterations include increases in apoB and apoC-III, uric acid, prothrombotic factors (fibrinogen, plasminogen activator inhibitor 1), serum viscosity, asymmetric dimethylarginine, homocysteine, white blood cell count, proinflammatory cytokines, C-reactive protein, urine albumin/creatinine ratio, nonalcoholic fatty liver disease (NAFLD) and/or nonalcoholic steatohepatitis (NASH), polycystic ovary syndrome, and obstructive sleep apnea.

NONALCOHOLIC FATTY LIVER DISEASE NAFLD has become the most common liver disease, in part a consequence of the insulin resistance of the metabolic syndrome. The mechanism relates to increases in free fatty acid flux and reductions in intrahepatic fatty acid oxidation with resultant increases in triglyceride biosynthesis and hepatocellular accumulation, with variable inflammation and oxidative stress. The more serious NASH, a consequence of NAFLD in some patients and a precursor of cirrhosis and end-stage liver disease, includes a more substantial proinflammatory contribution. NAFLD affects ~25% of the global population and up to 45% of patients with the metabolic syndrome; over half of these patients have NASH. As the prevalence of overweight/obesity and the metabolic syndrome increases, NASH may become one of the more common causes of end-stage liver disease and hepatocellular carcinoma.

HYPERURICEMIA (See also Chap. 417) Hyperuricemia reflects defects in insulin action on the renal tubular reabsorption of uric acid and may contribute to hypertension through its effect on the endothelium. An increase in asymmetric dimethylarginine, an endogenous inhibitor of nitric oxide synthase, also relates to endothelial dysfunction. In addition, increases in the urine albumin/creatinine ratio may relate to altered endothelial pathophysiology in the insulin-resistant state.

POLYCYSTIC OVARY SYNDROME (See also Chap. 392) Polycystic ovary syndrome is highly associated with insulin resistance (50–80%) and the metabolic syndrome, with a prevalence of the syndrome between 12 and 60% based on phenotypes D through A.

OBSTRUCTIVE SLEEP APNEA (See also Chap. 31) Obstructive sleep apnea is commonly associated with obesity, hypertension, increased circulating cytokines, impaired glucose tolerance, and insulin resistance. In fact, obstructive sleep apnea may predict metabolic syndrome, even in the absence of excess adiposity. Moreover, when biomarkers of insulin resistance are compared between patients with obstructive sleep apnea and weight-matched controls, insulin resistance is found to be more severe in those with apnea. Continuous positive airway pressure treatment improves insulin sensitivity in patients with obstructive sleep apnea.

DIAGNOSIS

The diagnosis of the metabolic syndrome relies on fulfillment of the criteria listed in Table 408-1, as assessed using tools at the bedside and in the laboratory. The medical history should include evaluation of symptoms for obstructive sleep apnea in all patients and polycystic ovary syndrome in premenopausal women. Family history will help determine risk for CVD and diabetes mellitus. Blood pressure and waist circumference measurements provide information necessary for the diagnosis.

Laboratory Tests Measurement of fasting lipids and glucose is needed in determining whether the metabolic syndrome is present. The measurement of additional biomarkers associated with insulin resistance can be individualized. Such tests might include those for apoB, hsCRP, fibrinogen, uric acid, urinary albumin/creatinine ratio, and liver function. A sleep study should be performed if symptoms of obstructive sleep apnea are present. If polycystic ovary syndrome is suspected based on clinical features and anovulation, testosterone, luteinizing hormone, and follicle-stimulating hormone should be measured. NAFLD can be further assessed by the NAFLD fibrosis score (FIB4) or elastography.

TREATMENT

The Metabolic Syndrome

LIFESTYLE (SEE ALSO CHAP. 402)

Obesity, particularly abdominal, is the driving force behind the metabolic syndrome. Thus, weight reduction is the primary approach to the disorder. With at least a 5% and more so with 10% weight reduction, improvement in insulin sensitivity results in favorable modifications in many components of the metabolic syndrome. In general, recommendations for weight loss include a combination of caloric restriction, increased physical activity, and behavior modification. Caloric restriction is the most important component, whereas increases in physical activity are important for maintenance of weight loss. Some but not all evidence suggests that the addition of exercise to caloric restriction may promote greater weight loss from the visceral depot. The tendency for weight regain after successful weight reduction underscores the need for long-lasting behavioral changes.

Diet Before prescribing a weight-loss diet, it is important to emphasize that it has taken the patient a long time to develop an expanded fat mass; thus, the correction need not occur quickly. Given that ~3500 kcal = 1 lb of fat, an ~500-kcal restriction daily equates to weight reduction of 1 lb per week. Diets restricted in carbohydrate typically provide a more rapid initial weight loss. However, after 1 year, the amount of weight reduction is minimally more reduced or no different from that with caloric restriction alone. Thus, adherence to the diet is more important than the chosen diet. Moreover, there is concern about low-carbohydrate diets enriched in saturated fat, particularly for patients at risk for ASCVD. Therefore, a high-quality dietary pattern—i.e., a diet enriched in fruits, vegetables, whole grains, lean poultry, and fish—should be encouraged to maximize overall health benefit.

Physical Activity Before prescribing a physical activity program to patients with the metabolic syndrome, it is important to ensure that the increased activity does not incur risk. Some high-risk patients should undergo formal cardiovascular evaluation before initiating an exercise program. For an inactive participant, gradual increases in physical activity should be encouraged to enhance adherence and avoid injury. Although increases in physical activity can lead to modest weight reduction, 60–90 min of moderate- to high-intensity daily activity is required to achieve this goal. Even if an overweight or obese adult is unable to undertake this level of activity, a health benefit will follow from at least 30 min of moderate-intensity activity daily. The caloric value of 30 min of a variety of activities can be found at *https://www.health.harvard.edu/diet-and-weight-loss/calories-burned-in-30-minutes-of-leisure-and-routine-activities*. Of note, a variety of routine activities, such as gardening, walking, and housecleaning, require moderate caloric expenditure. Thus, physical activity should not be defined solely in terms of formal exercise such as jogging, swimming, or tennis.

Behavior Modification Behavioral treatment typically includes recommendations for dietary restriction and more physical activity that predicts sufficient weight loss that benefits metabolic health. The subsequent challenge is the duration of the program because weight regain so often follows successful weight reduction. Improved long-term outcomes often follow a variety of methods, such as a personal or group counselor, the Internet, social media, and telephone follow-up to maintain contact between providers and patients.

Obesity (See also Chap. 402) In some patients with the metabolic syndrome, treatment options need to extend beyond lifestyle intervention. Weight-loss drugs come in two major classes: appetite suppressants and absorption inhibitors. Appetite suppressants approved by the U.S. Food and Drug Administration (FDA) include phentermine (for short-term use [3 months] only) as well as the more recent additions phentermine/topiramate, naltrexone/bupropion, high-dose (3.0 mg) liraglutide (rather than 1.8 mg, the maximum for treatment of type 2 diabetes), semaglutide (2.4 mg) which are approved without restrictions on the duration of therapy. In clinical trials, the phentermine/topiramate extended-release combination resulted in ~8% weight loss relative to placebo in 50% of patients. Side effects include palpitations, headache, paresthesias, constipation, and insomnia. Naltrexone/bupropion extended release reduces body weight by ≥10% in ~20% of patients; however, the drug combination is contraindicated in patients with seizure disorders or any condition that predisposes to seizures. Naltrexone/bupropion also increases pulse and blood pressure and should not be given to patients with uncontrolled hypertension. High-dose liraglutide, a glucagon-like peptide 1 (GLP-1) receptor agonist, results in ~6% weight loss relative to placebo with ~33% of patients with >10% weight loss. Common side effects are limited to the upper gastrointestinal tract, including nausea and, less frequently, emesis. Semaglutide (2.4 mg weekly), recently FDA approved has been shown to produce an average weight loss of 14.9% over 68 weeks.

Orlistat inhibits fat absorption by ~30% and is moderately effective compared with placebo (~4% more weight loss). Moreover, orlistat reduced the incidence of type 2 diabetes, an effect that was especially evident among patients with impaired glucose tolerance at baseline. This drug is often difficult to take because of oily leakage per rectum. In general, for all weight-loss drugs, greater weight reduction leads to greater improvement in metabolic syndrome components, including the conversion from prediabetes to type 2 diabetes.

Metabolic or bariatric surgery is an important option for patients with the metabolic syndrome who have a body mass index of >40 kg/m^2 or >35 kg/m^2 with comorbidities. An evolving application for metabolic surgery includes patients with a body mass index as low as 30 kg/m^2 and type 2 diabetes. Gastric bypass or vertical sleeve gastrectomy results in dramatic weight reduction

and improvement in most features of the metabolic syndrome. A survival benefit with gastric bypass has also been realized.

LDL CHOLESTEROL (SEE ALSO CHAP. 407)

The rationale for the development of criteria for the metabolic syndrome by NCEP was to go beyond LDL cholesterol in identifying and reducing the risk of ASCVD. The working assumption by the panel was that LDL cholesterol goals had already been achieved and that increasing evidence supports a linear reduction in ASCVD events because of progressive lowering of LDL cholesterol with statins with subsequent benefit using additional LDL cholesterol–lowering agents. The 2019 American College of Cardiology (ACC)/American Health Association (AHA) Cholesterol Guidelines have no specific recommendations for patients with the metabolic syndrome; however, they recommend that patients aged 20–75 years with LDL cholesterol levels ≥190 mg/dL should use a high-intensity statin (e.g., atorvastatin 40–80 mg or rosuvastatin 20–40 mg daily) and those with type 2 diabetes aged 40–75 years should use a moderate-intensity statin and, if or when risk estimate is high, a high-intensity statin. For patients with the metabolic syndrome but without diabetes, the 10-year ASCVD risk estimator should be employed, and patients with a risk ≥7.5% and ≤20% or patients aged 20–59 with elevated lifetime risk should have a discussion with their provider about initiating statin therapy for primary prevention of ASCVD. A coronary calcium score may help in making this decision.

Diets restricted in saturated fats (<6% of calories) and trans fats (as few as possible) should be applied aggressively. Although evidence is controversial, dietary cholesterol can also be restricted. If LDL cholesterol remains elevated, pharmacologic intervention is needed. Based on substantial evidence, treatment with statins, which lower LDL cholesterol by 15–60%, is the first-choice medication intervention. Of note, for each doubling of the statin dose, LDL cholesterol is further lowered by only ~6%. Hepatotoxicity (more than a threefold increase in hepatic aminotransferases) is rare, but myopathy occurs in ~10–20% of patients. The cholesterol absorption inhibitor ezetimibe is well tolerated and should be the second-choice medication intervention. Ezetimibe typically reduces LDL cholesterol by 15–20%. Bempedoic acid alone or in combination with ezetimibe is another option, with up to a 35% lowering of LDL cholesterol with the combination. Bempedoic acid can increase plasma uric acid. Proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors are potent LDL cholesterol–lowering drugs (~45–60%) but are not needed for most patients with the metabolic syndrome. Of course, if these patients also have familial hypercholesterolemia or insufficient LDL cholesterol lowering on statins with or without ezetimibe, a PCSK9 inhibitor should be considered. The bile acid sequestrants cholestyramine, colestipol, and colesevelam may be more effective than ezetimibe alone, but because they can increase triglyceride levels, they must be used with caution in patients with the metabolic syndrome when fasting triglycerides are >300 mg/dL. Side effects include gastrointestinal symptoms (palatability, bloating, belching, constipation, anal irritation). Nicotinic acid has similar LDL cholesterol–lowering capabilities (<20%). Fibrates are best employed to lower LDL cholesterol when triglycerides are not elevated. Fenofibrate may be more effective than gemfibrozil in this setting.

TRIGLYCERIDES (SEE ALSO CHAP. 407)

The 2019 ACC/AHA Cholesterol Guidelines stated that fasting triglycerides >500 mg/dL should be treated to prevent more serious hypertriglyceridemia and pancreatitis. Although a fasting triglyceride value of >150 mg/dL is a component of the metabolic syndrome, post hoc analyses of multiple fibrate trials have suggested reduction in the primary ASCVD outcome in patients (with or without concomitant statin therapy) with fasting triglycerides >200 mg/dL, often in the setting of reduced levels of HDL cholesterol. It remains uncertain whether triglycerides cause ASCVD or if levels are just associated with increased ASCVD risk.

A fibrate (gemfibrozil or fenofibrate) is one drug class of choice to lower fasting triglyceride levels, which are typically reduced by 30–45%. Concomitant administration with drugs metabolized by the 3A4 cytochrome P450 system (including some statins) increases the risk of myopathy. In these cases, fenofibrate may be preferable to gemfibrozil. In the Veterans Affairs HDL Intervention Trial, gemfibrozil was administered to men with known CHD and levels of HDL cholesterol <40 mg/dL. A coronary disease event and mortality rate benefit was experienced predominantly among men with hyperinsulinemia and/or diabetes, many of whom were identified retrospectively as having the metabolic syndrome. Of note, the degree of triglyceride lowering in this trial or other fibrate trials did not predict benefit.

Other drugs that lower triglyceride levels include statins, nicotinic acid, and prescription omega-3 fatty acids. For this purpose, an intermediate or high dose of the "more potent" statins (atorvastatin, rosuvastatin) is needed. The effect of nicotinic acid on fasting triglycerides is dose related and ~20–35%, an effect that is less pronounced than that of fibrates. In patients with the metabolic syndrome and diabetes, nicotinic acid may increase fasting glucose levels, and clinical trials with nicotinic acid plus a statin have failed to reduce ASCVD events. Prescriptions of omega-3 fatty acid preparations that include high doses of eicosapentaenoic acid (EPA) with or without docosahexaenoic acid (DHA) (~1.5–4.5 g/d) lower fasting triglyceride levels by ~25–40%. The two omega-3 randomized controlled trials associated with ASCVD risk reduction, JELIS and REDUCE-IT, used EPA only, whereas STRENGTH, which was terminated prematurely because of futility, used EPA plus DHA. Here, no drug interactions with fibrates or statins occur, and the main side effect of their use is eructation with a fishy taste. Freezing the nutraceutical can partially block this unpleasant side effect. Importantly, lowering triglycerides with any of the pharmaceuticals has not proven to be an independent predictor of CVD outcomes.

HDL CHOLESTEROL (SEE ALSO CHAP. 407)

Very few lipid-modifying compounds increase HDL cholesterol levels. Statins, fibrates, and bile acid sequestrants have modest effects (5–10%), whereas ezetimibe and omega-3 fatty acids have no effect. Nicotinic acid is the only currently available drug with predictable HDL cholesterol–raising properties. The response is dose related, and nicotinic acid can increase HDL cholesterol by up to 30% above baseline. After several trials of nicotinic acid versus placebo in statin-treated patients, there is no evidence that raising HDL cholesterol with nicotinic acid beneficially affects ASCVD events in patients with or without the metabolic syndrome.

BLOOD PRESSURE (SEE ALSO CHAP. 277)

The direct relationship between blood pressure and all-cause mortality rate has been well established in studies comparing patients with hypertension (>140/90 mmHg), patients with prehypertension (>120/80 mmHg but <140/90 mmHg), and individuals with normal blood pressure (<120/80 mmHg). In patients who have the metabolic syndrome without diabetes, the best choice for the initial antihypertensive medication is an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin II receptor blocker, as these two classes of drugs are effective and well tolerated. Additional agents include a diuretic, calcium channel blocker, beta blocker, and mineralocorticoid inhibitor, such as the recently FDA approved mineralocorticoid receptor antagonist finerenone. In all patients with hypertension, a sodium-restricted dietary pattern enriched in fruits and vegetables, whole grains, and low-fat dairy products should be advocated. Home monitoring of blood pressure may assist in maintaining good blood pressure control.

IMPAIRED FASTING GLUCOSE (SEE ALSO CHAP. 403)

In patients with the metabolic syndrome and type 2 diabetes, aggressive glycemic control may favorably modify fasting levels of triglycerides and/or HDL cholesterol. In patients with impaired fasting glucose who do not have diabetes, a lifestyle intervention that includes weight reduction, dietary saturated fat restriction, and increased physical activity has been shown to reduce the incidence

of type 2 diabetes. Metformin also reduces the incidence of diabetes, although the effect is less pronounced than that of lifestyle intervention.

INSULIN RESISTANCE (SEE ALSO CHAP. 404)

Several drug classes (biguanides, thiazolidinediones [TZDs]) increase insulin sensitivity. Because insulin resistance is the primary pathophysiologic mechanism for the metabolic syndrome, representative drugs in these classes reduce its prevalence. Both metformin and TZDs enhance insulin action in the liver and suppress endogenous glucose production. TZDs, but not metformin, also improve insulin-mediated glucose uptake in muscle and adipose tissue. In a meta-analysis of nine trials involving 12,026 participants, the TZD pioglitazone versus placebo was associated with reduction in ASCVD events in patients with insulin resistance (metabolic syndrome), prediabetes and type 2 diabetes. However, adverse effects including weight gain, bone fracture, and congestive heart failure with/or without edema were seen. Benefit of TZDs has been seen in patients with NAFLD, and with metformin in women with polycystic ovary syndrome, and both drug classes have been shown to reduce markers of inflammation.

Section 4 Disorders of Bone and Mineral Metabolism

409 Bone and Mineral Metabolism in Health and Disease

F. Richard Bringhurst, Henry M. Kronenberg, Eva S. Liu

BONE STRUCTURE AND METABOLISM

Bone is a dynamic tissue that is remodeled constantly throughout life. The arrangement of compact and cancellous bone provides strength and density suitable for both mobility and protection. Compact or cortical bone forms the roughly cylindrical shell of long bones; cancellous or trabecular bone forms the plate-like meshwork that internally supports the cortical shell. In addition, bone provides a reservoir for calcium, magnesium, phosphorus, sodium, and other ions necessary for homeostatic functions. Bone also hosts and regulates hematopoiesis by providing niches for hematopoietic cell proliferation and differentiation. The skeleton is highly vascular and receives ~10% of the cardiac output. Remodeling of bone is accomplished by two distinct cell types: osteoblasts produce bone matrix, and osteoclasts resorb the matrix. The activities of these cells are coordinated by osteocytes, long-lived regulatory cells embedded within bone matrix.

The extracellular components of bone consist of a solid mineral phase in close association with an organic matrix, of which 90–95% is type I collagen **(Chap. 413)**. The noncollagenous portion of the organic matrix is heterogeneous and contains serum proteins such as albumin as well as many locally produced proteins, whose functions are incompletely understood. Those proteins include cell attachment/signaling proteins such as thrombospondin, osteopontin, and fibronectin; calcium-binding proteins such as matrix gla protein and osteocalcin; and proteoglycans such as biglycan and decorin. Some of the proteins organize collagen fibrils; others influence mineralization and binding of the mineral phase to the matrix.

The mineral phase is made up of calcium and phosphate and is best characterized as a poorly crystalline hydroxyapatite. The mineral phase of bone is deposited initially in intimate relation to the collagen fibrils and is found in specific locations in the "holes" between the collagen fibrils. This architectural arrangement of mineral and matrix results in a two-phase material well suited to withstand mechanical stresses. The organization of collagen influences the amount and type of mineral phase formed in bone. Although the primary structures of type I collagen in skin and bone tissues are similar, there are differences in posttranslational modifications and distribution of intermolecular cross-links. The holes in the packing structure of the collagen are larger in mineralized collagen of bone and dentin than in unmineralized collagens such as those in tendon. Single amino acid substitutions in the helical portion of either the α1 (*COL1A1*) or α2 (*COL1A2*) chains of type I collagen disrupt the organization of bone in the disease, osteogenesis imperfecta. The severe skeletal fragility associated with this group of disorders highlights the importance of the fibrillar matrix in the structure of bone **(Chap. 413)**.

Osteoblasts synthesize and secrete the organic matrix and regulate its mineralization. They are derived from cells of mesenchymal origin **(Fig. 409-1A)**. Active osteoblasts are found on the surface of newly forming bone. As an osteoblast secretes matrix, which then is mineralized, the cell may become an *osteocyte*, still connected with its nutrient supply through a series of canaliculi. Osteocytes account for the vast majority of the cells in bone. They are thought to be the mechanosensors in bone that communicate signals to surface osteoblasts and osteoclasts and their progenitors through the canalicular network and thereby serve as master regulators of bone formation and resorption. Remarkably, osteocytes also secrete fibroblast growth factor 23 (FGF23), a major hormonal regulator of phosphate metabolism (see below). Mineralization of the matrix, both in trabecular bone and in osteones of compact cortical bone (*Haversian systems*), begins soon after the matrix is secreted (primary mineralization) but is not completed for several weeks or even longer (secondary mineralization). Although this mineralization takes advantage of the high concentrations of calcium and phosphate, already near saturation in serum, mineralization is a carefully regulated process that is dependent on the activity of osteoblast-derived alkaline phosphatase, which probably works by hydrolyzing inhibitors of mineralization, such as pyrophosphate.

Genetic studies in humans and mice have identified several key genes that control osteoblast development. *Runx2* is a transcription factor expressed specifically in chondrocyte (cartilage cells) and osteoblast progenitors as well as in hypertrophic chondrocytes and mature osteoblasts. *Runx2* regulates the expression of several important osteoblast proteins, including osterix (another transcription factor needed for osteoblast maturation), osteopontin, bone sialoprotein, type I collagen, osteocalcin, and receptor-activator of nuclear factor (NF)-κB (RANK) ligand. *Runx2* expression is regulated in part by bone morphogenic proteins (BMPs). *Runx2*-deficient mice are devoid of

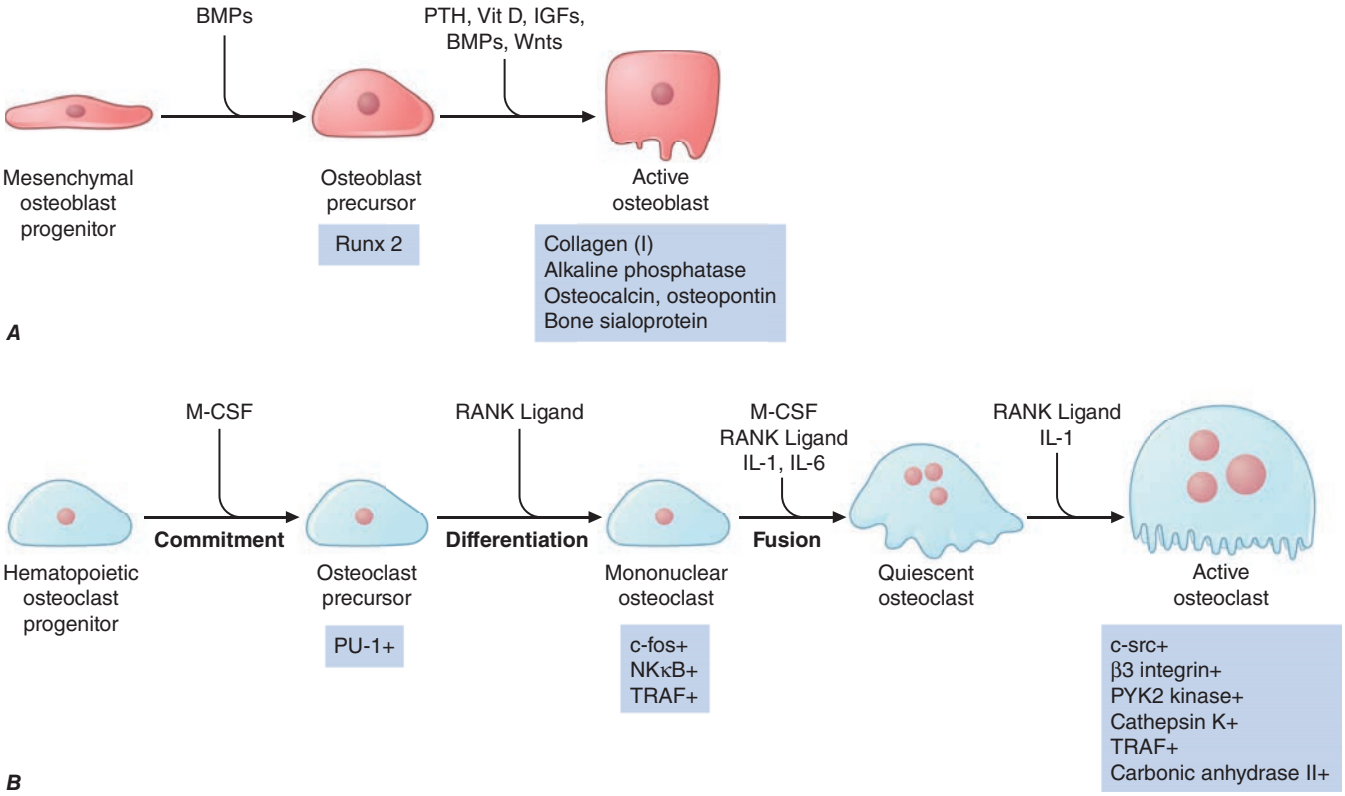

FIGURE 409-1 Pathways regulating development of (*A*) osteoblasts and (*B*) osteoclasts. Hormones, cytokines, and growth factors that control cell proliferation and differentiation are shown above the *arrows*. Transcription factors and other markers specific for various stages of development are depicted below the arrows. BMPs, bone morphogenic proteins; IGFs, insulin-like growth factors; IL-1, interleukin 1; IL-6, interleukin 6; M-CSF, macrophage colony-stimulating factor; NFκB, nuclear factor-κB; PTH, parathyroid hormone; PU-1, a monocyte- and B lymphocyte–specific ets family transcription factor; RANK ligand, receptor activator of NFκB ligand; Runx2, Runt-related transcription factor 2; TRAF, tumor necrosis factor receptor–associated factor; Vit D, vitamin D; wnts, wingless-type mouse mammary tumor virus integration site. *(Modified with permission from T Suda et al: Modulation of osteoclast differentiation and function by the new members of the tumor necrosis factor receptor and ligand families. Endocr Rev 20:345, 1999.)*

osteoblasts, whereas mice with a deletion of only one allele (*Runx2* +/–) exhibit a delay in formation of the clavicles and some cranial bones. The latter abnormalities are similar to those in the human disorder *cleidocranial dysplasia*, which is also caused by heterozygous inactivating mutations in *Runx2*.

The paracrine signaling molecule, Indian hedgehog (Ihh), also plays a critical role in osteoblast development, as evidenced by Ihh-deficient mice that lack osteoblasts in the type of bone formed on a cartilage mold (endochondral ossification). Signals originating from members of the wnt (an amalgam of "wingless," the *Drosophila* developmental gene and "int-1," an analogous mammalian gene activated by integration of a mouse tumor viral genome nearby) family of paracrine factors are also important for osteoblast proliferation and differentiation. Osteocytes regulate osteoblasts partly by secreting a potent inhibitor of wnt signaling called sclerostin. Numerous other growth-regulatory factors affect osteoblast function, including the three closely related transforming growth factor βs, fibroblast growth factors (FGFs) 2 and 18, platelet-derived growth factor, and insulin-like growth factors (IGFs) I and II. Hormones such as parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] activate receptors expressed by osteoblasts to assure mineral homeostasis and influence a variety of bone cell functions. Osteoclasts that resorb bone (see below) also regulate osteoblasts by releasing growth factors from bone matrix and by synthesizing proteins that can directly regulate osteoblastogenesis.

Resorption of bone is carried out mainly by *osteoclasts*, multinucleated cells that are formed by fusion of cells derived from the common precursor of macrophages and osteoclasts. Thus, these cells derive from the hematopoietic lineage, quite different from the mesenchymal lineage cells that become osteoblasts. Multiple factors that regulate osteoclast development have been identified **(Fig. 409-1*B*)**. Factors produced by osteocytes, osteoblasts, and marrow stromal cells allow cells of the osteoblast lineage to control osteoclast development and activity. Macrophage colony-stimulating factor (M-CSF) plays a critical role during several steps in the pathway and ultimately leads to fusion of osteoclast progenitor cells to form multinucleated, active osteoclasts. RANK ligand, a member of the tumor necrosis factor (TNF) family, is expressed on the surface of osteocytes, osteoblasts, and stromal fibroblasts. In a process involving cell-cell interactions, RANK ligand binds to the RANK receptor on osteoclast progenitors, stimulating osteoclast differentiation and activation. Alternatively, a soluble decoy receptor, referred to as osteoprotegerin, can bind RANK ligand and inhibit osteoclast differentiation. Several growth factors and cytokines (including interleukins 1, 6, and 11; TNF; and interferon γ) modulate osteoclast differentiation and function. Most hormones that influence osteoclast function do not target these cells directly but instead target cells of the osteoblast lineage to increase production of M-CSF and RANK. Both PTH and 1,25$(OH)_2$D increase osteoclast number and activity by this indirect mechanism. Calcitonin, in contrast, binds to its receptor on the basal surface of osteoclasts and directly inhibits osteoclast function. Estradiol has multiple cellular targets in bone, including osteoclasts, immune cells, and osteoblasts; actions on all these cells serve to decrease osteoclast number and decreased bone resorption.

Osteoclast-mediated resorption of bone takes place in scalloped spaces (*Howship's lacunae*) where the osteoclasts are attached through a specific αvβ3 integrin to components of the bone matrix such as osteopontin. The osteoclast forms a tight seal to the underlying matrix and secretes protons, chloride, and proteinases into a confined space that has been likened to an extracellular lysosome. The active osteoclast surface forms a ruffled border that contains a specialized proton pump ATPase that secretes acid that solubilizes the mineral phase. Carbonic anhydrase (type II isoenzyme) within the osteoclast generates the needed protons. The bone matrix is resorbed in the acid environment adjacent to the ruffled border by proteases, such as cathepsin K, that act at low pH.

In the embryo and the growing child, bone develops mostly by replacing previously calcified cartilage (endochondral bone formation) with subsequent remodeling or, in a few bones, is formed without a cartilage matrix (intramembranous bone formation). During endochondral bone formation, chondrocytes proliferate, secrete and mineralize a matrix, enlarge (hypertrophy), and then die, enlarging bone and providing the matrix and factors that stimulate endochondral bone formation. This program is regulated by both local factors such as IGF-I and -II, Ihh, parathyroid hormone–related peptide (PTHrP), BMPs, and FGFs and by systemic hormones such as growth hormone, glucocorticoids, and estrogen. Some hypertrophic chondrocytes do not die but, instead, through still poorly understood steps, can become osteoblasts and bone stromal cells.

New bone, whether formed in infants or in adults during repair, has a relatively high ratio of cells to matrix and is characterized by coarse fiber bundles of collagen that are interlaced and randomly dispersed (woven bone). In adults, the more mature bone is organized with fiber bundles regularly arranged in parallel or concentric sheets (lamellar bone). In long bones, deposition of lamellar bone in a concentric arrangement around blood vessels forms the Haversian systems. Growth in length of bones is dependent on proliferation of cartilage cells and the endochondral sequence at the growth plate. Growth in width and thickness is accomplished by formation of bone at the periosteal surface and by resorption at the endosteal surface, with the rate of formation exceeding that of resorption. In adults, after the growth plates of cartilage close through the actions of estrogen, growth in length and endochondral bone formation cease. Even in adults, however, remodeling of bone (within Haversian systems as well as along the surfaces of trabecular bone) continues throughout life. In adults, ~4% of the surface of trabecular bone (such as iliac crest) is involved in active resorption, whereas 10–15% of trabecular surfaces are covered with osteoid, unmineralized new bone formed by osteoblasts. Radioisotope studies indicate that as much as 18% of the total skeletal calcium is deposited and removed each year. Thus, bone is an active metabolizing tissue that requires an intact blood supply. The cycle of bone resorption and formation is a highly orchestrated process, directed by osteocytes and carried out by the basic multicellular unit, which is composed of a group of osteoclasts and osteoblasts **(Fig. 409-2)**.

The response of bone to fractures, infection, and interruption of blood supply and to expanding lesions is relatively limited. Dead bone must be resorbed, and new bone must be formed, a process carried out in association with growth of new blood vessels into the involved area. In injuries that disrupt the organization of the tissue, such as a fracture, in which apposition of fragments is poor or when motion exists at the fracture site, progenitor stromal cells recapitulate the endochondral bone formation of early development and form cartilage that is replaced by bone and, variably, fibrous tissue. When there is good apposition with fixation and little motion at the fracture site, repair occurs predominantly by formation of new bone without other mediating tissue.

Remodeling of bone occurs along lines of force generated by mechanical stress. The signals from these mechanical stresses are sensed by osteocytes, which transmit signals to osteoclasts and osteoblasts or their precursors. One such signal made by osteocytes is sclerostin, an inhibitor of wnt signaling. Mechanical forces suppress sclerostin production and thus increase bone formation by osteoblasts. Expanding lesions in bone such as tumors induce resorption at the surface in contact with the tumor by producing ligands such as PTHrP that stimulate osteoclast differentiation and function. Thus, bone plasticity reflects the interaction of cells with each other and with the environment.

Measurement of the products of osteoblast and osteoclast activity can assist in the diagnosis and management of bone diseases. Osteoblast activity can be assessed by measuring serum bone-specific alkaline phosphatase. Similarly, osteocalcin, a protein secreted from osteoblasts, is made virtually only by osteoblasts. Measurement of an amino-terminal fragment of procollagen I is also an effective index of bone formation. Osteoclast activity can be assessed by measurement of products of collagen degradation. Collagen molecules are covalently linked to each other in the extracellular matrix through the formation of hydroxypyridinium cross-links **(Chap. 413)**. After digestion by osteoclasts, these cross-linked peptides can be measured both in urine and in blood.

CALCIUM METABOLISM

Over 99% of the 1–2 kg of calcium present normally in the adult human body resides in the skeleton, where it provides mechanical stability and serves as a reservoir sometimes needed to maintain extracellular fluid (ECF) calcium concentration **(Fig. 409-3)**. Skeletal calcium accretion first becomes significant during the third trimester of fetal life, accelerates throughout childhood and adolescence, reaches a peak in early adulthood, and gradually declines thereafter at rates that rarely exceed 1–2% per year. These slow changes in total skeletal calcium content contrast with relatively high daily rates of closely matched fluxes of calcium into and out of bone (~250–500 mg each), a process mediated by coupled osteoblastic and osteoclastic activity. Another 0.5–1% of skeletal calcium is freely exchangeable (e.g., in chemical equilibrium) with that in the ECF.

The concentration of ionized calcium in the ECF must be maintained within a narrow range because of the critical role calcium plays in a wide array of cellular functions, especially those involved in neuromuscular activity, secretion, and signal transduction. Intracellular cytosolic free calcium levels are ~100 nmol/L and are 10,000-fold lower than ionized calcium concentration in the blood and ECF (1.1–1.3 mmol/L). Cytosolic calcium does not play the structural role played by extracellular calcium; instead, it serves a signaling function. The steep chemical gradient of calcium from outside to inside the cell promotes rapid calcium influx through various membrane calcium channels that can be activated by hormones, metabolites, or neurotransmitters, swiftly changing cellular function. In blood, total calcium concentration is normally 2.2–2.6 m*M* (8.5–10.5 mg/dL), of which ~50% is ionized. The remainder is bound ionically to negatively charged proteins (predominantly albumin and immunoglobulins) or loosely complexed with phosphate, citrate, sulfate, or other anions. Alterations in serum protein concentrations directly affect the total blood calcium concentration even if the ionized

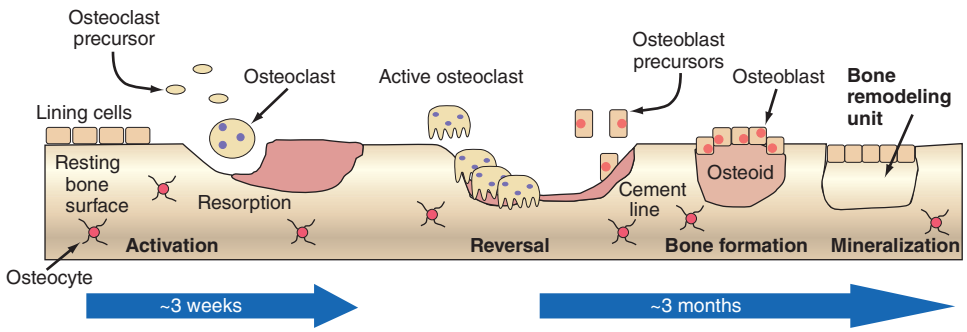

FIGURE 409-2 Schematic representation of bone remodeling. The cycle of bone remodeling is carried out by the basic multicellular unit (BMU), which consists of a group of osteoclasts and osteoblasts. In cortical bone, the BMUs tunnel through the tissue, whereas in cancellous bone, they move across the trabecular surface. The process of bone remodeling is initiated by the recruitment of osteoclast precursors, perhaps to sites of microdamage. These precursors fuse to form multinucleated, active osteoclasts that mediate bone resorption. Osteoclasts adhere to bone and subsequently remove it by acidification and proteolytic digestion. As the BMU advances, osteoclasts leave the resorption site and osteoblasts, derived from marrow precursors and previously inactive bone lining cells, move in to cover the excavated area and begin the process of new bone formation by secreting osteoid, which eventually is mineralized into new bone. After osteoid mineralization, osteoblasts flatten and form a layer of lining cells over new bone, become osteocytes, or die.

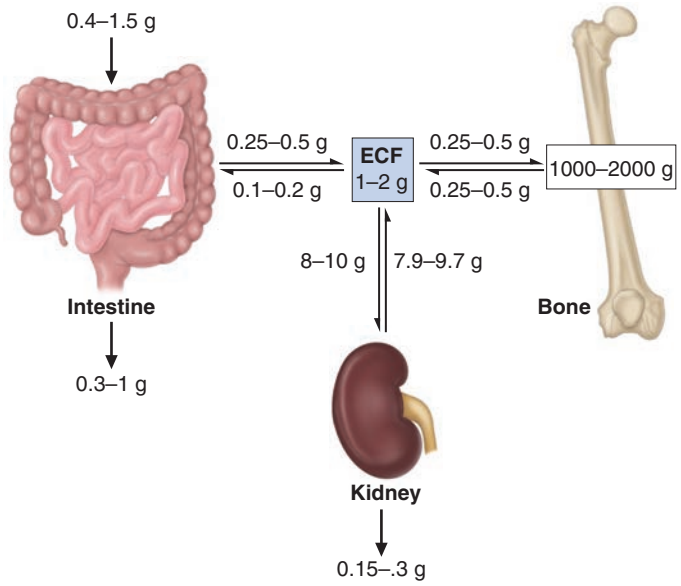

FIGURE 409-3 Calcium homeostasis. Schematic illustration of calcium content of extracellular fluid (ECF) and bone as well as of diet and feces; magnitude of calcium flux per day as calculated by various methods is shown at sites of transport in intestine, kidney, and bone. Ranges of values shown are approximate and were chosen to illustrate certain points discussed in the text. In conditions of calcium balance, rates of calcium release from and uptake into bone are equal.

calcium concentration remains normal. An algorithm to correct for protein changes adjusts the total serum calcium (in mg/dL) upward by 0.8 times the deficit in serum albumin (g/dL) or by 0.5 times the deficit in serum immunoglobulin (in g/dL). Such corrections provide only rough approximations of actual free calcium concentrations, however, and may be misleading, particularly during acute illness. Acidosis also alters ionized calcium by reducing its association with proteins. The best practice is to measure blood ionized calcium directly by a method that employs calcium-selective electrodes in acute settings during which calcium abnormalities might occur.

Control of the ionized calcium concentration in the ECF ordinarily is accomplished by adjusting the rates of calcium movement across intestinal and renal epithelia and into and out of bone. These adjustments are mediated mainly via changes in blood levels of the hormones PTH and $1,25(OH)_2D$. Acting via binding to calcium-sensing receptors (CaSRs) on the surface of parathyroid cells, blood ionized calcium suppresses PTH secretion by reducing levels of PTH mRNA and promoting the cleavage of PTH to inactive peptides. Also, ionized calcium indirectly affects PTH secretion by lowering $1,25(OH)_2D$ production. This active vitamin D metabolite inhibits PTH production by an incompletely understood mechanism of negative feedback (Chap. 410).

Normal dietary calcium intake in the United States varies widely, ranging from 10 to 37 mmol/d (400–1500 mg/d). A National Academy of Medicine (formerly, Institute of Medicine) analysis recommends a daily allowance of 25–30 mmol (1000–1200 mg) for most adults. Intestinal absorption of ingested calcium involves both active (transcellular) and passive (paracellular) mechanisms. Passive calcium absorption is nonsaturable and approximates 5% of daily calcium intake, whereas active absorption involves apical calcium entry via specific ion channels (TRPV5 in the kidney and TRPV6 in the intestine), whose expression is controlled principally by $1,25(OH)_2D$. This active transport mechanism normally accounts for absorption of 20–70% of dietary calcium. Active calcium transport occurs mainly in the proximal small bowel (duodenum and proximal jejunum), although some active calcium absorption occurs in most segments of the small intestine. Optimal rates of calcium absorption require gastric acid. This is especially true for weakly dissociable calcium supplements such as calcium carbonate. In fact, large boluses of calcium carbonate are poorly absorbed because of their neutralizing effect on gastric acid. In achlorhydric subjects and for those taking drugs that inhibit gastric acid secretion, supplements should be taken with meals to optimize their absorption. Use of calcium citrate may be preferable in these circumstances. Calcium absorption may also be blunted in disease states such as pancreatic or biliary insufficiency, in which ingested calcium remains bound to unabsorbed fatty acids or other food constituents. At high levels of calcium intake, synthesis of $1,25(OH)_2D$ is reduced; this decreases the rate of active intestinal calcium absorption. The opposite occurs with dietary calcium restriction. Some calcium, ~2.5–5 mmol/d (100–200 mg/d), is excreted as an obligate component of intestinal secretions and is not regulated by calciotropic hormones.

The feedback-controlled hormonal regulation of intestinal absorptive efficiency results in a relatively constant daily net calcium absorption of ~5–10 mmol/d (200–400 mg/d) despite large changes in daily dietary calcium intake. This daily load of absorbed calcium is excreted by the kidneys in a manner that is also tightly regulated by the concentration of ionized calcium in the blood. Approximately 8–10 g/d of calcium is filtered by the glomeruli, of which only 2–3% appears in the urine. Most filtered calcium (65%) is reabsorbed in the proximal tubules via a passive, paracellular route that is coupled to concomitant NaCl reabsorption and not specifically regulated. The cortical thick ascending limb of Henle's loop (cTAL) reabsorbs roughly another 20% of filtered calcium, also via a paracellular mechanism. Calcium reabsorption in the cTAL requires a tight-junctional protein called paracellin-1 and is inhibited by increased blood concentrations of calcium or magnesium, acting via the CaSR, which is highly expressed on basolateral membranes in this nephron segment. Operation of the renal CaSR provides a mechanism, independent of those engaged directly by PTH or $1,25(OH)_2D$, by which serum ionized calcium can control renal calcium reabsorption. Finally, ~10% of filtered calcium is reabsorbed in the distal convoluted tubules (DCTs) by a transcellular mechanism. Calcium enters the luminal surface of the cell through specific apical calcium channels (TRPV5), whose number is regulated. It then moves across the cell in association with a specific calcium-binding protein (calbindin-D28k) that buffers cytosolic calcium concentrations from the large mass of transported calcium. Ca^{2+}-ATPases and Na^+/Ca^{2+} exchangers actively extrude calcium across the basolateral surface and thereby maintain the transcellular calcium gradient. All these processes are stimulated directly or indirectly by PTH. The DCT is also the site of action of thiazide diuretics, which lower urinary calcium excretion by inducing sodium depletion and thereby augmenting proximal calcium reabsorption. Conversely, dietary sodium loads, or increased distal sodium delivery caused by loop diuretics or saline infusion, induce calciuresis.

The homeostatic mechanisms that normally maintain a constant serum ionized calcium concentration may fail at extremes of calcium intake or when the hormonal systems or organs involved are compromised. Thus, even with maximal activity of the vitamin D–dependent intestinal active transport system, sustained calcium intakes <5 mmol/d (<200 mg/d) cannot provide enough net calcium absorption to replace obligate losses via the intestine, the kidney, sweat, and other secretions. In this case, increased blood levels of PTH and $1,25(OH)_2D$ activate osteoclastic bone resorption to obtain needed calcium from bone, which leads to progressive bone loss and negative calcium balance. Increased PTH and $1,25(OH)_2D$ also enhance renal calcium reabsorption, and $1,25(OH)_2D$ enhances calcium absorption in the gut. At very high calcium intakes (>100 mmol/d [>4 g/d]), passive intestinal absorption continues to deliver calcium into the ECF despite maximally downregulated intestinal active transport and renal tubular calcium reabsorption. This can cause severe hypercalciuria, nephrocalcinosis, progressive renal failure, and hypercalcemia (e.g., "milk-alkali syndrome"). Deficiency or excess of PTH or vitamin D, intestinal disease, and renal failure represent other commonly encountered challenges to normal calcium homeostasis (Chap. 410).

PHOSPHORUS METABOLISM

Although 85% of the ~600 g of body phosphorus is present in bone mineral, phosphorus is also a major intracellular constituent both as the free anion(s) and as a component of numerous organophosphate compounds, including structural proteins, enzymes, transcription

factors, carbohydrate and lipid intermediates, high-energy stores (ATP [adenosine triphosphate], creatine phosphate), and nucleic acids. Unlike calcium, phosphorus exists intracellularly at concentrations close to those present in ECF (e.g., 1–2 mmol/L). In cells and in the ECF, phosphorus exists in several forms, predominantly as $H_2PO_4^-$ or $NaHPO_4^-$, with perhaps 10% as HPO_4^{2-}. This mixture of anions will be referred to here as "phosphate." In serum, ~12% of phosphorus is bound to proteins. Concentrations of phosphates in blood and ECF generally are expressed in terms of elemental phosphorus, with the normal range in adults being 0.75–1.45 mmol/L (2.5–4.5 mg/dL). Because the volume of the intracellular fluid compartment is twice that of the ECF, measurements of ECF phosphate may not accurately reflect phosphate availability within cells that follows even modest shifts of phosphate from one compartment to the other.

Phosphate is widely available in foods and is absorbed efficiently (65%) by the small intestine even in the absence of vitamin D. However, phosphate absorptive efficiency may be enhanced (to 85–90%) via active transport mechanisms that are stimulated by $1,25(OH)_2D$. These mechanisms involve activation of Na^+/PO_4^{2-} co-transporters, such as Npt2b, that move phosphate into intestinal cells against an unfavorable electrochemical gradient. Daily net intestinal phosphate absorption varies widely with the composition of the diet but is generally in the range of 500–1000 mg/d. Phosphate absorption can be inhibited by large doses of calcium salts or by sevelamer hydrochloride (Renagel), strategies commonly used to control levels of serum phosphate in renal failure. Aluminum hydroxide antacids also reduce phosphate absorption but are used less commonly because of the potential for aluminum toxicity. Low serum phosphate stimulates renal proximal tubular synthesis of $1,25(OH)_2D$, perhaps by suppressing blood levels of FGF23 (see below).

Serum phosphate levels vary by as much as 50% on a normal day. This reflects the effect of food intake but also an underlying circadian rhythm that produces a nadir between 7 and 10 A.M. Carbohydrate administration, especially as IV dextrose solutions in fasting subjects, can decrease serum phosphate by >0.7 mmol/L (2 mg/dL) during treatment of ketoacidosis or during metabolic or respiratory alkalosis. Because of this wide variation in serum phosphate, it is best to perform measurements in the basal, fasting state.

Control of serum phosphate is determined mainly by the rate of renal tubular reabsorption of the filtered load, which is ~4–6 g/d. Because intestinal phosphate absorption is highly efficient, urinary excretion is not constant but varies directly with dietary intake. The fractional excretion of phosphate (ratio of phosphate to creatinine clearance) is generally in the range of 10–15%. The proximal tubule is the principal site at which renal phosphate reabsorption is regulated. This is accomplished by changes in the levels of apical expression and activity of specific Na^+/PO_4^{2-} co-transporters (NaPi-2a and NaPi-2c) in the proximal tubule. Levels of these transporters at the apical surface of these cells are reduced rapidly by PTH, a major hormonal regulator of renal phosphate excretion. FGF23 can impair phosphate reabsorption dramatically by a similar mechanism. Activating *FGF23* mutations cause the rare disorder autosomal dominant hypophosphatemic rickets (ADHR). In contrast to PTH, FGF23 also leads to reduced synthesis of $1,25(OH)_2D$, which may worsen the resulting hypophosphatemia by lowering intestinal phosphate absorption. Renal reabsorption of phosphate is responsive to changes in dietary intake such that experimental dietary phosphate restriction leads to a dramatic lowering of urinary phosphate within hours, preceding any decline in serum phosphate (e.g., filtered load). This physiologic renal adaptation to changes in dietary phosphate availability occurs independently of PTH and may be mediated in part by changes in levels of serum FGF23. Findings in *FGF23*-knockout mice suggest that FGF23 normally acts to lower blood phosphate and $1,25(OH)_2D$ levels. In turn, elevation of blood phosphate increases blood levels of FGF23.

Renal phosphate reabsorption is impaired by hypocalcemia, hypomagnesemia, and severe hypophosphatemia. Phosphate clearance is enhanced by ECF volume expansion and impaired by dehydration. Phosphate retention is an important pathophysiologic feature of renal insufficiency **(Chap. 311)**.

HYPOPHOSPHATEMIA

Causes Hypophosphatemia can occur by one or more of three primary mechanisms: (1) inadequate intestinal phosphate absorption, (2) excessive renal phosphate excretion, and (3) rapid redistribution of phosphate from the ECF into bone or soft tissue **(Table 409-1)**. Because phosphate is so abundant in foods, inadequate intestinal absorption is almost never observed now that aluminum hydroxide antacids, which bind phosphate in the gut, are no longer widely used. Fasting or starvation, however, may result in depletion of body phosphate and predispose to subsequent hypophosphatemia during refeeding, especially if this is accomplished with IV glucose alone.

Chronic hypophosphatemia usually signifies the presence of a persistent renal tubular phosphate-wasting disorder. Excessive activation of PTH/PTHrP receptors in the proximal tubule as a result of primary or secondary hyperparathyroidism or because of the PTHrP-mediated hypercalcemia syndrome in malignancy **(Chap. 410)** is among the more common causes of renal hypophosphatemia. Familial hypocalciuric hypercalcemia and Jansen's chondrodystrophy are rare examples of genetic disorders in this category **(Chap. 410)**.

Several genetic and acquired diseases cause PTH/PTHrP receptor-independent tubular phosphate wasting with associated rickets and osteomalacia. All these diseases manifest severe hypophosphatemia; renal phosphate wasting, sometimes accompanied by aminoaciduria; inappropriately low blood levels of $1,25(OH)_2D$; low-normal serum levels of calcium; and evidence of impaired cartilage or bone mineralization. Analysis of these diseases led to the discovery of the hormone FGF23, which is an important physiologic regulator of phosphate metabolism. FGF23 decreases phosphate reabsorption in the proximal tubule and also suppresses the 1α-hydroxylase responsible for synthesis of $1,25(OH)_2D$. FGF23 is synthesized by cells of the osteoblast lineage, primarily osteocytes. High-phosphate diets increase FGF23 levels, and low-phosphate diets decrease them. ADHR was the first disease linked to abnormalities in FGF23. ADHR results from activating mutations in the gene that encodes FGF23. These mutations alter a cleavage site that ordinarily allows for inactivation of intact FGF23. Several other genetic disorders feature elevated FGF23 and hypophosphatemia. The most common of these is X-linked hypophosphatemic rickets (XLH), which results from inactivating mutations in an endopeptidase termed *PHEX* (*p*hosphate-regulating gene with *h*omologies to *e*ndopeptidases on the *X* chromosome) that is expressed most abundantly on the surface of osteocytes and mature osteoblasts. Patients with XLH usually have high FGF23 levels, and ablation of the *FGF23* gene reverses the hypophosphatemia found in the mouse version of XLH. How inactivation of PHEX leads to increased levels of FGF23 has not been determined. Two rare autosomal recessive hypophosphatemic syndromes associated with elevated FGF23 are due to inactivating mutations of dentin matrix protein 1 (DMP1) and ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1), respectively, both of which normally are highly expressed in bone and presumably regulate FGF23 production. An unusual hypophosphatemic disorder, tumor-induced osteomalacia (TIO), is an acquired disorder in which tumors, usually of mesenchymal origin and generally histologically benign, secrete FGF23 that induces renal phosphate wasting. The hypophosphatemic syndrome resolves completely within hours to days after successful resection of the responsible tumor. Such tumors typically express large amounts of FGF23 mRNA, and patients with TIO usually exhibit elevations of FGF23 in their blood.

Dent's disease is an X-linked recessive disorder caused by inactivating mutations in *CLCN5*, a chloride transporter expressed in endosomes of the proximal tubule; features include hypercalciuria, hypophosphatemia, and recurrent kidney stones. Renal phosphate wasting is common among poorly controlled diabetic patients and alcoholics, who therefore are at risk for iatrogenic hypophosphatemia when treated with insulin or IV glucose, respectively. Diuretics and certain other drugs and toxins can cause defective renal tubular phosphate reabsorption (Table 409-1).

In hospitalized patients, hypophosphatemia is often attributable to massive redistribution of phosphate from the ECF into cells. Insulin

TABLE 409-1 Causes of Hypophosphatemia

I. Reduced renal tubular phosphate reabsorption
- A. PTH/PTHrP-dependent
  1. Primary hyperparathyroidism
  2. Secondary hyperparathyroidism
     - a. Vitamin D deficiency/resistance
     - b. Calcium starvation/malabsorption
     - c. Bartter's syndrome
     - d. Autosomal recessive renal hypercalciuria with hypomagnesemia
  3. PTHrP-dependent hypercalcemia of malignancy
  4. Familial hypocalciuric hypercalcemia
- B. PTH/PTHrP-independent
  1. Excess FGF23 or other "phosphatonins"
     - a. X-linked hypophosphatemic rickets (XLH)
     - b. Autosomal recessive hypophosphatemia (ARHP)
     - c. Autosomal recessive hypophosphatemic rickets (ARHR) (DMP1, ENPP1 deficiency)
     - d. Tumor-induced osteomalacia syndrome (TIO)
     - e. McCune-Albright syndrome (fibrous dysplasia)
     - f. Epidermal nevus syndrome
  2. Intrinsic renal disease
     - a. Fanconi's syndrome(s)
     - b. Cystinosis
     - c. Wilson's disease
     - d. NaPi-2a or NaPi-2c mutations
  3. Other systemic disorders
     - a. Poorly controlled diabetes mellitus
     - b. Alcoholism
     - c. Hyperaldosteronism
     - d. Hypomagnesemia
     - e. Amyloidosis
     - f. Hemolytic-uremic syndrome
     - g. Renal transplantation or partial liver resection
     - h. Rewarming or induced hyperthermia
  4. Drugs or toxins
     - a. Ethanol
     - b. Acetazolamide, other diuretics
     - c. High-dose estrogens or glucocorticoids
     - d. Heavy metals (lead, cadmium, saccharated ferric oxide)
     - e. Toluene, *N*-methyl formamide
     - f. Cisplatin, ifosfamide, foscarnet, rapamycin

II. Impaired intestinal phosphate absorption
- A. Aluminum-containing antacids
- B. Sevelamer

III. Shifts of extracellular phosphate into cells
- A. Intravenous glucose
- B. Insulin therapy for prolonged hyperglycemia or diabetic ketoacidosis
- C. Catecholamines (epinephrine, dopamine, albuterol)
- D. Acute respiratory alkalosis
- E. Gram-negative sepsis, toxic shock syndrome
- F. Recovery from starvation or acidosis
- G. Rapid cellular proliferation
  1. Leukemic blast crisis
  2. Intensive erythropoietin, other growth factor therapy

IV. Accelerated net bone formation
- A. After parathyroidectomy
- B. Treatment of vitamin D deficiency, Paget's disease
- C. Osteoblastic metastases

Abbreviations: PTH, parathyroid hormone; PTHrP, parathyroid hormone–related peptide.

therapy for diabetic ketoacidosis is a paradigm for this phenomenon, in which the severity of the hypophosphatemia is related to the extent of antecedent depletion of phosphate and other electrolytes **(Chap. 404)**. The hypophosphatemia is usually greatest at a point many hours after initiation of insulin therapy and is difficult to predict from baseline measurements of serum phosphate at the time of presentation, when prerenal azotemia can obscure significant phosphate depletion. Other factors that may contribute to such acute redistributive hypophosphatemia include antecedent starvation or malnutrition, administration of IV glucose without other nutrients, elevated blood catecholamines (endogenous or exogenous), respiratory alkalosis, and recovery from metabolic acidosis.

Hypophosphatemia also can occur transiently (over weeks to months) during the phase of accelerated net bone formation that follows parathyroidectomy for severe primary hyperparathyroidism or during treatment of vitamin D deficiency or lytic Paget's disease. This is usually most prominent in patients who preoperatively have evidence of high bone turnover (e.g., high serum levels of alkaline phosphatase). Osteoblastic metastases can also lead to this syndrome.

Clinical and Laboratory Findings The clinical manifestations of severe hypophosphatemia reflect a generalized defect in cellular energy metabolism because of ATP depletion, a shift from oxidative phosphorylation toward glycolysis, and associated tissue or organ dysfunction. Acute, severe hypophosphatemia occurs mainly or exclusively in hospitalized patients with underlying serious medical or surgical illness and preexisting phosphate depletion due to excessive urinary losses, severe malabsorption, or malnutrition. Chronic hypophosphatemia tends to be less severe, with a clinical presentation dominated by musculoskeletal complaints such as bone pain, osteomalacia, pseudofractures, and proximal muscle weakness or, in children, rickets and short stature.

Neuromuscular manifestations of severe hypophosphatemia are variable but may include muscle weakness, lethargy, confusion, disorientation, hallucinations, dysarthria, dysphagia, oculomotor palsies, anisocoria, nystagmus, ataxia, cerebellar tremor, ballismus, hyporeflexia, impaired sphincter control, distal sensory deficits, paresthesia, hyperesthesia, generalized or Guillain-Barré–like ascending paralysis, seizures, coma, and even death. Serious sequelae such as paralysis, confusion, and seizures are likely only at phosphate concentrations <0.25 mmol/L (<0.8 mg/dL). Rhabdomyolysis may develop during rapidly progressive hypophosphatemia. The diagnosis of hypophosphatemia-induced rhabdomyolysis may be overlooked, as up to 30% of patients with acute hypophosphatemia (<0.7 m*M*) have creatine phosphokinase elevations that peak 1–2 days after the nadir in serum phosphate, when the release of phosphate from injured myocytes may have led to a near normalization of circulating levels of phosphate.

Respiratory failure and cardiac dysfunction, which are reversible with phosphate treatment, may occur at serum phosphate levels of 0.5–0.8 mmol/L (1.5–2.5 mg/dL). Renal tubular defects, including tubular acidosis, glycosuria, and impaired reabsorption of sodium and calcium, may occur. Hematologic abnormalities correlate with reductions in intracellular ATP and 2,3-diphosphoglycerate and may include erythrocyte microspherocytosis and hemolysis; impaired oxyhemoglobin dissociation; defective leukocyte chemotaxis, phagocytosis, and bacterial killing; and platelet dysfunction with spontaneous gastrointestinal hemorrhage.

TREATMENT

Hypophosphatemia

Severe hypophosphatemia (<0.75 mmol/L [<2 mg/dL]), particularly in the setting of underlying phosphate depletion, constitutes a dangerous electrolyte abnormality that should be corrected promptly. Unfortunately, the cumulative deficit in body phosphate cannot be predicted directly from knowledge of the circulating level of phosphate, and therapy must be approached empirically. The threshold for IV phosphate therapy and consequently the dose of phosphate to be administered should reflect consideration of renal function, the likely severity and duration of the underlying phosphate depletion,

TABLE 409-2 Intravenous Therapy for Hypophosphatemia

CONSIDER			
Likely severity of underlying phosphate depletion			
Concurrent parenteral glucose administration			
Presence of neuromuscular, cardiopulmonary, or hematologic complications of hypophosphatemia			
Renal function (reduce dose by 50% if serum creatinine >220 μmol/L [>2.5 mg/dL])			
Serum calcium level (correct hypocalcemia first; reduce dose by 50% in hypercalcemia)			
Guidelines			
SERUM PHOSPHORUS, MM (MG/DL)	**RATE OF INFUSION, MMOL/H**	**DURATION, H**	**TOTAL ADMINISTERED, MMOL**
<0.8 (<2.5)	2	6	12
<0.5 (<1.5)	4	6	24
<0.3 (<1)	8	6	48

Note: Rates shown are calculated for a 70-kg person; levels of serum calcium and phosphorus must be measured every 6–12 h during therapy; infusions can be repeated to achieve stable serum phosphorus levels >0.8 mmol/L (>2.5 mg/dL); most formulations available in the United States provide 3 mmol/mL of sodium or potassium phosphate.

and the presence and severity of symptoms consistent with those of hypophosphatemia. In adults, phosphate may be safely administered IV as neutral mixtures of sodium or potassium phosphate salts at initial doses of 0.2–0.8 mmol/kg of elemental phosphorus over 6 h (e.g., 10–50 mmol over 6 h), with doses >20 mmol/6 h reserved for those who have serum levels <0.5 mmol/L (1.5 mg/dL) and normal renal function. A suggested approach is presented in Table 409-2. Serum levels of phosphate and calcium must be monitored closely (every 6–12 h) throughout treatment. It is necessary to avoid a serum calcium-phosphorus product >50 mg^2/dL^2 to reduce the risk of heterotopic calcification. Hypocalcemia, if present, should be corrected before administering IV phosphate. Less severe hypophosphatemia, in the range of 0.5–0.8 mmol/L (1.5–2.5 mg/dL), usually can be treated with oral phosphate in divided doses of 750–2000 mg/d as elemental phosphorus; higher doses can cause bloating and diarrhea.

Management of chronic hypophosphatemia requires knowledge of the cause(s) of the disorder. Hypophosphatemia related to the secondary hyperparathyroidism of vitamin D deficiency usually responds to treatment with vitamin D and calcium alone. XLH, ADHR, TIO, and related renal tubular disorders usually are managed with divided oral doses of phosphate, often with calcium and $1,25(OH)_2D$ supplements to bypass the block in renal $1,25(OH)_2D$ synthesis and prevent secondary hyperparathyroidism caused by suppression of ECF calcium levels. Care must be taken to be sure that oral calcium and phosphate are not administered at the same time, to avoid precipitation before absorption. Thiazide diuretics may be used to prevent nephrocalcinosis in patients who are managed this way. Complete normalization of hypophosphatemia is generally not possible in these conditions. Burosumab, a human monoclonal antibody that inhibits FGF23, has been approved for the treatment of XLH. It corrects hypophosphatemia, improves bone pain, and heals fractures in both adults and children.

Optimal therapy for TIO is extirpation of the responsible tumor, which may be localized by radiographic skeletal survey or bone scan (many are located in bone) or by radionuclide scanning using sestamibi or labeled octreotide. Successful treatment of TIO-induced hypophosphatemia with octreotide has been reported in a small number of patients. Burosumab treatment, originally used for XLH, also shows promise as a treatment for TIO.

HYPERPHOSPHATEMIA

Causes When the filtered load of phosphate and glomerular filtration rate (GFR) are normal, control of serum phosphate levels is achieved by adjusting the rate at which phosphate is reabsorbed by the proximal tubular NaPi-2 co-transporters. The principal hormonal regulators of NaPi-2 activity are PTH and FGF23. Hyperphosphatemia, defined in adults as a fasting serum phosphate concentration >1.8 mmol/L (5.5 mg/dL), usually results from impaired glomerular filtration, hypoparathyroidism, excessive delivery of phosphate into the ECF (from bone, gut, or parenteral phosphate therapy), or a combination of these factors (Table 409-3). The upper limit of normal serum phosphate concentrations is higher in children and neonates (2.4 mmol/L [7 mg/dL]). It is useful to distinguish hyperphosphatemia caused by impaired renal phosphate excretion from that which results from excessive delivery of phosphate into the ECF (Table 409-3).

TABLE 409-3 Causes of Hyperphosphatemia

- I. Impaired renal phosphate excretion
  - A. Renal insufficiency
  - B. Hypoparathyroidism
    1. Developmental
    2. Autoimmune
    3. After neck surgery or radiation
    4. Activating mutations of the calcium-sensing receptor
  - C. Parathyroid suppression
    1. Parathyroid-independent hypercalcemia
       a. Vitamin D or vitamin A intoxication
       b. Sarcoidosis, other granulomatous diseases
       c. Immobilization, osteolytic metastases
       d. Milk-alkali syndrome
    2. Severe hypermagnesemia or hypomagnesemia
  - D. Pseudohypoparathyroidism
  - E. Acromegaly
  - F. Tumoral calcinosis
  - G. Heparin therapy
- II. Massive extracellular fluid phosphate loads
  - A. Rapid administration of exogenous phosphate (intravenous, oral, rectal)
  - B. Extensive cellular injury or necrosis
    1. Crush injuries
    2. Rhabdomyolysis
    3. Hyperthermia
    4. Fulminant hepatitis
    5. Cytotoxic therapy
    6. Severe hemolytic anemia
  - C. Transcellular phosphate shifts
    1. Metabolic acidosis
    2. Respiratory acidosis

In chronic renal insufficiency, reduced GFR leads to phosphate retention. Hyperphosphatemia in turn further impairs renal synthesis of $1,25(OH)_2D$, increases FGF23 levels, and stimulates PTH secretion and parathyroid gland hypertrophy both directly and indirectly (by lowering blood ionized calcium levels). Thus, hyperphosphatemia is a major cause of the secondary hyperparathyroidism of renal failure and must be addressed early in the course of the disease (Chaps. 311 and 410).

Hypoparathyroidism leads to hyperphosphatemia via increased expression of NaPi-2 co-transporters in the proximal tubule. Hypoparathyroidism, or parathyroid suppression, has multiple potential causes, including autoimmune disease; developmental, surgical, or radiation-induced absence of functional parathyroid tissue; vitamin D intoxication or other causes of PTH-independent hypercalcemia; cellular PTH resistance (pseudohypoparathyroidism or hypomagnesemia); infiltrative disorders such as Wilson's disease and hemochromatosis; and impaired PTH secretion caused by hypermagnesemia, severe hypomagnesemia, or activating mutations in the CaSR. Hypocalcemia may also contribute directly to impaired phosphate clearance, as calcium infusion can induce phosphaturia in hypoparathyroid subjects. Increased tubular phosphate reabsorption also occurs in acromegaly, during heparin administration, and in tumoral calcinosis. Tumoral

calcinosis is caused by a rare group of genetic disorders in which FGF23 is processed in a way that leads to low levels of active FGF23 in the bloodstream. This may result from mutations in the FGF23 sequence or via inactivating mutations in the *GALNT3* gene, which encodes a galactosaminyl transferase that normally adds sugar residues to FGF23 that slow its proteolysis. A similar syndrome results from FGF23 resistance due to inactivating mutations of the FGF23 co-receptor Klotho. These abnormalities cause elevated serum $1,25(OH)_2D$, parathyroid suppression, increased intestinal calcium absorption, and focal hyperostosis with large, lobulated periarticular heterotopic ossifications (especially at shoulders or hips) and are accompanied by hyperphosphatemia. In some forms of tumoral calcinosis, serum phosphorus levels are normal.

When large amounts of phosphate are delivered rapidly into the ECF, hyperphosphatemia can occur despite normal renal function. Examples include overzealous IV phosphate therapy, oral or rectal administration of large amounts of phosphate-containing laxatives or enemas (especially in children), extensive soft tissue injury or necrosis (crush injuries, rhabdomyolysis, hyperthermia, fulminant hepatitis, cytotoxic chemotherapy), extensive hemolytic anemia, and transcellular phosphate shifts induced by severe metabolic or respiratory acidosis.

Clinical Findings The clinical consequences of acute, severe hyperphosphatemia are due mainly to the formation of widespread calcium phosphate precipitates and resulting hypocalcemia. Thus, tetany, seizures, accelerated nephrocalcinosis (with renal failure, hyperkalemia, hyperuricemia, and metabolic acidosis), and pulmonary or cardiac calcifications (including development of acute heart block) may occur. The severity of these complications relates to the elevation of serum phosphate levels, which can reach concentrations as high as 7 mmol/L (20 mg/dL) in instances of massive soft tissue injury or tumor lysis syndrome.

TREATMENT

Hyperphosphatemia

Therapeutic options for management of severe hyperphosphatemia are limited. Volume expansion may enhance renal phosphate clearance. Aluminum hydroxide antacids or sevelamer may be helpful in chelating and limiting absorption of offending phosphate salts present in the intestine. Hemodialysis is the most effective therapeutic strategy and should be considered early in the course of severe hyperphosphatemia, especially in the setting of renal failure and symptomatic hypocalcemia.

MAGNESIUM METABOLISM

Magnesium is the major intracellular divalent cation. Normal concentrations of extracellular magnesium and calcium are crucial for normal neuromuscular activity. Intracellular magnesium forms a key complex with ATP and is an important cofactor for a wide range of enzymes, transporters, and nucleic acids required for normal cellular function, replication, and energy metabolism. The concentration of magnesium in serum is closely regulated within the range of 0.7–1 mmol/L (1.5–2 meq/L; 1.7–2.4 mg/dL), of which 30% is protein-bound and another 15% is loosely complexed to phosphate and other anions. One-half of the 25 g (1000 mmol) of total body magnesium is located in bone, only one-half of which is insoluble in the mineral phase. Almost all extraskeletal magnesium is present within cells, where the total concentration is 5 m*M*, 95% of which is bound to proteins and other macromolecules. Because only 1% of body magnesium resides in the ECF, measurements of serum magnesium levels may not accurately reflect the level of total body magnesium stores.

Dietary magnesium content normally ranges from 6 to 15 mmol/d (140–360 mg/d), of which 30–40% is absorbed, mainly in the jejunum and ileum. Intestinal magnesium absorptive efficiency is stimulated by $1,25(OH)_2D$ and can reach 70% during magnesium deprivation. Urinary magnesium excretion normally matches net intestinal absorption and is ~4 mmol/d (100 mg/d). Regulation of serum magnesium concentrations is achieved mainly by control of renal magnesium reabsorption. Only 20% of filtered magnesium is reabsorbed in the proximal tubule, whereas 60% is reclaimed in the cTAL and another 5–10% in the DCT. Magnesium reabsorption in the cTAL occurs via a paracellular route that requires both a lumen-positive potential, created by NaCl reabsorption, and tight-junction proteins encoded by members of the Claudin gene family. Magnesium reabsorption in the cTAL is increased by PTH but inhibited by hypercalcemia or hypermagnesemia, both of which activate the CaSR in this nephron segment.

HYPOMAGNESEMIA

Causes Hypomagnesemia usually signifies substantial depletion of body magnesium stores (0.5–1 mmol/kg). Hypomagnesemia can result from intestinal malabsorption; protracted vomiting, diarrhea, or intestinal drainage; defective renal tubular magnesium reabsorption; or rapid shifts of magnesium from the ECF into cells, bone, or third spaces (Table 409-4). Dietary magnesium deficiency is unlikely except possibly in the setting of alcoholism. A rare genetic disorder that causes selective intestinal magnesium malabsorption has been described (primary infantile hypomagnesemia). Another rare inherited disorder (hypomagnesemia with secondary hypocalcemia) is caused by mutations in the gene encoding TRPM6, a protein that, along with TRPM7, forms a channel important for both intestinal and distal-tubular renal transcellular magnesium transport. Malabsorptive states, often compounded by vitamin D deficiency, can critically limit magnesium absorption and produce hypomagnesemia despite the compensatory effects of secondary hyperparathyroidism and of hypocalcemia and hypomagnesemia to enhance cTAL magnesium reabsorption. Diarrhea or surgical drainage fluid may contain ≥5 mmol/L of magnesium. Proton pump inhibitors (omeprazole and others) may produce hypomagnesemia by an unknown mechanism that does not involve renal wasting of magnesium.

Several genetic magnesium-wasting syndromes have been described, including inactivating mutations of genes encoding the DCT NaCl co-transporter (Gitelman's syndrome), proteins required for cTAL Na-K-2Cl transport (Bartter's syndrome), claudin 16 or claudin 19 (autosomal recessive renal hypomagnesemia with hypercalciuria), a DCT Na^+,K^+-ATPase γ-subunit (autosomal dominant renal hypomagnesemia with hypocalciuria), DCT K^+ channels (Kv1.1, Kir4.1), and a mitochondrial gene encoding a tRNA. Activating mutations of the CaSR can cause hypomagnesemia as well as hypocalcemia. ECF expansion, hypercalcemia, and severe phosphate depletion may impair magnesium reabsorption, as can various forms of renal injury, including those caused by drugs such as cisplatin, cyclosporine, aminoglycosides, and pentamidine as well as the epidermal growth factor (EGF) receptor inhibitory antibody cetuximab (EGF action is required for normal DCT apical expression of TRPM6) (Table 409-4). A rising blood concentration of ethanol directly impairs tubular magnesium reabsorption, and persistent glycosuria with osmotic diuresis leads to magnesium wasting and probably contributes to the high frequency of hypomagnesemia in poorly controlled diabetic patients. Magnesium depletion is aggravated by metabolic acidosis, which causes intracellular losses as well.

Hypomagnesemia due to rapid shifts of magnesium from ECF into the intracellular compartment can occur during recovery from diabetic ketoacidosis, starvation, or respiratory acidosis. Less acute shifts may be seen during rapid bone formation after parathyroidectomy, with treatment of vitamin D deficiency, or with osteoblastic metastases. Large amounts of magnesium may be lost with acute pancreatitis, extensive burns, or protracted and severe sweating and during pregnancy and lactation.

Clinical and Laboratory Findings Hypomagnesemia may cause generalized alterations in neuromuscular function, including tetany, tremor, seizures, muscle weakness, ataxia, nystagmus, vertigo, apathy, depression, irritability, delirium, and psychosis. Patients are usually asymptomatic when serum magnesium concentrations are >0.5 mmol/L (1 meq/L; 1.2 mg/dL), although the severity of symptoms may not correlate well with serum magnesium levels. arrhythmias may occur, including sinus tachycardia, other supraventricular tachycardias, and ventricular arrhythmias. Electrocardiographic abnormalities may include prolonged PR or QT intervals, T-wave flattening or inversion, and ST straightening. Sensitivity to digitalis toxicity may be enhanced.

Other electrolyte abnormalities often seen with hypomagnesemia, including hypocalcemia (with hypocalciuria) and hypokalemia, may not be easily corrected unless magnesium is administered as well. The hypocalcemia may be a result of concurrent vitamin D deficiency, although hypomagnesemia can cause impaired synthesis of $1,25(OH)_2D$, cellular resistance to PTH, and, at very low serum magnesium (<0.4 mmol/L [<0.8 meq/L; <1 mg/dL]), a defect in PTH secretion; these abnormalities are reversible with therapy.

TREATMENT

Hypomagnesemia

Mild, asymptomatic hypomagnesemia may be treated with oral magnesium salts ($MgCl_2$, MgO, $Mg[OH]_2$) in divided doses totaling 20–30 mmol/d (40–60 meq/d). Diarrhea may occur with larger doses. More severe hypomagnesemia should be treated parenterally, preferably with IV $MgCl_2$, which can be administered safely as a continuous infusion of 50 mmol/d (100 meq Mg^{2+}/d) if renal function is normal. If GFR is reduced, the infusion rate should be lowered by 50–75%. Use of IM $MgSO_4$ is discouraged; the injections are painful and provide relatively little magnesium (2 mL of 50% $MgSO_4$ supplies only 4 mmol). $MgSO_4$ may be given IV instead of $MgCl_2$, although the sulfate anions may bind calcium in serum and urine and aggravate hypocalcemia. Serum magnesium should be monitored at intervals of 12–24 h during therapy, which may continue for several days because of impaired renal conservation of magnesium (only 50–70% of the daily IV magnesium dose is retained) and delayed repletion of intracellular deficits, which may be as high as 1–1.5 mmol/kg (2–3 meq/kg).

It is important to consider the need for calcium, potassium, and phosphate supplementation in patients with hypomagnesemia. Vitamin D deficiency frequently coexists and should be treated with oral or parenteral vitamin D or 25(OH)D (but not with $1,25(OH)_2D$, which may impair tubular magnesium reabsorption, possibly via PTH suppression). In severely hypomagnesemic patients with concomitant hypocalcemia and hypophosphatemia, administration of IV magnesium alone may worsen hypophosphatemia, provoking neuromuscular symptoms or rhabdomyolysis, due to rapid stimulation of previously suppressed PTH secretion. This is avoided by administering both calcium and magnesium.

HYPERMAGNESEMIA

Causes Hypermagnesemia is rarely seen in the absence of renal insufficiency as normal kidneys can excrete large amounts (250 mmol/d) of magnesium. Mild hypermagnesemia due to excessive reabsorption in the cTAL occurs with CaSR mutations in familial hypocalciuric hypercalcemia and has been described in some patients with adrenal insufficiency, hypothyroidism, or hypothermia. Massive exogenous magnesium exposures, usually via the gastrointestinal tract, can overwhelm renal excretory capacity and cause life-threatening hypermagnesemia (Table 409-5). A notable example of this is prolonged retention of even normal amounts of magnesium-containing cathartics in patients with intestinal ileus, obstruction, or perforation. Extensive soft tissue injury or necrosis also can deliver large amounts of magnesium into the ECF in patients who have suffered trauma, shock,

sepsis, cardiac arrest, or severe burns. Further, infusion of magnesium in pregnant women with eclampsia can lead to hypocalcemia.

Clinical and Laboratory Findings The most prominent clinical manifestations of hypermagnesemia are vasodilation and neuromuscular blockade, which may appear at serum magnesium concentrations >2 mmol/L (>4 meq/L; >4.8 mg/dL). Hypotension that is refractory to vasopressors or volume expansion may be an early sign. Nausea, lethargy, and weakness may progress to respiratory failure, paralysis, and coma, with hypoactive tendon reflexes, at serum magnesium levels >4 mmol/L. Other findings may include gastrointestinal hypomotility or ileus; facial flushing; pupillary dilation; paradoxical bradycardia; prolongation of PR, QRS, and QT intervals; heart block; and, at serum magnesium levels approaching 10 mmol/L, asystole.

Hypermagnesemia, acting via the CaSR, causes hypocalcemia and hypercalciuria due to both parathyroid suppression and impaired cTAL calcium reabsorption.

TREATMENT

Hypermagnesemia

Successful treatment of hypermagnesemia generally involves identifying and interrupting the source(s) of magnesium and employing measures to increase magnesium clearance from the ECF. Use of magnesium-free cathartics or enemas may be helpful in clearing ingested magnesium from the gastrointestinal tract. Vigorous IV hydration should be attempted, if appropriate. Hemodialysis is effective and may be required in patients with significant renal insufficiency. Calcium, administered IV in doses of 100–200 mg over 1–2 h, has been reported to provide temporary improvement in signs and symptoms of hypermagnesemia.

VITAMIN D

SYNTHESIS AND METABOLISM

1,25-Dihydroxyvitamin D [1,25(OH)$_2$D] is the major steroid hormone involved in regulation of mineral ion homeostasis. Vitamin D and its metabolites are hormones and hormone precursors rather than vitamins, since in the proper biologic setting, they can be synthesized endogenously (Fig. 409-4). In response to ultraviolet radiation of the skin, a photochemical cleavage results in the formation of vitamin D from 7-dehydrocholesterol. Cutaneous production of vitamin D is decreased by melanin and high solar protection factor sunblocks, which effectively impair skin penetration by ultraviolet light. The increased use of sunblocks in North America and Western Europe and a reduction in the magnitude of solar exposure of the general population over the past several decades has led to an increased reliance on dietary sources of vitamin D. In the United States and Canada, these sources largely consist of fortified cereals and dairy products, in addition to fish oils and egg yolks. Vitamin D from plant sources is in the form of vitamin D$_2$, whereas that from animal sources is vitamin D$_3$. These two forms have equivalent biologic activity and are activated equally well by the vitamin D hydroxylases in humans. Vitamin D enters the circulation, whether absorbed from the intestine or synthesized cutaneously, bound to vitamin D–binding protein, an α-globulin synthesized in the liver. Vitamin D is subsequently 25-hydroxylated in the liver by a cytochrome P450 oxidase in the mitochondria and microsomes. The activity of this hydroxylase is not tightly regulated, and the resultant metabolite, 25-hydroxyvitamin D [25(OH)D], is the major circulating and storage form of vitamin D. Approximately 88% of 25(OH)D circulates bound to the vitamin D–binding protein, 0.03% is free, and the rest circulates bound to albumin. The half-life of 25(OH)D is ~2–3 weeks, with that of 25(OH)D$_2$ being shorter than that of 25(OH)D$_3$ due to a lower affinity of vitamin D–binding protein for the former. The half-life of 25(OH)D is also greatly shortened when vitamin D–binding protein levels are reduced, as can occur with increased urinary losses in the nephrotic syndrome.

The second hydroxylation, required for the formation of the mature hormone, occurs in the kidney (Fig. 409-5). The 25-hydroxyvitamin

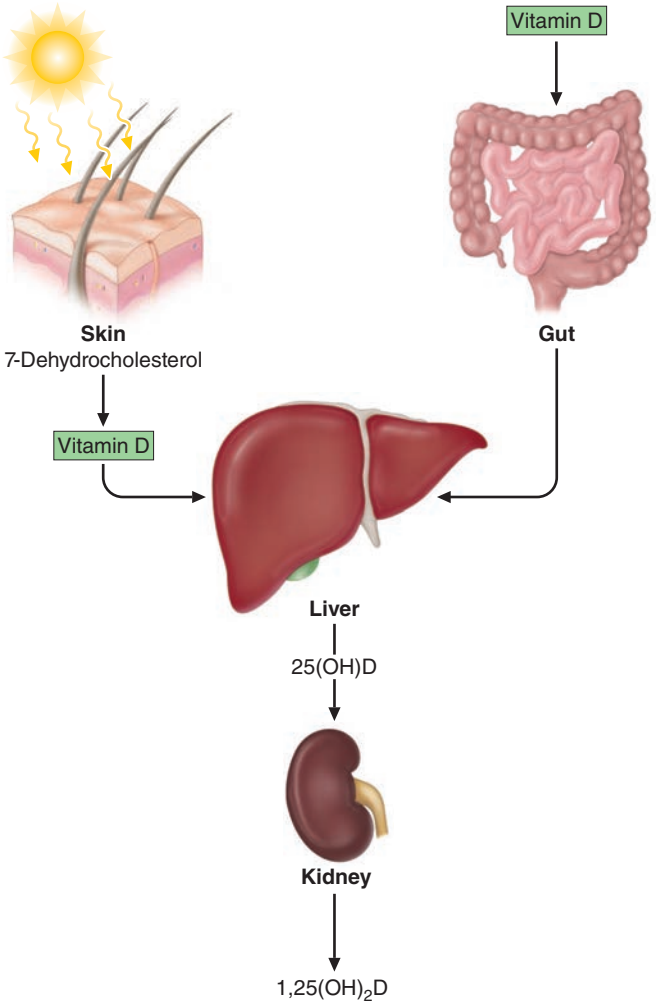

FIGURE 409-4 Vitamin D synthesis and activation. Vitamin D is synthesized in the skin in response to ultraviolet radiation and also is absorbed from the diet. It is then transported to the liver, where it undergoes 25-hydroxylation. This metabolite is the major circulating form of vitamin D. The final step in hormone activation, 1α-hydroxylation, occurs in the kidney.

D-1α-hydroxylase (encoded by the *CYP27B1* gene) is a tightly regulated cytochrome P450–like mixed-function oxidase expressed in the proximal convoluted tubule cells of the kidney. PTH and hypophosphatemia are the major inducers of this microsomal enzyme in the kidney, whereas calcium, FGF23, and the enzyme's product, 1,25(OH)$_2$D, repress it. The 25-hydroxyvitamin D-1α-hydroxylase is also present in numerous other cell types, where it is not subject to hormonal regulation. It is expressed in epidermal keratinocytes, but keratinocyte production of 1,25(OH)$_2$D is not thought to contribute to circulating levels of this hormone. In addition to being present in the trophoblastic layer of the placenta, the 1α-hydroxylase is produced by macrophages associated with granulomas and lymphomas. In these latter pathologic states, the activity of the enzyme is induced by interferon γ and TNF-α but is not regulated by calcium or 1,25(OH)$_2$D; therefore, hypercalcemia, associated with elevated levels of 1,25(OH)$_2$D, may be observed. Treatment of sarcoidosis-associated hypercalcemia with glucocorticoids, ketoconazole, or chloroquine reduces 1,25(OH)$_2$D production and effectively lowers serum calcium. In contrast, chloroquine has not been shown to lower the elevated serum 1,25(OH)$_2$D levels in patients with lymphoma.

The major pathway for inactivation of vitamin D metabolites is an additional hydroxylation step by the vitamin D 24-hydroxylase, an enzyme that is expressed in most tissues. 1,25(OH)$_2$D is the major inducer of this enzyme; therefore, this hormone promotes its own inactivation, thereby limiting its biologic effects. FGF23 also induces this hydroxylase, thereby reducing circulating 1,25(OH)$_2$D levels by increasing its inactivation, as well as by impairing its synthesis.

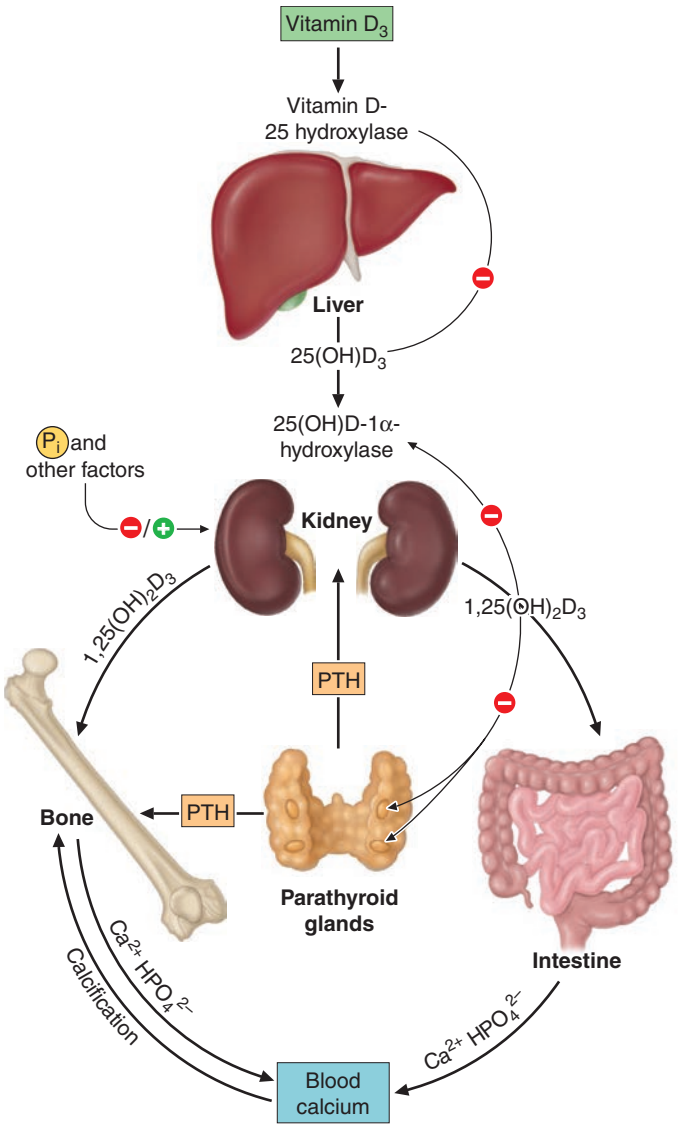

FIGURE 409-5 Schematic representation of the hormonal control loop for vitamin D metabolism and function. A reduction in the serum calcium below ~2.2 mmol/L (8.8 mg/dL) prompts a proportional increase in the secretion of parathyroid hormone (PTH) and so mobilizes additional calcium from the bone. PTH promotes the synthesis of 1,25$(OH)_2$D in the kidney, which in turn stimulates the mobilization of calcium from bone and intestine and regulates the synthesis of PTH by negative feedback.

Mutations of the gene encoding this enzyme (*CYP24A1*) can lead to infantile hypercalcemia, and in those less severely affected, long-standing hypercalciuria, nephrocalcinosis, and nephrolithiasis can occur.

Polar metabolites of 1,25$(OH)_2$D are secreted into the bile and reabsorbed via the enterohepatic circulation. Impairment of this recirculation, which is seen with diseases of the terminal ileum, leads to accelerated losses of vitamin D metabolites.

ACTIONS OF 1,25$(OH)_2$D

1,25$(OH)_2$D mediates its biologic effects by binding to a member of the nuclear receptor superfamily, the vitamin D receptor (VDR). This receptor belongs to the subfamily that includes the thyroid hormone receptors, the retinoid receptors, and the peroxisome proliferator–activated receptors; however, in contrast to the other members of this subfamily, only one VDR isoform has been isolated. The VDR binds to target DNA sequences as a heterodimer with the retinoid X receptor, recruiting a series of coactivators that modify chromatin and approximate the VDR to the basal transcriptional apparatus, resulting in the induction of target gene expression. The mechanism of transcriptional repression by the VDR varies with different target genes but has been shown to involve either interference with the action of activating transcription factors or the recruitment of novel proteins to the VDR complex, resulting in transcriptional repression.

The affinity of the VDR for 1,25$(OH)_2$D is approximately three orders of magnitude higher than that for other vitamin D metabolites. In normal physiologic circumstances, these other metabolites are not thought to stimulate receptor-dependent actions. However, in states of vitamin D toxicity, the markedly elevated levels of 25(OH)D may lead to hypercalcemia by interacting directly with the VDR and by displacing 1,25$(OH)_2$D from vitamin D–binding protein, resulting in increased bioavailability of the active hormone.

The VDR is expressed in a wide range of cells and tissues. The molecular actions of 1,25$(OH)_2$D have been studied most extensively in tissues involved in the regulation of mineral ion homeostasis. This hormone is a major inducer of calbindin 9K, a calcium-binding protein expressed in the intestine, which is thought to play an important role in the active transport of calcium across the enterocyte. The two major calcium transporters expressed by intestinal epithelia, TRPV5 and TRPV6 (transient receptor potential vanilloid), are also vitamin D responsive. By inducing the expression of these and other genes in the small intestine, 1,25$(OH)_2$D increases the efficiency of intestinal calcium absorption, and it also has been shown to have several important actions in the skeleton. The VDR is expressed in osteoblasts and regulates the expression of several genes in this cell. These genes include the bone matrix proteins osteocalcin and osteopontin, which are upregulated by 1,25$(OH)_2$D, in addition to type I collagen, which is transcriptionally repressed by 1,25$(OH)_2$D. Both 1,25$(OH)_2$D and PTH induce the expression of RANK ligand, which promotes osteoclast differentiation and increases osteoclast activity, by binding to RANK on osteoclast progenitors and mature osteoclasts. This is the mechanism by which 1,25$(OH)_2$D induces bone resorption. 1,25$(OH)_2$D regulates phosphate homeostasis, primarily by inducing the expression of FGF23 in osteocytes. However, the skeletal features associated with VDR-knockout mice (rickets, osteomalacia) are largely corrected by increasing calcium and phosphorus intake, underscoring the importance of vitamin D action in the gut.

The VDR is expressed in the parathyroid gland, and 1,25$(OH)_2$D has been shown to have antiproliferative effects on parathyroid cells and to suppress the transcription of the parathyroid hormone gene. These effects of 1,25$(OH)_2$D on the parathyroid gland are an important part of the rationale for current therapies directed at preventing and treating hyperparathyroidism associated with renal insufficiency.

The VDR is also expressed in tissues and organs that do not play a role in mineral ion homeostasis. Notable in this respect is the observation that 1,25$(OH)_2$D has an antiproliferative effect on several cell types, including keratinocytes, breast cancer cells, and prostate cancer cells. The effects of 1,25$(OH)_2$D and the VDR on keratinocytes are particularly intriguing, since the VDR is primarily a transcriptional repressor in these cells. Alopecia is seen in humans and mice with mutant VDRs but is not a feature of vitamin D deficiency; thus, the effects of the VDR on the hair follicle are ligand-independent.

VITAMIN D DEFICIENCY

The mounting concern about the relationship between solar exposure and the development of skin cancer has led to increased reliance on dietary sources of vitamin D. Although the prevalence of vitamin D deficiency varies, the third National Health and Nutrition Examination Survey (NHANES III) revealed that vitamin D deficiency is prevalent throughout the United States, with the prevalence being >29% in obese children. The clinical syndrome of vitamin D deficiency can be a result of deficient production of vitamin D in the skin, lack of dietary intake, accelerated losses of vitamin D, impaired vitamin D activation, or resistance to the biologic effects of 1,25$(OH)_2$D (**Table 409-6**). The elderly and nursing home residents are particularly at risk for vitamin D deficiency, since both the efficiency of vitamin D synthesis in the skin and the absorption of vitamin D from the intestine decline with age. The presence of terminal ileal disease also results in impaired enterohepatic circulation of vitamin D metabolites. While intestinal malabsorption of dietary fats and short bowel syndrome, including that associated with intestinal bypass surgery, lead to vitamin D deficiency, the cause

TABLE 409-6 Causes of Impaired Vitamin D Action

Vitamin D deficiency	Impaired 1α-hydroxylation
Impaired cutaneous production	Hypoparathyroidism
Dietary absence	Ketoconazole
Malabsorption (short gut syndrome, gastric bypass)	1α-hydroxylase mutation
Accelerated loss of vitamin D	FGF23 excess
Increased metabolism (barbiturates, phenytoin, rifampin)	Oncogenic osteomalacia
Impaired enterohepatic circulation	Hypophosphatemic rickets
Nephrotic syndrome	Fibrous dysplasia
CYP3A4 mutation	Chronic kidney disease
Impaired 25-hydroxylation	Target organ resistance
Liver disease, isoniazid	Vitamin D receptor mutation
25-Hydroxylase mutation	Phenytoin
	Other
	Obesity
